Tharsis and Elysium. The canyons of Valles Marineris terminate to the west near the crest of the Tharsis rise, a vast bulge on the Martian surface more than 8,000 kilometres across and 8 kilometres high at its centre. Near the top of the rise are three of the planet's largest volcanoes—Ascraeus Mons, Arsia Mons, and Pavonis Mons—which tower 18, 17, and 14 kilometres, respectively, above the mean radius. Just off the rise to the northwest is the planet's tallest volcano, Olympus Mons, and at the north end is yet another large volcano, Alba Patera (approaching 7 kilometres high). What formed Tharsis is not known; it may have resulted from a combination of uplift and the accumulation of huge volumes of volcanic deposits.

Largest volcanoes on Mars

Another rise is located in the northern region of Elysium at about 215° W longitude. Much smaller than Tharsis, being only 2,000 kilometres across and 6 kilometres high, the Elysium rise is also the site of several volcanoes.

THE INTERIOR

The interior of Mars is poorly known. Planetary scientists have yet to conduct a successful seismic experiment via spacecraft that would provide direct information on internal structure and so must rely on indirect inferences. The moment of inertia of Mars indicates that it has a central core with a radius of 1,300–2,000 kilometres. Isotopic data from meteorites determined to have come from Mars (see below *Meteorites from Mars*) demonstrate unequivocally that the planet differentiated—separated into a metal-rich core and rocky mantle—at the end of the planetary accretion period 4.5 billion years ago. The planet has no detectable magnetic field that would indicate convection (heat-induced flow) in the core today. Large regions of magnetized rock have been detected in the oldest terrains, however, which suggests that very early Mars did have a magnetic field but that it disappeared as the planet cooled and the core solidified.

Evidence for ancient magnetic field

Mars is almost certainly volcanically active today, although at a very low level. Some Martian meteorites, which are all volcanic rocks, show ages as young as a few hundred million years, and some volcanic surfaces on the planet are so sparsely cratered that they must be only tens of millions of years old. Thus Mars was volcanically active in the geologically recent past, which implies that its mantle is warm and undergoing melting locally.

Mars's gravitational field is very different from Earth's. On Earth, excesses and deficits of mass in the surface crust, owing to the presence of large mountains and ocean deeps, respectively, tend to be offset by compensating masses at depth (isostatic compensation). Thus, the pull of gravity on Earth is the same on high mountains as it is over the ocean. This is also true for Mars's oldest terrains, such as the Hellas basin, the southern highlands, and the northern plains. The younger terrains such as the Tharsis and Elysium domes, however, are only partly compensated. Associated with both of these regions are gravity highs—that is, places where the measured gravity is significantly higher than elsewhere because of the large mass of the domes.

Because the gravity over the southern highlands is roughly the same as that over the low-lying northern plains, the southern highlands must be underlain by a thicker crust of material that is less dense than the mantle below it. Estimates of the thickness of the Martian crust range from only 3 kilometres under the Isidis impact basin, which is just north of the equator and east of Syrtis Major, to more than 90 kilometres at the south end of the Tharsis rise.

METEORITES FROM MARS

By 2002, scientists had identified more than 20 meteorites that have come from Mars. Suspicions about their origin were first raised when some meteorites that appeared to be volcanic rocks were found to have ages of about 1.3 billion years instead of the 4.5 billion years of all other meteorites. These rocks had to have come from a body that was geologically active in the comparatively recent past, and Mars was the most likely candidate. The rocks also have similar ratios of oxygen isotopes, which are distinctively different from those for Earth rocks, lunar rocks, and other meteorites. A Martian origin was finally proved when it was found that several of them contained trapped gases having a composition identical to that of the Martian atmosphere as measured by the Viking landers. The rocks are thought to have been ejected from the Martian surface by large impacts. They then went into solar orbit for several million years before falling on Earth. Claims in the mid-1990s of finding evidence for past microscopic life in one of the meteorites have been viewed skeptically by the general science community (see below *The question of life on Mars*).

THE SATELLITES

Little was learned about the two moons of Mars, Phobos and Deimos, after their discovery in 1877 until orbiting spacecraft observed them a century later. Viking 1 flew to within 100 kilometres of Phobos, and Viking 2 to within 30 kilometres of Deimos.

Phobos revolves around Mars once every 7 hours 39 minutes. It moves in an exceptionally close orbit, at a mean distance from the surface of about 6,000 kilometres—less than twice the planet's radius. Gravitational (tidal) forces slow the motion of Phobos and may ultimately cause the satellite to collide with Mars, possibly in less than 100 million years. Deimos suffers the opposite fate. It moves in a more distant orbit, and tidal forces are causing it to recede from the planet. Phobos and Deimos are not visible from all locations on the planet because of their small size, proximity to Mars, and near-equatorial orbits.

Close orbit of Phobos

Both moons are irregular chunks of rock, roughly ellipsoidal in shape. Phobos is the larger (see Table 11). Phobos's rugged surface is covered with impact craters. The largest crater, Stickney, is about half as wide as the moon itself. Its surface also exhibits a widespread system of linear fractures, or grooves, many of which are geometrically related to Stickney. In contrast, the surface of Deimos appears smooth, as its many craters are almost completely buried by fine debris, and it shows no fracture system. The albedo, or reflectivity, of both moons is very low, similar to that of the most primitive types of meteorites. One theory of the origin of the moons is that they are asteroids that were captured when Mars was forming.

Table 11: Satellites of Mars

property	Deimos	Phobos
Orbital radius (mean distance from centre of planet)	23,459 km	9,378 km
Orbital period (sidereal period)	1.26244 Earth days	0.31891 Earth days
Mean orbital velocity	1.4 km/s	2.1 km/s
Rotation period	sync.*	sync.*
Dimensions	$15 \times 12.2 \times 10.4$ km	$26.6 \times 22.2 \times 18.6$ km
Area	525 km^2	1,625 km^2
Mass	1.8×10^{15} kg	1.08×10^{16} kg
Mean density	1.8 g/cm^3	1.9 g/cm^3
Mean escape velocity	6 m/s	10 m/s
Albedo	0.07	0.06

*Sync. = synchronous rotation; the rotation and orbital periods are the same.

SPACECRAFT EXPLORATION

Between 1960 and 1980, the exploration of Mars was a major objective of both the U.S. and Soviet space programs. U.S. spacecraft successfully flew by Mars (Mariners 4, 6, and 7), orbited the planet (Mariner 9 and Vikings 1 and 2), and placed lander modules on its surface (Vikings 1 and 2). Three Soviet probes (Mars 2, 3, and 5) also investigated Mars, two of them reaching its surface. Mars 3 was the first spacecraft to soft-land an instrumented capsule on the planet, on Dec. 2, 1971.

The central theme of the Viking missions was the search

Figure 40: Phobos (left) and Deimos (right), photographed by Vikings 1 and 2, respectively, in 1977. The smooth texture of the surface of Deimos is contrasted with the grooved, pitted, and cratered surface of Phobos. The large cavity on Phobos is Stickney crater.

for extraterrestrial life. No unequivocal evidence of biological activity was found (see below *The question of life on Mars*), but various instruments on the two orbiters and two landers returned detailed information concerning Martian geology, meteorology, and the physics and chemistry of the upper atmosphere. Vikings 1 and 2 were placed into orbit in June and August 1976, respectively. Lander modules descended to the surface from the orbiters after suitable sites were found. Viking 1 landed in the region of Chryse Planitia (22° N, 48° W) on July 20, 1976, and Viking 2 landed 6,700 kilometres away in Utopia Planitia (48° N, 226° W) on Sept. 3, 1976.

Amid failures of several U.S. missions to Mars in the 1990s, Mars Pathfinder successfully set down in Chryse Planitia (19° N, 33° W) on July 4, 1997, and deployed a robotic wheeled surface rover called Sojourner. This was followed by Mars Global Surveyor, which reached Mars in September 1997 and systematically mapped various properties of the planet from orbit for several years beginning in March 1999. These included Mars's gravity and magnetic fields, surface topography, and surface mineralogy. The spacecraft also carried cameras for making both wide-angle and detailed images of the surface at resolutions down to 1.5 metres. In October 2001 Mars Odyssey entered Mars orbit and started mapping such properties as surface chemical composition, distribution of near-surface ice, and the physical properties of near-surface materials.

A wave of spacecraft converged on Mars in late 2003 and early 2004 with mixed outcomes. Nozomi, launched by Japan in 1998 on a leisurely trajectory, was first to reach the vicinity of the planet, but malfunctions prevented it from entering Mars orbit. In mid-2003 the European Space Agency's Mars Express was launched on a half-year journey to the Red Planet. Carrying instruments to study the atmosphere, surface, and subsurface, it entered Mars orbit on December 25; however, its lander, named Beagle 2,

Mars Express

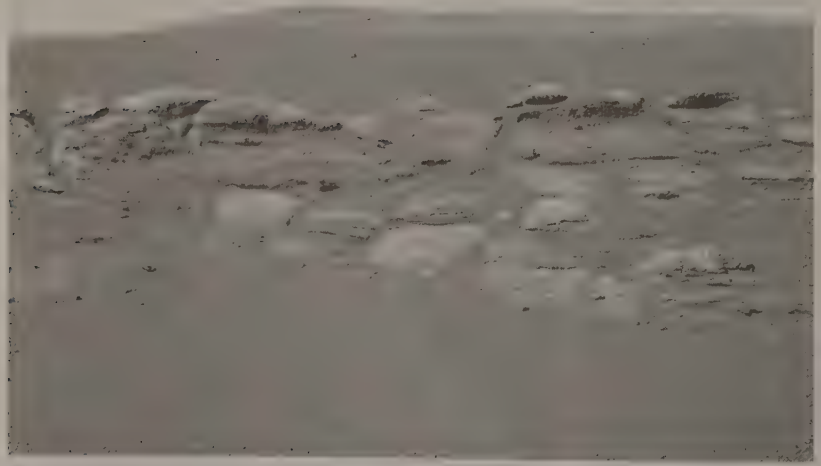

Figure 41: A portion of rock outcropping within a small crater in the Meridiani Planum region of Mars, shown in an image made by the robotic rover Opportunity in January 2004. The outcropping varies in height from 30 to 45 centimetres (12 to 18 inches) along the crater. As interpreted by mission scientists, the rock layers apparently were laid down as deposits at the bottom of a body of flowing salt water, probably on the shoreline of an ancient sea.

which was to examine the rocks and soil for signs of past or present life, failed to establish radio contact after presumably descending to the Martian surface the same day. Within weeks of its arrival, the Mars Express orbiter detected vast fields of water ice as well as carbon dioxide ice at the south pole and confirmed that the southern summer remnant cap contains permanently frozen water.

Spirit and Opportunity rovers

Also launched in mid-2003 was the U.S. Mars Exploration Rover Mission, which comprised twin robotic landers, Spirit and Opportunity. Spirit touched down in Gusev crater (15° S, 175° E) on Jan. 3, 2004. Three weeks later, on January 24, Opportunity landed in Meridiani Planum (2° S, 6° W), on the opposite side of the planet. The wheeled rovers, each carrying cameras and a suite of instruments, analyzed the rocks, soil, and dust around their landing sites, which had been chosen because they appeared to have been affected by water in Mars's past. Both rovers found evidence of past water; perhaps the most dramatic was the discovery by Opportunity of rocks that appeared to have been laid down at the shoreline of an ancient body of salty water.

THE MAPPING OF MARS

The first known map of Mars was produced in 1830 by Wilhelm Beer and Johann Heinrich von Mädler of Germany. The Italian astronomer Giovanni Schiaparelli prepared the first modern astronomical map of Mars in 1877, which contained the basis of the system of nomenclature still in use today. The names on his map are in Latin and are formulated mostly in terms of the ancient geography of the Mediterranean area. This map also showed, for the first time, indications of an interconnecting system of straight lines on the bright areas that he described as *canali* (Italian: "channels"). Schiaparelli is usually credited with their first description, but his fellow countryman Pietro Angelo Secchi developed the idea of *canali* about a decade earlier. In the late 19th century the American astronomer Percival Lowell established an observatory in Flagstaff, Arizona, to observe Mars and produced ever more elaborate maps of the Martian canals until his death in 1916.

Observations made by Mars-orbiting spacecraft have led to many new maps presenting topography, geologic provinces, temperatures, mineral distribution, and a variety of other data. The prime meridian on Mars, the equivalent of the Greenwich meridian on Earth, is defined by a small crater named Airy-0 located in the crater Airy.

THE QUESTION OF LIFE ON MARS

The possible presence of life on Mars has been an essential element of general discussions of the planet since Schiaparelli first included *canali* on his maps. Lowell was particularly responsible for popularizing the notion that these markings were the result of biological activity, intelligent or otherwise. Nevertheless, as discussed above, it has been clear since the 1960s that such features do not exist.

Viking biological experiments

The biological experiments aboard the two Viking landers addressed three issues: (1) the nature of organic material, if any, on the Martian surface, (2) the possible presence of objects on the surface whose appearance or motion would suggest living or fossilized organisms, and (3) the possible presence in Martian soil of agents that, under prescribed conditions, could indicate metabolic processes. The results related to the first issue were unambiguous—a direct, extremely sensitive chemical analysis of samples at both lander sites showed no trace of complex organic materials. Addressing the second issue, the cameras on the landers found no evidence of biological agents or activity.

Three separate instruments addressed the last issue. One was designed to look for signs of photosynthesis or chemosynthesis—that is, signs of biological activity supported by solar or chemical energy, respectively—in samples of Martian soil. This experiment produced some positive indications, but the experimenters believed that they could be best explained by nonbiological processes. A second experiment measured gases released from a soil sample as it was exposed to a humid atmosphere or treated with a solution of organic nutrients. This experiment also produced a positive result in that the samples liberated oxygen in response to the nutrient. This reaction, however, also occurred even after samples had been baked on site at 145° C (293° F) for three hours, leading experimenters to conclude that the source of oxygen was nonbiological. The final experiment looked for the release of radioactive gas when a soil sample was exposed to a solution of radioactive organic nutrient. A positive result was again obtained, and in this case a baked control sample remained inert. Nevertheless, given the results of the other Viking experiments, most investigators believe that the re-

sults of the labeled release experiment also can be explained nonbiologically.

The Martian surface is almost certainly devoid of life at the present time. It is exposed to ultraviolet radiation from the Sun without any reduction in intensity by the atmosphere; organic compounds in the soil are destroyed, probably by a combination of oxidation and photochemical processes; and average temperatures are so cold and the water content of the atmosphere so low that liquid water, universally accepted as essential for life, is unlikely to be available. These considerations have encouraged scientists to shift their search for life on Mars to the search for past life. As was indicated above, different lines of evidence suggest that conditions on early Mars were much more hospitable to life than subsequently. If life did gain a foothold, it now may survive only in protected niches well below the hostile surface. The current strategy, therefore, is to focus on evidence of past life and then look for present life deep below the surface, where liquid water might be available.

Purported fossils in a Martian meteorite

This strategy was underscored by the findings from the Martian meteorite ALH84001, which was collected from an Antarctic ice field in 1984. It is the oldest known rock from Mars, having formed about 4.5 billion years ago when the planet itself was accreting. It contains organic materials, evidence of mineral deposition from liquid water, and a number of structures similar to primitive terrestrial fossils. Although most scientists conclude that these findings do not provide good evidence for past life, they have stimulated closer examination of the Martian meteorites and have emphasized the need for obtaining samples from Mars, particularly of ancient rocks that were being formed or already present when conditions on Mars were more Earthlike. (M.J.S.B./M.C.Ma./M.H.Ca.)

Jupiter

Jupiter, designated ♃ in astronomy, is the most massive of the planets of the solar system and fifth in distance from the Sun. It is one of the brightest objects in the night sky; only the Moon, Venus, and sometimes Mars are more brilliant. When ancient astronomers named the planet for the Roman ruler of the gods and heavens (also known as Jove), they had no idea of the planet's true dimensions, but the name is appropriate, for Jupiter is larger than all the other planets combined. It takes nearly 12 years to orbit the Sun, and it rotates once about every 10 hours, more than twice as fast as Earth; its colourful cloud bands can be seen even with a small telescope. It has a narrow system of rings and at least 39 moons, one larger than the planet Mercury and three larger than Earth's Moon. Some astronomers speculate that Jupiter's moon Europa may be hiding an ocean of warm water—and possibly even some kind of life—beneath an icy crust.

Jupiter has an internal heat source—*i.e.*, it emits more energy than it receives from the Sun. The pressure in its deep interior is so high that the hydrogen there exists in a metallic state. This giant has the strongest magnetic field of any planet and a magnetosphere so large that, if it could be seen from Earth, its apparent diameter would exceed that of the Moon. Jupiter's system is also the source of intense bursts of radio noise, at some frequencies occasionally radiating more energy than the Sun. Despite all its superlatives, however, Jupiter is made almost entirely of only two elements, hydrogen and helium, and its mean density is not much more than the density of water.

Galileo orbiter and probe mission

Knowledge about the Jovian system grew dramatically after the mid-1970s as a result of explorations by three spacecraft missions—Pioneers 10 and 11 in 1973–74, Voyagers 1 and 2 in 1979, and the Galileo orbiter and probe, which arrived at Jupiter in December 1995. The Pioneer spacecraft served as scouts for the Voyagers, showing that the radiation environment was tolerable and mapping out the main characteristics of the planet. The greater number and increased sophistication of the Voyager instruments provided so much new information that it was still being analyzed when the Galileo mission began. The previous missions had all been flybys, but Galileo released a probe into Jupiter's atmosphere and then went into orbit about the planet for intensive investigations of the entire system over several years. Yet another view of the Jovian system was provided in 2000 by the flyby of the Cassini spacecraft on its way to Saturn. Observations of the impacts of the fragmented nucleus of Comet Shoemaker-Levy 9 with Jupiter's atmosphere in 1994 also yielded information about its composition and structure.

BASIC ASTRONOMICAL DATA

Jupiter has an equatorial diameter of about 143,000 kilometres and orbits the Sun at a mean distance of 778 million kilometres. Table 12 shows additional physical and orbital data. Of special interest are the planet's low mean density of 1.33 grams per cubic centimetre—in contrast with Earth's 5.52 grams per cubic centimetre—coupled with its large dimensions and mass and short rotation period. The low density and large mass indicate that Jupiter's composition and structure are quite unlike those of Earth and the other inner planets.

Three rotation periods, all within a few minutes of each other, have been established. The two periods called System I (9 hours 50 minutes 30 seconds) and System II (9 hours 55 minutes 41 seconds) refer to the speed of rotation

Table 12: Planetary Data for Jupiter

Mean distance from Sun	778,570,000 km (5.2 AU)
Eccentricity of orbit	0.049
Inclination of orbit to ecliptic	1.3°
Jovian year (sidereal period of revolution)	11.86 Earth years
Equatorial radius*	71,492 km
Polar radius*	66,854 km
Mass	18.99×10^{26} kg
Mean density	1.33 g/cm^3
Gravity*	2,312 cm/s^2
Escape velocity	59.5 km/s
Rotation periods	
System I (±10° from equator)	9 h 50 min 30 s
System II (higher latitudes)	9 h 55 min 41 s
System III (magnetic field)	9 h 55 min 29 s
Mean synodic period†	398.88 Earth days
Inclination of equator to orbit	3.13°
Dimensions of Great Red Spot	20,000 × 12,000 km
Mean opposition visual magnitude	−2.70
Magnetic field strength at equator	4.3 gauss
Number of known moons	39

*Calculated for the altitude at which 1 bar of atmospheric pressure is exerted. †Time required for the planet to return to the same position in the sky relative to the Sun as seen from Earth.

at the equator and at higher latitudes, respectively, as exhibited by features observed in the planet's visible cloud layers. Jupiter has no solid surface; the transition from the gaseous atmosphere to the fluid interior occurs gradually at great depths. Thus the variation in rotation period at different latitudes does not imply that the planet itself rotates with either of these mean velocities. In fact, the true rotation period of Jupiter is System III (9 hours 55 minutes 29 seconds), which is the period of rotation of Jupiter's magnetic field, first deduced from Earth-based observations at radio wavelengths and confirmed by direct spacecraft measurements. This period applies to the massive interior of the planet, where the magnetic field is generated.

THE OUTER LAYERS

The clouds and the Great Red Spot. Even a modest telescope can show much detail on Jupiter. The region of the planet's atmosphere that is visible from Earth contains several different types of clouds that are separated both vertically and horizontally. Changes in these cloud systems can occur over periods of hours, but an underlying pattern of latitudinal currents has maintained its stability for decades. It has become traditional to describe the appearance of the planet in terms of a standard nomenclature for its alternating dark bands, called belts, and bright bands, called zones. The underlying currents, however, seem to persist longer than this pattern.

Stability of underlying currents

The close-up views of Jupiter transmitted from the Voyager spacecraft revealed a variety of cloud forms, including many elliptical features reminiscent of storm systems on Earth. All these systems are in motion, appearing and disappearing on timescales that vary with their sizes and locations. Also observed to vary are the pastel shades of colours present in the cloud layers—from the tawny yellow that seems to characterize the main layer, through browns and blue-grays, to the well-known salmon-coloured Great Red Spot, Jupiter's largest and longest-lived feature. Chemical differences in cloud composition are presumed to be the cause of the variations in colour.

Unlike Earth, where local weather is often influenced by the varied nature of the planet's surface, Jupiter has no solid surface. In the absence of topographic features, the planet's large-scale circulation is dominated by latitudinal currents. The lack of a solid surface with physical boundaries and regions with different heat capacities makes the persistence of these currents and their associated cloud patterns all the more remarkable. The Great Red Spot, for example, moves in longitude with respect to all three of the planet's rotation systems, yet it does not move in latitude. The white ovals found just south of the Great Red Spot exhibit similar behaviour; white ovals of this size are found nowhere else on the planet. The dark brown clouds, evidently holes in the tawny cloud layer, are found almost exclusively near 18° N latitude. The blue-gray or purple areas, from which the strongest thermal emission is detected, occur only in the equatorial region of the planet.

Nature of the Great Red Spot. The true nature of Jupiter's unique Great Red Spot was still unknown at the start of the 21st century, despite extensive observations from the Voyager and Galileo spacecraft. On a planet whose cloud patterns have lifetimes often counted in days, the Great Red Spot has survived as long as detailed observations of Jupiter have been made—at least 300 years. Its present dimensions are about 20,000 by 12,000 kilometres, making it large enough to accommodate both Earth and Mars. These huge dimensions are probably responsible for the feature's longevity and possibly for its distinct colour.

Voyager observations revealed that the material within the Great Red Spot rotates counterclockwise once every seven days, corresponding to superhurricane-force winds of 400 kilometres per hour at the periphery. The Voyager images also recorded a large number of interactions between the spot and much smaller disturbances moving in the current at the same latitude. The interior of the spot is remarkably tranquil, with no clear evidence for the expected upwelling of material from lower depths. The Great Red Spot, therefore, appears to be a huge anticyclone, a vortex or eddy whose diameter is presumably accompanied by a great depth that allows the feature to reach well below and well above the main cloud layers.

Cloud composition. Jupiter's visible clouds are formed at different altitudes in the planet's atmosphere. Except for the top of the Great Red Spot, the white clouds are the highest, with cloud-top temperatures of about 120 kelvins (K; −240° F, −150° C). These clouds consist of frozen ammonia crystals and are analogous to the water-ice cirrus clouds on Earth. The tawny clouds that are widely distributed over the planet occur at lower levels. They appear to form at a temperature of about 200 K (−100° F, −70° C), which suggests that they consist of condensed ammonium

Ammonia cirrus clouds

krypton (Kr)	8.7×10^{-9}	krypton-84	2.7 ± 0.5				
xenon (Xe)	8.8×10^{-10}	xenon-132	2.6 ± 0.5				

*The mixing ratio is the number of molecules of a given atmospheric constituent in a unit volume divided by the number of hydrogen molecules in that same volume.

hydrosulfide and that their colour is caused by other ammonia-sulfur compounds. Sulfur compounds are invoked as the likely colouring agents because sulfur is relatively abundant in the cosmos and hydrogen sulfide is notably absent from Jupiter's atmosphere above the clouds.

Jupiter is composed primarily of hydrogen and helium. Under equilibrium conditions—allowing all the elements present to react with one another at an average temperature for the visible part of the Jovian atmosphere—the abundant elements are all expected to combine with hydrogen. Thus it was surmised that methane, ammonia, water, and hydrogen sulfide would be present. Except for hydrogen sulfide, all these compounds have been found by spectroscopic observations from Earth. The apparent absence of hydrogen sulfide can be understood if it combines with ammonia to produce the postulated ammonium hydrosulfide clouds. The absence of detectable hydrogen sulfide above the clouds suggests that the chemistry that forms coloured sulfur compounds (if indeed there are any) must be driven by local lightning discharges rather than by ultraviolet radiation from the Sun.

Ammonia-sulfur clouds

Sulfur compounds have also been proposed to explain the dark brown coloration of the ammonia clouds detected at still lower levels, where the temperature is 260 K (8° F, −13° C). These clouds are seen through what are apparently holes in the otherwise ubiquitous tawny clouds.

The colour of the Great Red Spot has been attributed variously to the presence of complex organic molecules, red phosphorus, or yet another sulfur compound. Dark regions occur near the heads of white plume clouds near the planet's equator, where temperatures as high as 300 K (80° F, 27° C) have been measured. Despite their blue-gray appearance, they have a reddish tint. They appear to be cloud-free regions—hence the ability to "see" into them to great depths and measure high temperatures—that exhibit a blue colour (from Rayleigh scattering of sunlight) overlain with a thin haze of reddish material. That these so-called hot spots occur only near the equator, the elliptical dark brown clouds only near 18° north latitude, and the most prominent red colour on the planet only in the Great Red Spot implies a cloud chemistry whose localization is puzzling in such a dynamically active atmosphere.

Water clouds

At still lower depths, astronomers expect to find water-ice clouds and water-droplet clouds, both consisting of dilute solutions of ammonium hydroxide. Nevertheless, when the probe from the Galileo spacecraft entered Jupiter's atmosphere on Dec. 7, 1995, it failed to find these water clouds, even though it survived to a pressure level of 24 bars—nearly 24 times sea-level pressure on Earth—where the temperature was more than 400 K (260° F, 130° C). In fact, the probe also did not sense the upper cloud layers of ammonia and ammonium hydrosulfide. Unfortunately for studies of Jovian cloud physics, the probe had entered the atmosphere over a hot spot, where clouds were absent.

The atmosphere. *Proportions of constituents.* Before the Galileo mission, astronomers had relied on studies of the planet's spectrum to provide information about the composition, temperature, and pressure of the atmosphere. The presence of methane and ammonia was deduced in this way in the 1930s, while hydrogen was detected for the first time in 1960. Subsequent studies led to a growing list of new constituents, including the discovery of the arsenic compound arsine in 1990. Table 13 includes a list of Jupiter's atmospheric constituents and their abundances as determined by Earth-based, spacecraft, and atmospheric probe observations as of 2000.

If the condition of chemical equilibrium held rigorously in Jupiter's atmosphere, one would not expect to find molecules such as carbon monoxide or phosphine in the abundances measured. Neither would one expect the traces of acetylene, ethane, and other hydrocarbons that have been detected in the stratosphere. Evidently, there are sources of energy other than the molecular kinetic energy corresponding to local temperatures. Solar ultraviolet radiation is responsible for the breakdown of methane, and subsequent reactions of its fragments produce acetylene and ethane. In the convective region of the atmosphere, lightning discharges (observed by the Voyager and Galileo spacecraft) contribute to these processes. Still deeper, at temperatures around 1,200 K (1,700° F, 930° C), carbon monoxide is made by a reaction between methane and water vapour.

Galileo's probe carried a mass spectrometer that detected the constituent atoms and molecules in the atmosphere. As the probe descended through the atmosphere on its parachute, the spectrometer also studied variations in abundance with altitude. This experiment finally detected the previously missing hydrogen sulfide, which was found to be present even lower in the atmosphere than anticipated. Evidently this cloud-forming gas, like ammonia and water vapour, was depleted in the upper part of the aforementioned hot spot. It was not possible to measure oxygen, because this element is bound up in water, and the probe did not descend into the hot spot deeply enough to reach the region where this condensable vapour is well mixed.

Differences between Jupiter and the Sun

The elemental abundances in Jupiter's atmosphere can be compared with the composition of the Sun (see Table 13). If, like the Sun, the planet had formed by simple condensation from the primordial solar nebula that is thought to have given birth to the solar system, their elemental abundances should be the same. A surprising result from the Galileo probe was that all the elements that it could measure in the Jovian atmosphere showed the same approximately three-fold enrichment of their values in the Sun, relative to hydrogen. This has important implications for the formation of the planet (see below *Theories of the origin of the Jovian system*). Spectroscopy from Earth reveals a large spread in the values of other elements not measured by the probe. The abundances of the gases from which these elemental abundances are derived depend on dynamical phenomena in Jupiter's atmosphere—principally chemical reactions and vertical mixing. The significance of the helium depletion is discussed below in *The interior*.

Another difference with solar values is indicated by the presence of deuterium on Jupiter. This heavy isotope of

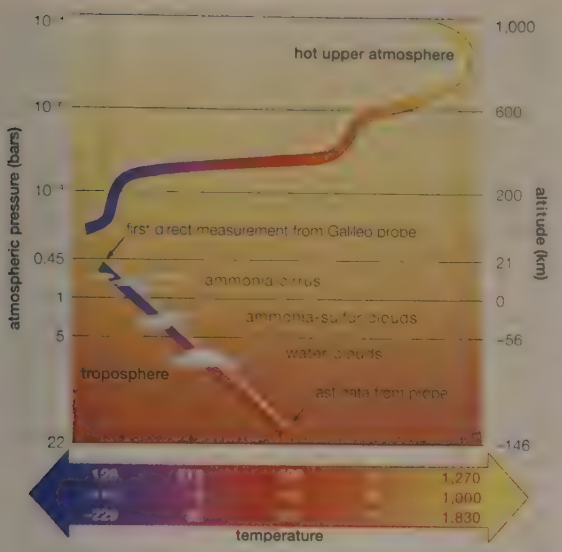

Figure 45: Profile of Jupiter's atmosphere as deduced from accelerometer data and direct measurements collected by the Galileo probe. The altitude reference level is set at one bar (sea-level pressure on Earth). Schematic clouds indicate the approximate positions of the expected cloud layers (see text).
EB Inc

hydrogen has disappeared from the Sun as a result of nuclear reactions in the solar interior, but no such reactions have occurred on Jupiter.

Temperature and pressure. The Galileo probe carried instruments to record both temperature and pressure during its atmospheric descent. This profile is illustrated in Figure 45, which includes the locations of the different cloud layers if they had occurred where expected.

It is notable in the profile that temperatures higher than the freezing point of water (273 K, 32° F, 0° C) were measured at pressures just a few times greater than sea-level pressure on Earth (about one bar). This is mainly a consequence of Jupiter's internal energy source, although some warming would occur just through the trapping of infrared radiation by the atmosphere. The temperature rise above the tropopause (upper part of Figure 45) is known as an inversion, because temperature normally decreases with height. The inversion is caused by the absorption of solar energy at these altitudes by gases and aerosol particles.

Other likely atmospheric constituents. The list of atmospheric abundances in Table 13 is certainly not complete. For example, astronomers expect monosilane to be present in the deep atmosphere, along with many other exotic species. Other nonequilibrium species should occur in the higher regions, accessible to future probes, as a result of chemical reactions driven by lightning or solar ultraviolet radiation, or at the poles (where, for example, benzene has been detected) by the precipitation of charged particles.

Relevance to origin-of-life research

The formation of complex organic molecules in Jupiter's atmosphere is of great interest in the study of the origin of life. The initial chemical processes that gave rise to living organisms on Earth may have occurred in transient microenvironments that resembled the present chemical composition of Jupiter, without the enormous amounts of hydrogen and helium. Thus, Jupiter may represent a vast natural laboratory in which the first steps toward the origin of life are being pursued again and again. Determining how complex prelife chemical processes can become under such conditions is one of the most fascinating problems confronting any program of space exploration.

Radio emission. Jupiter was the first planet found (in 1955) to be a source of radiation at radio wavelengths. The radiation was recorded at a frequency of 22 megahertz (corresponding to a wavelength of 13.6 metres, or 1.36 decametres). It took the form of noise bursts with peak intensities sometimes great enough to make Jupiter the brightest source in the sky at this wavelength, except for the Sun during its most active phase. These bursts constituted the first evidence for a Jovian magnetic field. Later observations at shorter (decimetre) wavelengths revealed that Jupiter is also a source of steady radio emission. It has become customary to refer to these two types of emission in terms of their characteristic wavelengths—decametre radiation and decimetre radiation.

The nonthermal component of the continuous, decimetre radiation is interpreted as synchrotron emission—that is, radiation emitted by extremely high-speed electrons moving in the planet's magnetic field within a toroidal, or doughnut-shaped, region surrounding Jupiter—a phenomenon closely analogous to that of Earth's Van Allen belts. The maximum emission occurs at a distance of two planetary radii from the centre of the planet and has been detected at 178–5,000 megahertz. The intensity of the emission and its plane of polarization vary with the same period, which can be explained if the axis of the planet's magnetic field is inclined by about 10° to the rotational axis. The period of these variations is the System III rotation period.

The radio emission at the intermittent, decametre wavelengths has been studied from Earth in the accessible range of 3.5–39.5 megahertz. Free of Earth's ionosphere, which blocks lower frequencies from reaching the surface, the radio-wave experiment on the Voyager spacecraft detected emissions from Jupiter down to 60 kilohertz, corresponding to a wavelength of five kilometres. The strength of the signal and the frequency of noise storms show a marked time dependence that led to the early detection of three sources, or emitting regions.

Effect of Io's position on radio emissions

The decametre noise storms are greatly affected by the position of Jupiter's moon Io in its orbit. For one source, events are much more likely to occur when Io is 90° from the position in which Earth, Jupiter, and Io are in a straight line than otherwise. The noise sources appear to be regions that lie in the line of sight toward the visible disk of the planet. The most promising explanation of this effect relates the emission to a small region of space linked to Io by magnetic field lines (a flux tube) that move with Io. Electrons moving in spirals around the magnetic field lines could produce the observed radiation. Interactions between these electrons and the Jovian ionosphere indeed were observed by the Voyager and Galileo spacecraft. The "footprint" of Io's flux tube on Jupiter's upper atmosphere can even be observed from Earth as a glowing spot associated with Jupiter's polar auroras.

The Jovian magnetosphere. The nonthermal radio emissions described above are the natural result of trapped charged particles interacting with Jupiter's magnetic field and ionosphere. Interpretation of these observations led to a definition of the basic characteristics of the planet's magnetosphere that was shown to be remarkably accurate by the Pioneer and Voyager spacecraft.

The basic magnetic field of the planet is dipolar in nature, generated by a hydromagnetic dynamo that is driven by convection within the electrically conducting outer layers of Jupiter's interior. The magnetic field strength at the equator is 4.3 gauss, compared with 0.3 gauss at Earth's surface. The axis of the magnetic dipole is offset by a tenth of Jupiter's equatorial radius of 71,500 kilometres from the planet's rotational axis, to which it is indeed inclined by 10°. The orientation of the Jovian magnetic field is opposite to the present orientation of Earth's field.

The magnetic field dominates the region around Jupiter in the shape of an extended teardrop. The round side of the teardrop faces the Sun, where the Jovian field repels the solar wind, forming a bow shock at a distance of about 3 million kilometres from the planet. Opposite the Sun, an immense magnetotail stretches out to the orbit of Saturn, a distance of 650 million kilometres. These dimensions make Jupiter's magnetosphere the largest permanent structure in the solar system, dwarfing the Sun's diameter of 1.4 million kilometres. Within this region, the most striking activity is generated by the moon Io, whose influence on the decametric radiation is discussed in the section above. An electric current of approximately five million amperes flows in the magnetic flux tube linking Jupiter and Io. This satellite is also the source of a toroidal cloud of ions, or plasma, that surrounds its orbit.

Size of Jupiter's magnetosphere

The auroras. Just as charged particles trapped in the Van Allen belts cause auroras on Earth when they crash

into the uppermost atmosphere near the magnetic poles, so do they also on Jupiter. Cameras on the Voyager and Galileo spacecraft succeeded in imaging ultraviolet auroral arcs on the nightside of Jupiter, while Earth-based observations have recorded infrared emissions from the H_3^+ ion at both poles and imaged the associated polar auroras. Evidently, protons (hydrogen ions, H^+) from the magnetosphere spiral into the planet's ionosphere along magnetic field lines, forming the excited H_3^+ ion as they crash into the atmosphere dominated by molecular hydrogen. The resulting emission produces the auroras. The relation of the ultraviolet and infrared auroras, the detailed interaction of Io's flux tube with Jupiter's ionosphere, and the possibility that ions from Io's torus are impinging on the planet's atmosphere remain active topics of research.

THE INTERIOR

The atmosphere of Jupiter constitutes a very small fraction of the planet. Because nothing can be directly observed below this thin outer layer, only indirect conclusions can be drawn about the composition of Jupiter's interior. The observed quantities with which astronomers can work are the atmospheric temperature and pressure, mass, radius, shape, rate of rotation, heat balance, and perturbations of satellite orbits and spacecraft trajectories. From these can be calculated the ellipticity—or deviation from a perfect sphere—of the planet and its departure from an ellipsoid shape. These latter quantities may also be predicted using theoretical descriptions, or models, for the internal distribution of material. Such models can then be tested by their agreement with the observations.

The basic difficulty in constructing a model that will adequately describe the internal conditions for Jupiter is the absence of extensive laboratory data on the properties of hydrogen and helium at pressures and temperatures that would exist near the centre of this giant planet. The central temperature is estimated to be close to 25,000 K (44,500° F, 24,700° C), to be consistent with an internal source of heat that allows Jupiter to radiate about twice as much energy as it receives from the Sun. The central pressure is in the range of 50–100 million atmospheres (about 50–100 megabars). At such tremendous pressures hydrogen is expected to be in a metallic state.

Metallic hydrogen

Despite the problems posed in establishing the properties of matter in these extreme conditions, the precision of the models has improved steadily. Perhaps the most significant early conclusion from them was the realization that Jupiter cannot be composed entirely of hydrogen; if it were, it would have to be considerably larger than it is to account for its mass. On the other hand, hydrogen must predominate, constituting at least 70 percent of the planet by mass, regardless of form—gas, liquid, or solid. The Galileo probe measured a proportion for helium of 24 percent by mass in Jupiter's upper atmosphere, compared with the 28 percent predicted if the atmosphere had the same composition as the original solar nebula. Because the planet as a whole should have that original composition, astronomers have concluded that some helium that was dissolved in the liquid hydrogen in the planet's interior has precipitated out of solution and sunk toward the planet's centre, leaving the atmosphere depleted of this gas.

Current models agree on a transition from molecular to metallic hydrogen at about a fourth of the distance down toward Jupiter's centre. It should be stressed that this is not a transition between a liquid and a solid but rather between two fluids with different electrical properties. No solid surface exists in any of these models, although most (but not all) models incorporate a dense core with a radius of 0.03–0.1 that of Jupiter (0.33–1.1 the radius of Earth).

The source of internal heat has not been completely resolved. The favoured explanation invokes a combination of the gradual release of primordial heat left from the planet's formation and the liberation of thermal energy from the precipitation of droplets of helium in the planet's deep interior. The lower helium abundance in Jupiter's atmosphere relative to the Sun (Table 13) supports this latter deduction. The first process is simply the cooling phase of the original "collapse" that converted potential energy to thermal energy at the time the planet accumulated its complement of solar nebula gas (see below *Theories of the origin of the Jovian system*).

THE SATELLITES AND RING SYSTEM

The first objects in the solar system discovered by means of a telescope—by Galileo in 1610—were the four brightest moons of Jupiter, now called the Galilean satellites. The fifth known Jovian moon, Amalthea, was also discovered by visual observation—by E.E. Barnard in 1892. All the other known satellites were found photographically or in spacecraft images. Jupiter's system of thin rings was detected in Voyager images in 1979.

Satellite groups. Data for the known Jovian moons are summarized in Table 14. Roman numerals are assigned to the first 16 known moons in order of their discovery. The orbits of the inner eight moons have low eccentricities and low inclinations—*i.e.*, the orbits are all nearly circular and in the plane of the planet's equator. Such moons are called "regular." The orbits of the moons beyond Callisto have much higher inclinations and eccentricities, making them "irregular." The two innermost satellites, Metis and Adrastea, are intimately associated with Jupiter's ring system, as sources of the fine particles and as gravitationally controlling "shepherds." There are probably additional members of each of these groups.

"Regular" and "irregular" moons

The Galilean satellites. Galileo proposed that the four Jovian moons he discovered in 1610 be named the Medicean stars, in honour of his patron, Cosimo II de' Medici, but they soon came to be known as the Galilean satellites. In order of increasing distance from the planet, they are called Io, Europa, Ganymede, and Callisto, for fig-

Pasiphae	VIII	1908	23,500,000	735 R	145	0.378	18	3×10^{17}	
Sinope	IX	1914	23,700,000	758 R	153	0.275	14	8×10^{16}	

*Between 1999 and 2001, 23 additional moons (including one seen in 1975 and then lost) were discovered photographically in Earth-based observations. All are irregular, with large orbital radii, eccentricities, and inclinations; 21 have retrograde orbits. Rough size estimates based on brightness place them between 2 and 8 km in diameter. Assigned numerical designations, they await official names. †R following the quantity indicates a retrograde orbit. ‡Quantities given in parentheses are poorly known. Unspecified quantities are unknown.

ures closely associated with Jupiter in Greek mythology. The names were assigned by the German astronomer Simon Marius, Galileo's contemporary and rival, who likely discovered the satellites independently.

Although approximate diameters and spectroscopic characteristics of the Galilean moons had been determined from Earth-based observations, it was the Voyager missions that indelibly established these four bodies as worlds in their own right. The Galileo mission provided a wealth of additional data. Before Voyager, it was known that Callisto and Ganymede were both as large as or larger than the planet Mercury; that they and Europa had surfaces covered with water ice; that Io's orbit was surrounded by a torus of atoms and ions that included sodium, potassium, and sulfur; and that the inner two Galilean moons had mean densities much greater than those of the outer two. This density gradient from Io to Callisto resembles that found in the solar system itself and seems to result from the same cause (see below *Theories of the origin of the Jovian system*). The density values suggest that Io and Europa have a rocky composition similar to that of the Moon, whereas roughly 50 percent of Ganymede and Callisto must be made of a much less dense substance, with water ice being the obvious candidate.

Lack of global heating and differentiation

Callisto. The icy surface of this satellite is so dominated by impact craters that there are no smooth plains like the dark maria observed on the Moon. Unmodified by any upwelling of material from internal activity, its appearance is consistent with the absence of a differentiated interior. Evidently no tidally induced global heating and consequent melting occurred on Callisto, unlike the other three Galilean moons. In addition to the predominant water ice, solid carbon dioxide is present on the surface, and a very tenuous carbon dioxide atmosphere is slowly escaping into space. Callisto has a weak magnetic field induced by Jupiter's field that may imply the existence of a layer of liquid water below its icy crust.

Ganymede. Unlike Callisto, Ganymede, an equally icy satellite, reveals distinct patches of dark and light terrain. This contrast is reminiscent of the Moon's surface, but the answer to which terrain came first—dark or light—is exactly reversed. In contrast to the Moon, the dark regions on Ganymede are the older areas, showing the heaviest concentration of craters. The light regions are younger, revealing a complex pattern of parallel and intersecting ridges and grooves in addition to unusually bright impact craters. This manifestation of active crustal movement and resurfacing is accompanied by clear evidence of internal differentiation. Unlike Callisto, Ganymede has an iron-rich core and a permanent magnetic field that is strong enough to create its own magnetosphere and auroras.

Europa. The surface of Europa is totally different from that of Ganymede or Callisto, despite the fact that the infrared spectrum of this object indicates that it, too, is covered with ice. There are few impact craters on Europa, indicating that the surface is relatively recent. Some scientists think the surface is so young that significant resurfacing is still taking place on the satellite. This resurfacing evidently consists of the outflow of water from the interior to form an instant frozen ocean.

Models for the differentiated interior suggest the presence of an iron-rich core surrounded by a silicate mantle surmounted by an icy crust some 150 kilometres thick. This moon possesses both induced and intrinsic magnetic fields. Slightly mottled regions on the surface have been found to contain salt deposits, suggesting evaporation of water from a reservoir below the crust. Europa's frozen surface is criss-crossed with dark and bright stripes and curvilinear ridges and grooves. The relief is extremely low, with ridge heights perhaps a few hundred metres at most. Europa thus has the smoothest surface of any solid body examined in the solar system thus far. The major open question is whether there is an ocean of liquid water beneath Europa's ice, warmed by the release of tidal energy in Europa's interior. If such an ocean and source of heat exist, the possible presence of at least microbial life forms must be admitted.

Possible water ocean on Europa

Io. Seen through a telescope from Earth, Io appears reddish orange. Its infrared spectrum shows no evidence of the absorption characteristics of water ice. Scientists expected Io's surface to look different from those of Jupiter's other moons, but the Voyager images revealed a landscape even more unusual than anticipated. Volcanic fissures, instead of impact craters, dot the surface. Nine volcanoes were observed in eruption when the two Voyager spacecraft flew by in 1979, while the closer encounters by Galileo indicated that as many as 300 volcanic vents may be active at a given time. This unprecedented level of activity makes Io the most tectonically active object in the solar system. The surface of the satellite is continually and completely replaced by this volcanism in just a few thousand years.

Various forms (allotropes) of sulfur appear to be responsible for the black, orange, and red areas on the moon's surface, while solid sulfur dioxide is probably the main constituent of the white areas. Sulfur dioxide was detected as a gas near one of the active volcanic plumes by Voyager's infrared spectrometer and was identified as a solid in ultraviolet and infrared spectra obtained from Earth-orbital and ground-based observations. These identifications provide sources for the sulfur and oxygen ions observed in the Jovian magnetosphere and prove that Io's volcanic activity is the source of its torus of particles.

The energy for this volcanic activity requires a special explanation, since radioactive heating is inadequate for a body as small as Io. The favoured explanation is that tides developed by a gravitational tug-of-war over Io between the other Galilean satellites and Jupiter release enough energy to account for the observed volcanism. The interior contains a dense, iron-rich core, which probably produces a magnetic field. The interactions of Io with Jupiter's magnetosphere and ionosphere are so complex, however, that it has been difficult to distinguish the satellite's own field from the current-produced fields in its vicinity.

Cause of Io's volcanism

NASA/JPL/Caltech

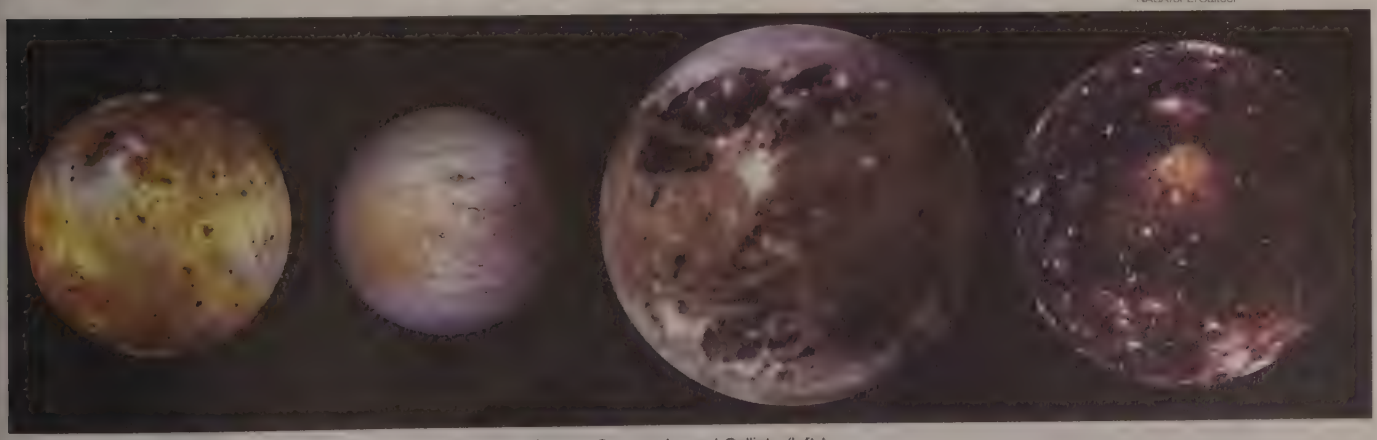

Figure 46: The four Galilean moons of Jupiter—Io, Europa, Ganymede, and Callisto (left to right)—assembled from images made by the Galileo spacecraft in 1996–97. Diameters of the moons are to scale. Colours have been enhanced to highlight surface features.

Other satellites. The only other Jovian moon that was close enough to the trajectories of the Voyager spacecraft to allow surface features to be seen was the tiny, irregularly shaped Amalthea. Like Io, its surface exhibits a reddish colour, which may result from a coating of sulfur compounds released by Io's volcanoes. In addition to providing new images of Amalthea, the Galileo orbiter was able to view the effect of impacts on Thebe and Metis. All three of these inner moons are tidally locked, keeping the same face oriented toward Jupiter. All three are some 30 percent brighter on their leading sides, presumably as a result of impacts by small meteoroids.

Before the turn of the 21st century, the eight outer moons then known had formed two groups: a more distant group in retrograde orbits around Jupiter—Ananke, Carme, Pasiphae, and Sinope—and a closer group in prograde orbits—Leda, Himalia, Lysithea, and Elara. (In the case of these moons, retrograde motion is in the direction opposite to Jupiter's spin and motion around the Sun, which are counterclockwise as viewed from above Jupiter's north pole, whereas prograde, or direct, motion is in the same direction.) With the discovery of a spate of additional outer moons beginning in 1999, this division was recognized as an oversimplification. There are clearly several groups of moons, each group apparently originating from an individual body that was captured by Jupiter and then broke up. The captures could have occurred near the time of Jupiter's formation when the planet was itself surrounded by a nebula that could slow down objects that entered it.

The ring system. As the Pioneer 10 spacecraft sped toward its closest approach to Jupiter in 1974, it detected a sudden decrease in the density of charged particles roughly 125,000 kilometres from Jupiter, just inside the orbit of its innermost moon, Metis. This led to the suggestion that a moon or a ring of material might be orbiting the planet at this distance. The existence of a ring was verified in 1979 by the first Voyager spacecraft when it crossed the planet's equatorial plane, and the second spacecraft recorded additional pictures, including a series taken in the shadow of the planet looking back at the ring material. The complex nature of this ring was elucidated by images obtained with the Galileo spacecraft in 1996–97.

The ring consists of four distinct components: an outer gossamer ring, whose outer radius coincides with the orbital radius of the satellite Thebe (222,000 kilometres); an inner gossamer ring bounded by the orbit of Amalthea (181,000 kilometres); the main ring, extending inward some 6,000 kilometres from the orbits of Adrastea (129,000 kilometres) and Metis (128,000 kilometres); and a halo of particles with a thickness of 25,000 kilometres that extends from the main ring inward to 92,000 kilometres. The ring comprises large numbers of micrometre- and smaller-sized particles that produce strong forward scattering of incident sunlight.

Association of rings and innermost moons

The presence of such small particles requires a source, and the association of the ring boundaries with the four satellites makes the source clear. The ring particles are generated by impacts on these satellites by micrometeoroids, cometary debris, and possibly volcanically produced material from Io. Some of the finest particles are electrically charged and respond to the rocking motion of the Jovian magnetic field as the planet rotates.

THEORIES OF THE ORIGIN OF THE JOVIAN SYSTEM

Explaining the origin of Jupiter and its satellites is part of the problem of explaining the origin of the solar system. Current thinking favours the gradual development of the Sun and planets from a huge cloud of gas and dust containing gravitational instabilities.

Early history of Jupiter. Given the planet's large proportion of hydrogen and its huge mass, it has been traditional to assume that Jupiter formed by condensation from the primordial solar nebula. This hypothesis implies that the elements should all be present on Jupiter in the same proportions that they occur in the Sun. However, the most recent evidence (see Table 13) indicates that the elemental proportions on Jupiter differ from the solar values.

Current models for Jupiter's origin suggest instead that a solid core of about 10 Earth masses formed first as a result of the accretion of icy planetesimals. This core would have developed an atmosphere of its own as the planetesimals released gases during accretion. As the mass of the core increased, it would have become capable of attracting gases from the surrounding solar nebula, thus accumulating the huge hydrogen-helium envelope that constitutes Jupiter's atmosphere and fluid mantle. The accumulating envelope would have mixed with the outgassed atmosphere from the core. Thus, the presently observed enrichment of the most abundant heavy elements in this envelope, compared with solar values (see Table 13), reflects the concentration of such elements in the core. As noted above, the mass spectrometer on the Galileo probe showed that these heavy elements are enriched by the same factor of about three. For this enrichment to include volatile substances like argon and molecular nitrogen requires that the icy planetesimals must have formed at temperatures of 30 K (−400° F, −240° C) or less. Just how this happened remains a puzzle, and its solution may ultimately help explain the presence of giant planets that have been detected very close to their stars in other planetary systems.

Explanation for elemental enrichments in Jovian atmosphere

Early history of the satellites. The inner eight moons of Jupiter are thought to have originated in much the same way as the planet itself. Just as the primordial solar nebula is believed to have broken up into accreting planetesimals, which became the planets, and a central condensation, which became the Sun, the accumulation of material into a protoplanetary cloud at Jupiter's orbit led to the formation of the planet and its inner satellites. The analogy goes further. The high temperature of the forming Jupiter apparently prevented volatile substances from condensing at the distances of the innermost satellites. Hence, Ganymede and Callisto, the most distant of the inner eight moons, represent the volatile-rich outer bodies in this system.

The origin of the outer satellites, with their orbits of high eccentricities and inclinations, is thought to be quite different. They are members of the population of irregular satellites in the solar system and have most likely been captured by Jupiter. Their ultimate origin, however, remains unclear. They may have first formed in the outer nebula of Jupiter, strayed away, and then been recaptured; alternately, they may have formed independently in the solar nebula itself and then been captured. Ongoing studies of these objects and their possible relatives among the Trojan asteroids may provide the answer. (T.C.O.)

Saturn

Saturn, designated ♄ in astronomy, is the second largest planet in mass and size. Its dimensions almost equal those of Jupiter, while its mass is about three times smaller; it has the lowest mean density of any object in the solar system. Both Saturn and Jupiter resemble stellar bodies in that their bulk chemical composition is dominated by hydrogen. However, Saturn's structure and evolutionary history differ significantly from its larger counterpart. Like the other giant planets Jupiter, Uranus, and Neptune, Saturn has an extensive satellite and ring system, which may provide clues to its origin and evolution. Saturn's dense and extended rings, which lie in its equatorial plane, are currently the most impressive in the solar system.

Saturn is the sixth planet in distance from the Sun, with an orbital semimajor axis of 1.427 billion kilometres. It never approaches the Earth more closely than about 1.2 billion kilometres, and thus Earth-based observations of Saturn always show a nearly fully illuminated disk, unlike the Voyager 1 image shown in Figure 47.

PRINCIPAL CHARACTERISTICS

Like most planets, Saturn has a regular orbit with prograde motion around the Sun and a small eccentricity and inclination to the ecliptic. In this regard, it resembles its inner neighbour Jupiter. Unlike Jupiter, however, Saturn has a substantial obliquity, or inclination of its equatorial plane to its orbital plane, of 26.7°. As a result, Saturn's rings are presented to Earth-based observers at opening angles ranging from 0° (edge on) to nearly 30°.

Saturn has no single rotation period. Cloud motions in its massive upper atmosphere can be used to trace out a

Figure 47: View of Saturn from Voyager 1 on Nov. 16, 1980, four days after its closest approach, at a distance of 5.3 million kilometres.
B.A. Smith/National Space Science Data Center

variety of rotation periods, with periods as short as about 10 hours, 10 minutes near the equator and increasing with some oscillation to about 30 minutes longer at latitudes higher than 40°. The rotation period of Saturn's deep interior can be determined from the rotation period of the magnetic field, which is presumed to be rooted in a metallic outer core. Measurement of the field's rotation is difficult because the field is highly axisymmetric. Small irregularities in the field appear to be related to periodic radio outbursts in the magnetosphere with a period of 10 hours, 39.4 minutes, which is taken to be the magnetic field rotation period. There are also radio bursts with periods of about 10 hours, 10 minutes, which originate with lightning in Saturn's atmosphere.

Magnetic field rotation

The equatorial diameter of Saturn, 120,536 kilometres, is measured with respect to the one-bar pressure level in its atmosphere, for Saturn has no solid surface in its outer layers. Saturn is the most oblate (flattened at the poles) of all the planets in the solar system, with a polar diameter (at one bar) of 108,728 kilometres, 10 percent smaller than the equatorial diameter. Correspondingly, the equatorial gravity of the planet, 8.96 metres per second squared (m/s^2), is only 74 percent of the polar gravity, 12.14 m/s^2. The mass of Saturn is 5.685×10^{26} kilograms, or 95.13 times the mass of the Earth, while its volume is 766 times the volume of the Earth. Saturn's mean density is 0.69 gram per cubic centimetre. The escape velocity from the one-bar level is high, 36 kilometres per second, and thus there has been no significant escape of gas from the planet since its formation. See Table 15 for some characteristics of Saturn.

THE ATMOSPHERE

Saturn's atmosphere is 91 percent hydrogen by mass and is thus the most hydrogen-rich atmosphere in the solar system. Helium, which is measured indirectly, comprises another 6 percent and is less abundant relative to hydrogen as compared with a gas of solar composition. If hydrogen, helium, and other elements were present in the same proportions as in the Sun's atmosphere, Saturn's atmosphere would be about 71 percent hydrogen and 28 percent helium by mass.

The remaining major molecules that have been observed in Saturn's atmosphere are methane (CH_4) and ammonia (NH_3), which are a factor of two to five times more abundant relative to hydrogen than in a gas of solar composition. Hydrogen sulfide (H_2S) and water (H_2O) are expected to be major constituents of the deeper atmosphere but have not yet been detected. Minor molecules that have been spectroscopically detected include phosphine (PH_3), carbon monoxide (CO), and germane (GeH_4); such molecules would not be present in detectable amounts in a hydrogen-rich atmosphere in chemical equilibrium. They may therefore be disequilibrium products of reactions at high pressure and temperature in Saturn's deep atmosphere well below the observable clouds. A number of disequilibrium hydrocarbons are observed in Saturn's stratosphere: acetylene (C_2H_2), ethane (C_2H_6), and, possibly, propane (C_3H_8) and methyl acetylene (C_3H_4). All of the latter may be produced by photochemical effects from solar radiation or by energetic particle bombardment.

Analysis of the refraction of starlight and radio waves has provided information on the distribution of temperature in Saturn's atmosphere from pressures of one-millionth bar to 1.3 bar. At pressures below 1 millibar the atmosphere is roughly isothermal at about 140–150 K. A stratosphere, where temperatures steadily decline with increasing pressure, extends from 1 to 60 millibars, where the coldest temperature in Saturn's atmosphere (82 K) occurs. At higher pressures the temperature increases once again in the troposphere, following the so-called adiabatic lapse rate. This region is analogous to the Earth's troposphere, in which the increase of temperature with pressure follows the thermodynamic relation for compression of a gas

Temperature distribution

Table 15: Planetary Data for Saturn

Distance from the Sun	mean 1,427,000,000 km maximum 1,507,000,000 km minimum 1,347,000,000 km
Eccentricity of orbit	0.056
Inclination of orbit to ecliptic	2.5
Sidereal period of revolution	29.46 years
Rotation period (magnetic field)	10 h 39.4 min
Mean synodic period	378.09 Earth days
Obliquity	26.7°
Diameter at 1 bar (equatorial)	120,536 km
Diameter at 1 bar (polar)	108,728 km
Mass	5.685×10^{26} kg
Volume	766 × Earth volume
Average density	0.69 g/cm³
Equatorial gravity	8.96 m/s²
Polar gravity	12.14 m/s²

without gain or loss of heat. Saturn's tropospheric lapse rate is significantly affected by the quantum mechanics of hydrogen molecules at low temperatures. The temperature is 135 K at a pressure of 1 bar and continues to increase at higher pressures following the adiabatic relation.

The critical point of hydrogen (the highest temperature and pressure at which liquid and gas phases can exist in equilibrium) occurs at 33 K and 13 bars. Since Saturn's atmosphere is everywhere at a temperature of 82 K or higher, the hydrogen behaves as a supercritical liquid as it is compressed without gain or loss of heat. Thus, there is no distinct interface between the higher atmosphere where the hydrogen behaves predominantly as a gas and the deeper atmosphere where it resembles a liquid. Saturn's troposphere does not terminate on any solid surface, but it apparently extends tens of thousands of kilometres below the visible clouds, reaching temperatures of thousands of kelvins and pressures in excess of one million bars.

Like other giant planets, Saturn's atmospheric circulation is dominated by zonal (east-west) flow. When referenced to the rotation of the magnetic field, virtually all the flow is to the east—*i.e.*, in the direction of rotation. A particularly active eastward flow is observed in the equatorial zone at latitudes below 20°, with a maximum zonal velocity of almost 0.5 kilometres per second. This equatorial jet is analogous to one on Jupiter but extends twice as wide in latitude and moves four times faster.

Zonal jets

The zonal flows are remarkably symmetric about Saturn's equator; that is, each jet at a given northern latitude has a counterpart at a similar southern latitude. Strong eastward jets (relative velocities in excess of 100 metres per second) are seen at 46° north and south and at about 60° north and south. Westward jets, which are nearly stationary in the magnetic field's frame, are seen at 40°, 55°, and 70° north and south. Earth-based observations of Saturn's clouds over many years agree with the detailed spacecraft observations of the jets and thus corroborate their stability over time.

The north-south symmetry suggests that the zonal flows may be connected in some fashion deep within the interior. Theoretical investigations have shown that differential rotation of a deep-convecting fluid planet will tend to occur along cylinders aligned about the mean rotation axis. Saturn's atmosphere may display a series of coaxial cylinders, each rotating at a unique rate, which give rise to the zonal jets at the surface. The continuity of the cylinders may be broken at a point where they intersect a major discontinuity within Saturn, such as a core (see Figure 48.)

The atmosphere of Saturn shows many smaller-scale time-variable features similar to those found in Jupiter, such as red, brown, and white spots, bands, eddies, and vortices. The atmosphere generally has a much blander appearance than Jupiter's, however, and is less active on a small scale. A spectacular exception occurred during September–November 1990, when a large white spot appeared near the equator, expanded to a size exceeding 20,000 kilometres, and eventually spread around the equator before fading.

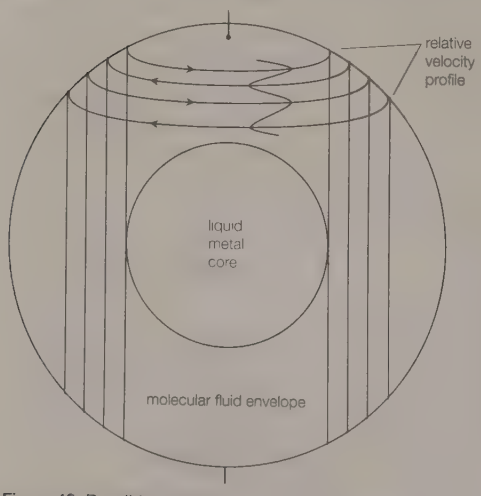

Figure 48: Possible cylindrical zonal flow in Saturn's interior.

The "surface" of Saturn that is seen through telescopes and in spacecraft images is actually a complex layer of clouds formed from molecules of minor species that condense in the hydrogen-rich atmosphere. Although aerosol particles formed from photochemical reactions are seen high in the atmosphere at pressures of 20–70 millibars, the main clouds commence at pressures exceeding 400 millibars, with the highest cloud deck expected to be formed of solid ammonia crystals. The base of the ammonia cloud deck is predicted to occur at a pressure of about 1.7 bars, where the ammonia crystals dissolve into the hydrogen gas and disappear abruptly. Nearly all information about deeper cloud layers has been obtained indirectly by constructing chemical models of the behaviour of compounds expected to be present in a gas of near solar composition following the temperature-pressure profile of Saturn's atmosphere. The bases of successively deeper cloud layers occur at 4.7 bars (ammonium hydrosulfide [NH_4SH] crystals) and at 10.9 bars (water-ice crystals with aqueous ammonia droplets). The actual clouds of Saturn display various shades of yellow, brown, and red, whereas all of the above clouds are colourless in the pure state. Thus, the observed shades are apparently produced by chemical impurities (phosphorus-bearing molecules are a prime candidate).

Cloud layers

INTERIOR STRUCTURE AND COMPOSITION

The low mean density of Saturn is direct evidence of the preponderance of hydrogen in its bulk composition. Under Saturnian conditions, hydrogen behaves as a liquid rather than a gas at pressures exceeding about one kilobar (corresponding to a depth of 1,000 kilometres below the clouds). At this depth the temperature is roughly 1,000 K, much higher than the critical temperature of hydrogen, and thus there is no identifiable interface at which the hydrogen layers are gaseous above and liquid below to distinguish between Saturn's atmosphere and interior. Even as a liquid, hydrogen is a highly compressible material, and a pressure in excess of one megabar is required to attain a density equal to the mean density of Saturn. Such pressure is achieved at a depth of 20,000 kilometres below the clouds.

Information about the interior structure of Saturn is obtained from studying its gravitational field, which is not spherically symmetric. The planet's rapid rotation and low mean density lead to distortion of its physical shape and the shape of its gravitational field, which can be measured precisely from the motion of spacecraft and eccentric ringlets. The degree of distortion from spherical symmetry is directly related to the relative amounts of mass concentrated in Saturn's central regions as opposed to its envelope. Such an analysis shows that Saturn is substantially more centrally condensed than Jupiter and therefore contains a significantly larger amount of material denser than hydrogen near its centre. Saturn's central regions contain about 50 percent hydrogen by mass, while Jupiter's contain approximately 67 percent hydrogen.

At a pressure of roughly two megabars and a temperature of about 6,000 K, the hydrogen is predicted to undergo a major phase transition to so-called liquid metallic hydrogen, which resembles a molten alkali metal such as lithium. This transition occurs at a radius about halfway between Saturn's atmosphere and centre. Evidence from the planet's gravitational field shows that the central metallic region is considerably denser than would be the case for pure hydrogen with solar proportions of helium. It is likely that the depletion of helium in Saturn's atmosphere is compensated by an excess of helium in the deeper metallic region, partially accounting for the increased density. A substantial quantity (perhaps nearly 30 Earth masses) of material denser than both hydrogen and helium may also be present in Saturn, but its precise distribution cannot be determined from available data. A rock and ice mixture

Liquid metallic hydrogen

of approximately 10–20 Earth masses is likely to be concentrated in a dense central core.

On average, Saturn absorbs 11×10^{16} watts of power from the Sun, while it radiates 20×10^{16} watts into space, primarily at infrared wavelengths between 20 and 100 micrometres. The difference between these numbers represents Saturn's present internal power, which must be derived from interior heat-generating processes. The specific internal power, which is the internal power per unit mass, is 1.5×10^{-10} watts per kilogram, which may be compared with the corresponding value for the Sun, 1.9×10^{-4} watts per kilogram, and for Jupiter, 1.7×10^{-10} watts per kilogram.

Although Saturn's specific internal power is similar to Jupiter's, it is evidently derived at least partially from a different source. A calculation of thermal evolution shows that Saturn could have originated with the gravitational collapse of gaseous hydrogen and helium from the original solar nebula onto a massive ice-rich core of perhaps 10 to 20 Earth masses. The core may have had a composition similar to that of the present icy Saturnian satellites. Jupiter may have undergone a similar origin, but with a greater amount of gas captured. The gas was heated to high temperatures (several tens of thousands of degrees kelvin) in the course of the capture. Jupiter's present internal power can then be understood as residual cooling of an initially hot planet over the age of the solar system, some 4.6 billion years, a mechanism similar to one once proposed (unsuccessfully) to explain the Sun's internal power. For Saturn, application of such a mechanism predicts a value for the cooling time that is too low by about a factor of two. That is to say, if the planet is assumed to be initially formed at a high temperature, the internal power drops below the present observed value after only 2.6 billion years. It has been theorized that the onset of hydrogen-helium immiscibility and thus the gradual sinking of helium liberates additional gravitational energy. As the helium separates from hydrogen in the metallic phase of hydrogen and "rains" into deeper levels, potential energy is converted into kinetic energy of helium droplet motion. This motion is then damped by friction and converted into heat, which is radiated into space, thus prolonging the duration of Saturn's internal power. This process is not believed to occur in Jupiter, which has a warmer interior and thus more helium miscibility. Detection of a substantial depletion of helium in Saturn's atmosphere by the Voyager spacecraft was taken as a vindication of the theory, details of which remain controversial.

Helium rain

MAGNETIC FIELD AND MAGNETOSPHERE

Saturn's magnetic field resembles that of a simple dipole or bar magnet with the axis of symmetry closely aligned (to within one degree) with Saturn's rotation axis and the centre of the equivalent dipole at the centre of the planet. The polarity of the field is opposite to that of the Earth's field; *i.e.*, the field lines emerge in Saturn's northern hemisphere and reenter the planet in the southern hemisphere. There are measurable deviations from a simple dipole field, which manifest themselves both in a north-south asymmetry and in a slightly higher polar surface field than would be predicted in a pure dipole model. The maximum polar surface field is 0.8 gauss (north) and 0.7 gauss (south), very similar to the Earth's polar surface field, while the equatorial surface field is 0.2 gauss.

The calculated electrical conductivity of Saturn's liquid metallic-hydrogen core is approximately 10^5 mhos per centimetre, about the same as that of lithium at one atmosphere pressure and a temperature just above its melting point. If slow circulation currents are present, as would be expected with the flow of heat to the surface accompanied by gravitational settling of denser components, sufficient dynamo action is expected to produce the observed magnetic field. Saturn's field is thus produced by essentially the same mechanism as produces the Earth's field. The deep field, in the vicinity of the dynamo region near the core, may be quite irregular. Theories hypothesize that magnetic field lines are made more axisymmetric before they reach the surface by passing through a nonconvecting, electrically conducting region that is rotating with respect to the field lines. Saturn's striking atmospheric differential rotation may be related to the action of much deeper currents involving the conducting core.

Generation of magnetic field

Saturn's magnetosphere (the region of space dominated by Saturn's magnetic field rather than interplanetary magnetic fields) extends to a distance of about 20 Saturn radii from the centre of the planet on the sunward side but with substantial fluctuation due to variations in the dynamic pressure from the solar wind. On the antisunward side the magnetosphere is drawn out into a long magnetotail, which extends to much greater distances. Saturn's satellites Titan and Hyperion orbit at distances close to the minimum magnetospheric dimensions and occasionally cross the boundary. As a consequence, charged particles from Titan's upper atmosphere may interact with the local magnetic field lines.

Saturn's inner magnetosphere, like the magnetospheres of the Earth and Jupiter, has a stable population of energetic protons (those having energies greater than tens of millions of electronvolts) spiraling along magnetic field lines. Unlike the magnetospheres of the Earth and Jupiter, however, this population is substantially altered by absorption of the energetic particles onto the surfaces of solid bodies orbiting within the field lines. "Holes" are seen in the particle populations on field lines that thread the rings and the orbits of satellites within the magnetosphere.

THE SATELLITES AND RINGS

Satellite system. Saturn possesses an extensive system of satellites, and all but the outermost have prograde, low-inclination and low-eccentricity orbits with respect to the planet. (Data on the Saturnian satellites are summarized in Table 16.) A small satellite (S18) with dimensions on the order of 10 kilometres has been observed within the ring system; its presence within the Encke gap (an area of decreased brightness in the A ring; see below *Ring system*) was deduced from its dynamical effects on the gap, and more such ring moons doubtlessly remain to be discovered. Indeed, the ring system itself consists of myriads of much smaller satellites.

The orbital and rotational dynamics of Saturn's satellites show complexities unique to this system. The small satellites S10, S11, and S17 orbit near the outer edge of the main ring system and should dynamically interact with it by receiving angular momentum from ring particles through collective gravitational interactions. The effects of this process are to reduce the spreading of the rings caused by inelastic collisions between ring particles and to drive these satellites to larger orbital radii. Because of the small size of the satellites, it is difficult to find a mechanism by which this process could have endured over the age of the solar system without driving the satellites far beyond their current positions. The sharpness of the outer edge of the ring system and the present orbits of the inner satellites are puzzling, and such features may imply that the current ring system is much younger than Saturn itself.

The satellites S15 and S16 are classical shepherd satellites, orbiting on either side of the F ring and confining its particles to a narrow band. The inner shepherd (S16) transmits angular momentum to the ring, pushing the ring outward and itself inward, while the outer shepherd (S15) receives angular momentum from the ring, pushing the ring inward and itself outward. The co-orbital satellites Janus and Epimetheus (S10 and S11) share the same average orbit, interacting with each other every few years in such a way that one transmits angular momentum to the other, which forces the latter into a slightly higher orbit and the former into a slightly lower orbit. At subsequent closest approach, the process repeats in the opposite direction. The satellites Tethys (S3) and Dione (S4) also have co-orbital satellites, but since Tethys and Dione are much more massive than their co-orbiters, there is no significant exchange of angular momentum. Instead, Tethys' co-orbiters S13 and S14 are located at the stable Lagrange points on Tethys' orbit, leading and following Tethys by 60°, in a manner precisely analogous to the Trojan asteroids in Jupiter's orbit. Dione possesses only a single Trojan-like companion, S12, which leads it by 60° on average.

Co-orbital satellites

The satellite pairs Mimas-Tethys, Enceladus-Dione, and Titan-Hyperion are in stable dynamical resonances, in the sense that they interact gravitationally in a periodic fashion so as to preserve the regularity. The ratio of the orbital periods of a satellite pair in resonance is approximately equal to a ratio of small whole numbers. The orbital periods of Titan and Hyperion are in the ratio 3:4, such that conjunction of Titan and Hyperion always occurs at Hyperion's apoapse (farthest point of its elliptical orbit from Saturn). Since the much larger body Titan always exerts a maximum gravitational perturbation at the same points on Hyperion's orbit, Hyperion is forced into a relatively large eccentricity. Analogously, Enceladus and Dione have orbital periods in the ratio 1:2, as is also the case for Mimas and Tethys. Resonances may be important in the structure of the system of the concerned satellites because they can force orbital eccentricities to relatively large values. Ordinarily, tidal interactions between satellites and Saturn tend to circularize the satellite orbits as well as to force the satellites into synchronous rotation. Once such a rotation state has been established, tides are stationary in the satellite's frame and do not cause energy dissipation. However, eccentricity forced by resonance causes time-variable tides on satellites, with accompanying energy dissipation and heating of the satellite's interior. Although calculations indicate that present tides on Saturn's satellites are not particularly significant as a heating mechanism, this may not have been true in the past. A tenuous and diffuse outer ring of Saturn, the so-called E ring, is associated with the orbit of Enceladus and may consist of material supplied by episodes of volcanism on Enceladus.

Although tidal friction ordinarily forces satellites into a state of synchronous rotation, Hyperion appears to be a spectacular exception to this rule. Because of its large orbital eccentricity and highly unspherical shape, there is a complicated interaction between Hyperion's spin and orbital angular momentum leading to a chaotic feedback process. Although Hyperion was observed from the Voyager spacecraft to be rotating with a nonsynchronous period of about 13 days, chaos theory shows that it is actually tumbling in an essentially unpredictable manner. As Mercury is the only object in the solar system known to be captured into a resonance with a ratio of rotational period to orbital period other than the usual 1:1 (Mercury's ratio is 2:3), so Hyperion is the only object known to be in chaotic rotation.

Titan

Titan is the only known satellite in the solar system with a dense atmosphere. The atmosphere was first detected spectroscopically in 1944, by Gerard P. Kuiper, who found evidence of methane absorption. However, studies of refraction of radio waves in the atmosphere carried out by the Voyager 1 spacecraft have shown that methane is a minor constituent of the atmosphere, comprising only 2 to 10 percent by number, and that spectroscopically inactive molecules predominate. Comparison of infrared and radio data shows that the mean molecular weight of the atmosphere is 28.6 atomic mass units. Thus, the most plausible major constituent is nitrogen (N_2; mean molecular weight 28), although some argon could also be present (mean molecular weight 36). The atmosphere of Titan is similar to that of the Earth in that it consists predominantly of nitrogen gas and has a surface pressure of 1.5 bars. However, Titan's atmosphere is much colder than the Earth's, with a surface temperature of 94 K, and contains no free oxygen. Titan visually appears as a uniform brownish globe; its surface is permanently veiled by dense clouds of uncertain composition, extending to altitudes of hundreds of kilometres.

A small troposphere extends from Titan's surface to an altitude of 42 kilometres, where a minimum temperature of 71 K is reached. Apparently temperatures are always above the condensation point of nitrogen, so that nitrogen clouds are not present. Methane clouds may be present in this region if methane has a mixing ratio exceeding 1.5 percent, but a liquid methane ocean at Titan's surface would require a mixing ratio of 12 percent and is not expected. The existence of an ocean of ethane (C_2H_6) has been suggested, but radar echoes from Titan reveal a mostly solid surface.

Titan's stratosphere extends from 50 to 200 kilometres in altitude, with temperatures steadily increasing with altitude to maximum values between 160 and 180 K. Studies of the refraction of starlight in Titan's upper atmosphere show that temperatures remain in this range up to altitudes of 450 kilometres, and spacecraft observations of the transmission of solar ultraviolet light give similar values at even higher altitudes. Many carbon-bearing molecules produced by photochemical processes in Titan's high atmosphere have been detected spectroscopically. These include carbon monoxide (CO), ethane (C_2H_6), propane (C_3H_8), acetylene (C_2H_2), ethylene (C_2H_4), hydrogen cyanide (HCN), methyl acetylene (C_3H_4), diacetylene (C_4H_2), cyanoacetylene (HC_3N), cyanogen (C_2N_2), and carbon dioxide (CO_2), all detected in trace amounts.

Particulates that absorb solar radiation are extraordinarily pervasive throughout Titan's atmosphere, attaining substantial tangential optical depth even at altitudes of 300 kilometres and gas pressures substantially below one millibar. Their typical sizes probably lie in the range of 0.1 micrometre. There is evidence that they grow to a substantially higher density in Titan's summer hemisphere, suggesting that they are a form of natural photochemical "smog." Solar heating of the particle layers creates a temperature inversion layer in Titan's stratosphere, preventing dissipation of the smog layer by convection.

Saturn's other satellites are much smaller than Titan and possess no detectable atmospheres. However, their low mean densities, as well as the spectroscopy of their

surface solids, indicate that they are rich in ice, probably mostly water ice, with perhaps some solids of more volatile species (possibly ammonia). Under the low solar equilibrium temperatures prevailing at Saturn, the ice behaves mechanically like rocky material in the inner solar system, and the surfaces of the satellites bear a superficial resemblance to the cratered rocky surface of the Moon but with many important differences. Images of satellites were obtained by the Voyager 1 and 2 spacecraft, but they vary in resolution and surface coverage and are in many cases far from complete.

Mimas reveals a heavily cratered surface similar to the lunar highlands, but it also possesses one of the largest impact structures (in relation to the satellite's size) in the solar system. The crater Herschel (named in honour of the 19th-century British astronomer William Herschel), situated on Mimas' leading hemisphere, is 130 kilometres in diameter (one-third of the diameter of Mimas), is roughly 10 kilometres deep, and has outer walls about 5 kilometres high.

Enceladus

Enceladus, which is suspected of possible volcanism, has a highly reflecting surface, with a normal reflectance exceeding that of newly fallen snow (see Figure 49). Few large craters are seen, while extensive ridged plains and crater-free areas give convincing evidence of fairly recent internal activity, possibly within the last 100 million years. Particles in the E ring centred on Enceladus' orbit have sizes in the range of one micrometre and could persist for only a few thousand years. Thus, an Enceladus event that produced them may have occurred that recently.

Tethys, although larger than Enceladus, shows little evidence of internal activity. Its heavily cratered surface appears to be quite old, although it displays subtle features indicative of creep or viscous flow in its icy lithosphere. Dione and Rhea exhibit heavily cratered surfaces similar to the lunar highlands, but with bright patches that may be freshly exposed ice. Although Dione is smaller than Rhea, it has more evidence of recent internal activity, including resurfaced plains and fracture systems.

The surface of Iapetus has not been studied in detail, but it shows a large asymmetry in reflectivity between its leading and trailing hemispheres. The leading hemisphere is remarkably dark, with the darkest material concentrated at the apex of orbital motion. The composition of the dark material is not known with certainty. The trailing hemisphere is heavily cratered, highly reflecting, and appears to be icy in composition. The low mean density of Iapetus suggests that the satellite as a whole is mostly ice.

Ring system. Saturn's ring system ranks among the most spectacular phenomena in the solar system. With a diameter of 270,000 kilometres, the system is an enormous object, yet its thickness does not exceed 100 metres, and its total mass comprises only about 3×10^{22} grams, similar to the mass of Mimas.

Like the rings of the other giant planets Jupiter, Uranus, and Neptune, those of Saturn lie for the most part within the classical Roche limit. This limit, which for the idealized case is at 2.44 Saturn radii, represents the closest distance at which a small satellite can approach a massive primary before it is torn apart by tidal forces. Conversely, small bodies within the Roche limit are prevented from aggregating into larger objects by tidal forces. The limit applies only to objects held together by gravitational attraction and thus does not restrict the stability of relatively small bodies for which molecular cohesion is important. Thus, small moons with sizes in the range of tens of kilometres or less can persist indefinitely within the Roche limit.

Particle size distribution

Although the individual particles that make up Saturn's rings cannot be seen directly, their size distribution can be deduced from their effect on the scattering of signals propagated through the rings from spacecraft and stars. This analysis shows a broad and continuous spectrum of particle sizes, ranging from centimetres to several metres, with larger objects being significantly fewer in number than smaller ones. This spectrum is consistent with the distribution that might be expected from repeated collision and shattering of initially larger objects. In some parts of the rings, where collisions are apparently more frequent, even smaller (dust-sized) grains are present, but these have short lifetimes owing to a variety of loss mechanisms. Clouds of the smaller grains apparently acquire electrical charges, interact with the magnetic field, and manifest themselves in the form of moving, wedge-shaped spokes that extend radially. Much larger ring moons—those of several kilometres—may exist within the rings but are apparently quite rare. Spectra of sunlight reflected from

B A Smith/National Space Science Data Center

Figure 49: View of Enceladus from Voyager 2, showing crater-free portions of the surface, possibly indicative of resurfacing by liquid water from the interior.

the rings show absorption by water ice, and the rings are highly reflective to visual light. Thus, it is conceivable that the rings were produced by the disruption of a satellite of the size and composition of Mimas.

The ring system shows structures on many scales, ranging from the broad divisions into the classical A, B, and C rings down to a myriad of individual ringlets with radial scales on the order of kilometres. The structures have provided a fertile field for investigating gravitational resonances and the collective effects of many small particles orbiting in close proximity. Although many of the structures can be understood theoretically, a large number remain enigmatic, and a complete synthesis of the system is still lacking. Because the Saturn ring system may be an analogue of the original disk-shaped system of particles out of which the solid planets formed, an understanding of its dynamics and evolution has implications for the origin of the solar system itself.

The structure of the rings is broadly described by the optical depth, τ, as a function of radial distance from the centre of Saturn. The optical depth, which is a measure of the average density of the rings, is defined as the natural logarithm of the ratio of the incident intensity of light of a specified wavelength to the emergent intensity, where the light is assumed to propagate in a direction perpendicular to the ring plane. Radio signals with wavelengths of several centimetres and greater are largely unaffected by the smallest ring particles and thus encounter smaller optical depths than signals with wavelengths in the visible region of the electromagnetic spectrum and shorter.

Ring locations and optical depths

The B ring is the thickest and broadest of the rings, extending from 1.52 to 1.95 Saturn radii, with optical depths between 1.2 and 1.8. It is separated from the outer major ring, the A ring, by the Cassini division. The Cassini division (1.95 to 2.02 Saturn radii) is not devoid of particles but exhibits complicated variations in τ, with an average value of 0.12. The A ring extends from 2.02 to 2.27 Saturn radii, with a τ value of about 0.7 to 0.6. Interior to the B ring lies the C ring (sometimes known as the Crepe ring), at 1.23 to 1.52 Saturn radii, with optical depths about 0.1. Interior to the C ring lies the extremely tenuous D ring (1.11 to 1.23 Saturn radii), visible only in reflected light. Exterior to the A ring lies the narrow, shepherded F ring at 2.33 Saturn radii. The tenuous G ring, at 2.8 Saturn radii, was originally detected by its influence on charged particles in Saturn's magnetosphere and is faintly discernible in Voyager images. The E ring extends from 3 to 8 Saturn radii.

Numerous gaps are seen in the distribution of optical depth in the major ring regions. Some of the major gaps have been named after famous astronomers who were associated with studies of Saturn. In addition to the Cassini division, they include the Maxwell gap (1.45 Saturn radii), the Huygens gap (1.95 Saturn radii), the Encke gap (2.21 Saturn radii), and the Keeler gap (2.26 Saturn radii). Of the latter four gaps, only the Encke gap was known prior to the existence of spacecraft images of Saturn.

Formation of gaps

Particles can be cleared from a region to form a gap by the gravitational effects of a moon about 10 kilometres in size orbiting within the gap region; such a moon (S18) was found within the Encke gap. The corresponding moon within the Keeler gap has not yet been found but is believed to exist. Gaps can also be cleared in ring regions that are in orbital resonance with satellites whose orbits are substantially interior or exterior to the rings. The condition for resonance is that orbital periods of the satellite and ring particle be in the ratio l:$(m-1)$, where l and m are integers. When this condition is satisfied, the satellite (if external to the ring) receives angular momentum from the resonant ring particles, launching a tightly wound spiral density wave in the ring and ultimately clearing a gap if the resonance is strong enough. The outer edge of the B ring (inner edge of the Cassini division) is in 2:1 resonance with Mimas and shows the two-lobed excursions in radius predicted by such a resonance. Similarly, the outer edge of the A ring, and of the main ring system itself, is in 7:6 resonance with the co-orbital satellites Janus and Epimetheus and is scalloped with seven lobes. Effects of other resonances with various orbital frequencies of external satellites are seen throughout the ring system, but many similar features have no such explanation.

HISTORY OF OBSERVATION

Saturn is easily visible to the naked eye as a point of light and has thus been known to man since prehistoric times. Its motions were systematically studied by various early cultures, and, as the farthest of the planets known to pre-telescopic astronomers, it was seen to be the slowest-moving. Its modern name comes to us from the Roman god of agriculture, known to the Greeks as Cronus, the father of Zeus.

The ring system was discovered by Galileo in 1610, when he first observed Saturn with a primitive telescope. However, Galileo's instrument produced images that were insufficiently clear for him to discern the true geometry of the system. Rather, he reported that Saturn was a triple planet: a central globe with smaller bodies nearly in contact on either side. In 1612 the image became a single globe because the rings essentially disappeared during the Earth's ring-plane passage. Later observations by Galileo showed that the curious appendages had reappeared. However, he apparently never deduced that the appendages were in fact a flat ring encircling the planet.

The Dutch scientist Christiaan Huygens began studying Saturn with an improved telescope in 1655, and he eventually correctly deduced that the planet was encircled by a flat ring and that the ring plane was inclined substantially to Saturn's orbital plane. He believed that the ring was solid, however, and that it had a substantial thickness. Cassini's discovery of a gap between the rings some years later cast doubt on the possibility of a solid ring, and Pierre-Simon Laplace of France published a theory in 1789 that the rings were made up of many smaller components. In 1857, James Clerk Maxwell demonstrated mathematically that the rings could be stable only if they were made up of a very large number of small particles.

Even under the optimal conditions attainable with an Earth-based telescope, features smaller than a few thousand kilometres on Saturn cannot be resolved. Thus, the great detail exhibited in the rings and atmosphere was largely unknown prior to spacecraft observations. Even the division reported in 1837 by Johann F. Encke of Germany was considered dubious until it was confirmed in 1978 by Harold Reitsema, who used measurements of an Iapetus eclipse by the rings to improve on normal Earth-based resolution.

Modern research on Saturn relies on special techniques used with Earth-based telescopes and space probes. Infrared spectroscopy of the rings, atmosphere, and satellites has yielded considerable information about their composition and thermal balance. Spatial resolution of the rings and atmospheric structures on the scale of kilometres is obtained by observing signals from stars that pass behind the planet as seen from the Earth, as occurred in 1989. In 1990 the "great white spot" was successfully observed with the Hubble Space Telescope from Earth orbit.

The greatest advances in knowledge of Saturn have come from three space probes. In 1973 and 1974, the two spacecraft Pioneer 10 and 11 encountered Jupiter, their nominal objective. Pioneer 10 then proceeded on an orbit into interstellar space. However, it was possible to use the Jupiter encounter to send Pioneer 11 on to Saturn, although this was not originally an objective of the mission. The retargeting was successful, and on Sept. 1, 1979, Pioneer 11 became the first man-made object to reach Saturn, passing through the ring plane at a distance of only 38,000 kilometres from the A ring and passing within 21,000 kilometres of Saturn's atmosphere. The Voyager 1 and 2 spacecraft, which carried much more elaborate imaging equipment, were specifically designed for scientific objectives at Saturn and encountered the planet on Nov. 12, 1980, and Aug. 25, 1981, respectively, after first encountering Jupiter. Intensive further study of the Saturn system will involve the use of a spacecraft specifically designed to orbit the planet and encounter its satellites repeatedly so as to secure more detailed information about the composition, geology, meteorology, and dynamics of the many bodies in the region. (W.B.H.)

Voyager encounters

Uranus

Uranus, symbol ♅ in astronomy, is the seventh planet in order of distance from the Sun. Its low density (1.285 grams per cubic centimetre) and large size (radius four times that of the Earth) place it among the four giant planets, which have no solid surfaces and are composed primarily of hydrogen, helium, water, and other volatile compounds. Absorption of red light by methane gas gives the planet a blue-green colour (see Figure 50). Uranus spins on its side; its rotation axis is tipped at an angle of 98° relative to its orbit axis. In addition, the magnetic field is tipped at an angle of 59° relative to the rotation axis. Uranus has 15 known satellites, ranging up to 789 kilometres in radius, and 10 narrow rings. Its mean distance from the Sun is 2,870.99 million kilometres, and its mean distance from the Earth at closest approach is 2,721.39 million kilometres.

PRINCIPAL CHARACTERISTICS

Basic information about the Uranian system is summarized in Table 17. The Uranian year is 84.01 Earth years. The eccentricity of the orbit is 0.0461, and the inclination of the orbit to the Earth's orbital plane is 0.774°. Low eccentricity and low inclination such as those of Uranus are characteristic of all planetary orbits. It is believed that collisions and gaseous drag took energy out of the orbits while the planets were forming and so reduced the eccentricities and inclinations to their present values. Thus, Uranus formed with the rest of the planets soon after the birth of the Sun.

The mass of Uranus, 8.684×10^{25} kilograms, is 85 percent that of Neptune. At the level where the atmospheric pressure is one bar (roughly equivalent to the Earth's sea-level pressure), the equatorial radius is 25,559 kilometres, which is 3.2 percent greater than that of Neptune. Thus Uranus and Neptune are nearly twin planets, although the difference in their respective bulk densities, 1.285 as compared with 1.64 grams per cubic centimetre, reveals a fundamental difference in composition and internal structure. Although Uranus and Neptune are significantly larger than the terrestrial planets, their radii are less than half those of the largest planets, Jupiter and Saturn. The equatorial surface gravity of Uranus is 8.69 metres per square second, which is 11 percent smaller than that of the Earth.

According to international convention, the north pole of a planet is defined as the pole that is above the equatorial plane of the solar system, regardless of the direction in which the planet is spinning. In terms of this definition, Uranus spins clockwise about its north pole, which is opposite to the spin of the Earth. When the Voyager 2 spacecraft flew by Uranus on Jan. 24, 1986, the north pole was in darkness and the Sun was almost directly overhead at the south pole. In 42 years (one-half the Uranian year), the Sun moves from being overhead at one pole to being overhead at the other. The 98° tilt is thought to have arisen during the final stages of planetary accretion when bodies comparable in size to the present planets collided in a series of violent events that knocked Uranus on its side.

Rotational periods

The rotational period of Uranus, 17.24 hours, was inferred when the Voyager spacecraft detected periodic radio emissions that were coming from charged particles trapped in the magnetic field. Direct measurements of the field showed that it is tipped at an angle of 58.6° relative to the rotation axis and that it rotates with the same period. Since the field is thought to be generated in the electrically conducting interior of the planet, the 17.24-hour period is assumed to be that of the interior. The rotation causes an oblateness, or flattening of the planet's poles such that the polar radius is 2.29 percent smaller than the equatorial radius. Winds in the atmosphere cause cloud markings to rotate at periods ranging from 18 hours to slightly more than 14 hours.

THE ATMOSPHERE

Molecular hydrogen (H_2) and helium (He) are the two main constituents of the atmosphere. Hydrogen is detectable from the Earth in the spectrum of sunlight scattered by the clouds of Uranus. The helium-to-hydrogen ratio was determined from the bending of the Voyager radio signal as it passed through the atmosphere. The ratio of the number of helium molecules to the total number of diatomic hydrogen and helium molecules is 0.15, while the corresponding mass ratio of helium to the total is 0.26. These values are consistent with the values inferred for the Sun and are significantly greater than the values inferred for the atmospheres of Jupiter and Saturn. It is assumed that all four of the giant planets have the same proportions of hydrogen and helium as the Sun but that the helium has settled toward the centres of Jupiter and Saturn. The processes that cause this settling have been shown not to operate on less massive planets like Uranus and Neptune.

Jet Propulsion Laboratory/National Aeronautics and Space Administration

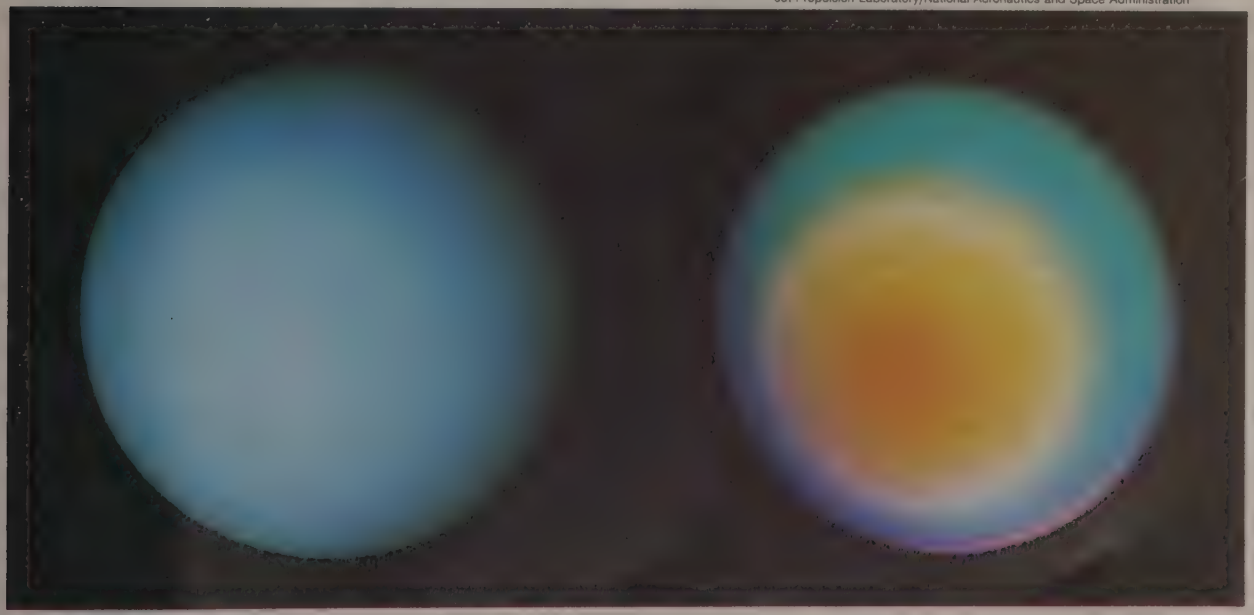

Figure 50: *Views of Uranus obtained by Voyager 2.*
(Left) The colour of this photograph was adjusted to simulate the view the human eye would normally see. (Right) The colour and brightness have been greatly exaggerated to enhance atmospheric features. The faint concentric bands are centred on the pole of rotation. (The small doughnut-shaped features are artifacts arising from dust in the camera.)

Table 17: Physical Data for Uranus

Mean distance from the Sun	2.87099×10^9 km (19.19 AU)
Orbital period (the Uranian year)	30,685 days (84.01 years)
Mean orbital velocity	6.81 km/s
Eccentricity of orbit	0.0461
Inclination of orbit to ecliptic	0.774°
Mass	8.684×10^{25} kg
Equatorial radius at one bar	25,559 km
Ellipticity	0.0229
Mean density	1.285 g/cm^3
Equatorial surface gravity	8.69 m/s^2
Equatorial escape velocity	21.3 km/s
Internal period of rotation	17.24 hours
Mean synodic period	369.66 Earth days
Inclination of equator to orbit	97.86°
Effective radiating temperature	59.1 K
Albedo	0.30
Magnetic dipole tilt relative to rotation axis	58.6°
Magnetic dipole strength at equator	0.228 gauss
Number of known satellites	15
Number of known rings	10

Methane (CH_4) absorbs strongly at near-infrared wavelengths, and it dominates that part of the spectrum even though the number of methane molecules is only 2.3 percent of the total. This estimate of the abundance was determined using Voyager 2 radio signals that probed to depths where the methane-to-hydrogen ratio is likely to be constant. If this constant is characteristic of the planet as a whole, the carbon-to-hydrogen (C:H) ratio of Uranus is 24 times that of the Sun. The large value of the C:H ratio suggests that the elements oxygen, nitrogen, and sulfur also are enriched relative to solar values. However, these elements are tied up in molecules of water (H_2O), ammonia (NH_3), and hydrogen sulfide (H_2S), which condense at levels below the part of the atmosphere that can be seen. Earth-based radio observations reveal a curious depletion of ammonia in the atmosphere, perhaps because hydrogen sulfide is more abundant and sequesters all the ammonia in cloud particles of ammonium hydrosulfide (NH_4SH). The Voyager ultraviolet spectrometer experiment detected traces of acetylene (C_2H_2) and ethane (C_2H_6) in abundances on the order of 10^{-8}. These gases are by-products of methane, which dissociates when ultraviolet light from the Sun strikes the upper atmosphere.

The average power radiated by Uranus is equivalent to that of a blackbody radiating at a temperature of 59.1 K. This radiation temperature is equal to the physical temperature of the atmospheric gases at a pressure of about 0.4 bar. Temperature decreases with height throughout this portion of the atmosphere up to the 70-millibar level, where it is about 52 K. The temperature rises from this point until it reaches 750 K in the exosphere (the top of the atmosphere at a distance of 1.1 Uranian radii from the planetary centre), where pressures are on the order of 10^{-12} bar. The cause of the high exospheric temperatures is uncertain, but it may involve a combination of ultraviolet absorption, electron bombardment, and inability of the gas to radiate at infrared wavelengths.

Atmospheric temperatures

Horizontal contrasts of temperature were measured by Voyager in two broad altitude ranges, one located in the range of 60 to 200 millibars and the other of 500 to 1,000 millibars. In both ranges the pole-to-pole temperature contrast is small, less than 1 K, despite the fact that the south pole was facing the Sun at the time of the Voyager encounter. This lack of global contrast is related to the efficient horizontal heat transfer and the large heat storage capacity of the deep atmosphere.

Although Uranus is nearly featureless, extreme contrast enhancement of the Voyager images reveals faint bands oriented parallel to circles of constant latitude (see Figure 50). Apparently the rotation of the planet and not the distribution of absorbed sunlight controls the cloud patterns. Rotation manifests itself through the Coriolis force, an effect that causes material moving on a rotating planet to appear to be deflected to either the right or the left depending on the sign of the latitude. Uranus therefore looks like a tipped-over version of Jupiter and Saturn in terms of cloud patterns.

The wind is the motion of the atmosphere relative to the rotating planet. At high latitudes on Uranus, as on the Earth, this relative motion is in the direction of the planet's rotation. At low (that is, equatorial) latitudes, the relative motion is in the opposite direction. On the Earth these directions are called east and west, respectively, but the more general terms are prograde and retrograde. The winds that exist on Uranus are several times stronger than those of the Earth. The wind is 200 metres per second (prograde) at a latitude of −55° and 110 metres per second (retrograde) at the equator. Neptune's equatorial winds are also retrograde, although those of Jupiter and Saturn are prograde. No satisfactory theory exists to explain these differences.

Winds

Uranus has no large spots like the Great Red Spot of Jupiter or the Great Dark Spot of Neptune. The measurements of the wind profile come from just four small spots whose contrast is no more than 2 or 3 percent relative to the surrounding atmosphere. Since the giant planets have no solid surfaces, the spots represent atmospheric storms. For reasons that are not clear, Uranus seems to have the smallest number of storms of any of the giant planets.

INTERIOR STRUCTURE AND COMPOSITION

Although Uranus has a somewhat lower density than Jupiter, it has a higher proportion of elements heavier than hydrogen and helium. Jupiter's greater mass (by a factor of 22) leads to a greater gravitational force and greater self-compression than on Uranus. If the two planets were made of the same material, Jupiter would be considerably denser than Uranus. Models proposed for the Uranian interior assume different ratios of rock (metals and their oxides), ice (water, methane, and ammonia), and gas (essentially hydrogen and helium). At the high temperatures and pressures within the giant planets, the "ices" will in fact be liquids. To be consistent with the bulk density data, the mass of rock plus ice must constitute roughly 80 percent of the total mass of Uranus, compared with 10 percent for Jupiter and 2 percent for a mixture of solar composition. In all models Uranus is a fluid planet, with the gaseous atmosphere gradually merging with the liquid interior. Pressure at the centre is about five megabars.

More information about the interior is obtained by comparing the model's response to centrifugal forces (as would arise from the planet's rotation) with the actual response measured as spacecraft are accelerated by the planet. This response is expressed in terms of the planet's oblateness. By measuring the degree of flattening at the poles as compared with the speed of rotation, one can infer the density distribution inside the planet. If two planets had the same mass and bulk density, the planet with most of its mass concentrated close to the centre would be less flattened by rotation. Before the Voyager mission, it was difficult to choose between models in which the three components rock, ice, and gas were separated into distinct layers and those in which the ice and gas were well mixed. From the large oblateness of Uranus combined with the planet's slow rotation, it now appears that the ice and gas are well mixed and a rocky core is small or nonexistent. The fact that the mixed model of Uranus fits the data better than the layered model may reveal information on the planet's formation. Instead of Uranus forming from a rock-ice core that subsequently captured gas from the solar nebula, the model seems to favour a process in which large, solid objects were continually captured into a giant planet that already contained major amounts of the gaseous component.

Uranus is different from the other giant planets in that it is not radiating a substantial amount of excess internal heat. The total heat output is determined from the measured infrared emissions, while the heat input is determined from the fraction of incident sunlight that is absorbed—*i.e.*, not scattered back into space. The fraction that is scattered is called the albedo, which for Uranus is about 0.3. The ratio of total power radiated to total power absorbed is between 1.00 and 1.06 for Uranus. (The equivalent ratios for the other giant planets are greater than 1.7.) Thus the internal heat source on Uranus is no more than 6 percent of the power absorbed. The small terrestrial planets generate relatively little internal heat; the comparable number for the Earth is only 10^{-4}.

Low internal heat output

It is not clear why Uranus has such a low internal heat output compared to the other Jovian planets. All the planets should have started warm, when gravitational energy was transformed into heat during planetary accretion. Over the age of the solar system, the Earth and the other smaller objects have lost most of their heat of formation. Being massive objects with cold surfaces, however, the giant planets store heat well and radiate poorly. Therefore, they should have retained large fractions of their heat of formation, which should still be escaping today. Chance events (collisions between large bodies) at the time of formation and the resulting differences in internal structure are one of the explanations that have been proposed to explain differences among the giant planets such as the anomalous heat output of Uranus.

MAGNETIC FIELD AND MAGNETOSPHERE

Like the other giant planets, Uranus has a magnetic field that is generated by convection currents in the electrically conducting interior. The magnetic dipole field, which resembles the field of a small but intense bar magnet, has a strength of 0.23 gauss in its equatorial plane at a distance of one Uranian equatorial radius (1 R_U) from the centre. The dipole axis is tilted with respect to the planet's rotation axis at an angle of 58.6°. This angle greatly exceeds that for the Earth (11°), Jupiter (9.6°), and Saturn (less than 1°). The magnetic centre is displaced by 0.3 R_U from the planet's centre. The displacement is mainly along the rotation axis toward the north pole.

The field is unusual not only because the dipole is tilted and offset from the centre of the planet but also because the small-scale components of the field are relatively large. This "roughness" suggests that the field is generated at shallow depths within the planet, because small-scale components of a field die out rapidly above the electrically conducting region. Thus the interior of Uranus must become electrically conducting closer to the surface than on Jupiter, Saturn, and the Earth. This inference is consistent with what is known about the internal composition, which must be mostly water, methane, and ammonia in order to match the average density of the planet. Since water and ammonia dissociate into positive and negative ions at relatively low pressures and temperatures, the field is expected to be generated close to the surface where these moderate conditions obtain.

Near-surface generation of the magnetic field

As with the other magnetic planets, the field repels the stream of charged particles (the solar wind) flowing outward from the Sun. The planetary magnetosphere—a huge cavity containing charged particles that are bound to the magnetic field—surrounds the planet and extends downstream from it. On the upstream side, the boundary between the magnetosphere and the solar wind is 18 R_U from the centre of the planet.

Because the largest Uranian satellites orbit within the magnetosphere, they absorb some of the trapped particles. The particles behave as if they were attached to the magnetic field lines, so that those lines intersecting a satellite in its orbit have fewer trapped particles than neighbouring field lines. The Uranian magnetosphere is composed of protons and electrons, indicating that the planet's upper atmosphere is supplying most of the material. There is no evidence of helium, which might originate from the solar wind, and no evidence of heavier ions, which might come from the Uranian satellites or their atmospheres.

Charged particles from the magnetosphere impinge on the upper atmosphere and stimulate the aurora. Auroral heating can just barely account for the high temperature (750 K) of the Uranian exosphere. One effect of the high temperature is that the atmosphere extends outward into the region occupied by ring particles and severely limits their orbital lifetime to values less than the age of the solar system.

THE SATELLITES AND RINGS

Uranus has 15 satellites and 10 narrow rings, all in nearly circular orbits with low inclinations relative to the equatorial plane of the planet. In general, the rings orbit closest to the planet, the smaller satellites orbit just outside the rings, and the larger satellites orbit farthest from the planet.

Satellites. Properties of the five major satellites are summarized in Table 18, and characteristics of the rings are given in Table 19. The 10 minor satellites, all of which were discovered by Voyager 2, have radii from 13 to 77 kilometres and orbit the planet at distances ranging from 49,750 to 86,000 kilometres. The innermost satellite, Cordelia, orbits just inside the outermost rings, Lambda and Epsilon.

Table 18: Major Satellites of Uranus

name	distance from centre of Uranus (km)	orbital period (days)	mean radius (km)	mean density (g/cm^3)
Miranda	129,780	1.414	236	1.15
Ariel	191,240	2.520	579	1.56
Umbriel	265,970	4.144	585	1.52
Titania	435,840	8.706	789	1.70
Oberon	582,600	13.463	761	1.64

The four largest satellites, Ariel, Umbriel, Titania, and Oberon, have densities that range from 1.5 to 1.7 grams per cubic centimetre, which is slightly greater than the density of a hypothetical satellite that is 60 percent ice and 40 percent rock. This hypothetical satellite would be obtained by cooling a mixture of solar composition and removing all the gaseous components. In contrast, Miranda and the smaller satellites of Saturn have densities that are slightly below the solar composition value, indicating a higher ice-to-rock ratio for these satellites.

Water ice shows up in the spectra of the five major satellites. At wavelengths outside the water bands, the spectral lines are neutral, indicating a gray colour. The Bond albedo, which is the ratio of sunlight reflected in all directions to incident sunlight, is low, ranging from 0.10 to 0.22 for the 5 large satellites and less than 0.1 for the 10 minor satellites. The obvious implication is that the surfaces consist of dirty water ice. The composition of the dark component is unknown. One possibility is carbon, originating from the inside of the planet or from the rings, which could release methane gas that later decomposes to produce solid carbon when bombarded by charged particles and solar ultraviolet light.

Low albedo

Two further observations indicate that the surfaces are porous and highly insulating. First, the reflectivity increases dramatically at opposition, when the observer is within 2° of the Sun as viewed from the planet. Such so-called opposition surges are characteristic of loosely stacked particles that shadow each other except in this special geometry. Second, the temperatures seem to follow the Sun during the day with no appreciable lag due to thermal inertia. Again, such behaviour is characteristic of porous surfaces.

Oberon and Umbriel display a dense population of large impact craters, similar to the lunar highlands and many of the oldest terrains in the solar system. In contrast, Titania and Ariel have far fewer craters in the large size range (50- to 100-kilometre diameter) but have comparable numbers in the smaller size ranges. The former craters are thought to date back more than four billion years to the early history of the solar system, while the latter are thought to reflect more recent events including, perhaps, secondary objects knocked loose from other satellites in the Uranian system. Thus the surfaces of Titania and Ariel are younger than those of Oberon and Umbriel. These differences do not follow an obvious pattern with respect to either distance from Uranus or satellite radius and are largely unexplained.

Volcanic deposits are generally flat, with lobate edges and surface ripples characteristic of fluid flow. Some of the deposits are bright, while some are dark. Since temperatures in the outer solar system are likely to be low, the erupting fluid was probably a water-ammonia mixture with a melting point well below the melting point of pure water ice. Brightness differences could reflect differences in the composition of the erupting fluid or differences in the history of the surface.

Riftlike canyons on all the Uranian satellites imply extension and fracturing of the surface. Miranda is the most

Figure 51: *Mosaic of Voyager 2 images of Miranda.*
The terrain of Miranda is characterized by extensive bands, ridges, and scarps. The unusual surface may be the result of a catastrophic impact that shattered the satellite followed by its reaccretion, in which subsurface materials became exposed and material formerly at the surface was buried in the interior. This view is centred on Miranda's south pole.
Jet Propulsion Laboratory/National Aeronautics and Space Administration

spectacular; some canyons are as much as 80 kilometres wide and 15 kilometres deep. The rupturing of the crust was caused by an expansion in the volume of the satellites, inferred to be in the range of 1 to 2 percent, except for Miranda, for which the expansions are 6 percent. Miranda's expansion could be explained if all the water in the satellite were once liquid and then froze in its interior after the crust had formed. Freezing under low pressure, the water would have expanded and thereby stretched the surface. The presence of liquid water at any stage of the satellite's history seems unlikely, however.

Unique appearance of Miranda

Miranda (Figure 51) has the appearance of an object that formed from separate pieces that did not totally merge. The basic surface is heavily cratered, but it is interrupted by three lightly cratered regions called coronae. These are fairly squarish, roughly one satellite radius on a side, and are surrounded by parallel bands that curve around the edges. The boundaries where the coronae meet the cratered terrain are sharp. The coronae are unlike any features found elsewhere in the solar system. Whether they reflect the satellite's heterogeneous origins, a giant impact that shattered the satellite, or a new pattern of eruption from the interior is not known.

Rings. The rings of Uranus were discovered from the Earth during stellar occultations—*i.e.*, when the planet passed between a star and the Earth, thereby momentarily blocking the star's light. The rings are narrow and fairly opaque (Table 19). Observed widths are simply the radial distances between the beginning and end of the occultation. Equivalent widths are the product (more precisely, the integral) of the radial distance and the fraction of starlight removed. The fact that the equivalent widths are generally less than the observed widths indicates that the rings are not completely opaque.

Combining the brightness in Voyager images with the equivalent widths from occultations, one finds that the ring particles reflect only 1 or 2 percent of the incident sunlight. The reflectance spectrum is nearly flat. Ordinary soot, which is mostly carbon, is the closest terrestrial analogue. It is not known whether the carbon comes from darkening of methane by particle bombardment or is intrinsic to the ring particles.

Propagation of the Voyager radio signal through the rings to the Earth reveals that the rings consist of mostly large particles with radii greater than 70 centimetres. Scattering of sunlight at large phase angles, when the rings are almost between the Sun and the Voyager camera, also reveals small dust particles, whose size is comparable to the wavelength of light. Only a small amount of dust is found in the main rings. Most microscopic-size particles are instead distributed in the spaces between the main rings, suggesting that the rings are losing mass as a result of collisions. The lifetime of the dust in orbit around Uranus is limited by drag exerted by the planet's extended atmosphere and by light pressure; the dust particles are driven to lower orbits and eventually fall into the Uranian atmosphere. The calculated orbital lifetimes are so short (1,000 years) that the dust must be rapidly and continually created.

Collisions between the tightly packed ring particles would naturally lead to an increase in the radial width of the

Table 19: Rings of Uranus

name	distance from centre of Uranus (km)	equivalent width* (km)	observed widths† (km)
6	41,837	0.66	1–2
5	42,235	1.23	2–7
4	42,571	1.06	1–6
Alpha	44,718	3.86	4–11
Beta	45,661	3.16	4–13
Eta	47,176	0.64	1–4
Gamma	47,627	3.13	2–8
Delta	48,300	2.69	3–8
Lambda	50,023	0.1	2–3
Epsilon	51,149	42.8	20–95

*Equivalent width is the product of width times fraction of light attenuated and is given for visible light. †The range of observed widths reflect real variations with respect to longitude as well as measurement error.

Figure 52: *Shepherd satellites of the Epsilon ring.* The two satellites Ophelia (1986U8) and Cordelia (1986U7) orbit outside and inside, respectively, of the Epsilon ring, thereby confining the ring particles through resonant gravitational interactions.

Jet Propulsion Laboratory/National Aeronautics and Space Administration

Shepherd satellites

rings. Satellites more massive than the rings can halt this spreading in a process known as shepherding. At certain radii, termed resonances, in which the satellite's orbital period is a whole number ratio of the ring particles' orbital period, the satellite exerts a net torque on the ring by gravitational interaction. As the satellite and ring exchange angular momentum, energy is dissipated by collisions among the ring particles. The outcome of this interaction is that the satellite and ring repel each other. The one in the outer orbit moves outward, and the one in the inner orbit moves inward. Since the satellite is much more massive than the ring, it prevents the ring from spreading across the radius at which resonance occurs. A pair of satellites on either side of a ring can maintain its narrow width.

The inner two satellites, Cordelia and Ophelia, orbit on either side of the Epsilon ring at exactly the right radii required for shepherding (see Figure 52). Shepherds for the other rings have not been found, perhaps because the shepherds are too small to be seen in the Voyager images. Small moons may also be the reservoir that supplies the dust that leaves the ring system. Atmospheric drag is so large that the rings may be short-lived, in which case their origin and history are still unknown.

HISTORY OF OBSERVATION

Uranus was discovered in 1781 by the English astronomer William Herschel, who had undertaken a survey of all stars down to eighth magnitude—*i.e.,* those about five times fainter than stars visible to the naked eye. On March 13, 1781, he found "a curious either nebulous star or perhaps a comet," distinguished from the stars by its clearly visible disk. Its lack of any trace of a tail and its slow motion led to the suggestion that the observations were consistent with a planet, rather than a comet or asteroid, moving in a nearly circular orbit. Observations of the orbit during the next 65 years revealed discrepancies—gravitational forces on Uranus that were not due to any known planet and which ultimately led to the discovery of Neptune in 1846.

Herschel suggested naming the new planet the Georgian Planet after his patron, King George III of England, while the French favoured the name Herschel. The planet was eventually named according to the tradition of naming planets for the gods of Greek and Roman mythology; Uranus is the father of Saturn, who is in turn the father of Jupiter.

The orbit of Uranus seemed to fit a simple equation, Bode's law, that had been developed in 1766 and was popularized in 1772 to explain the orbits of the six planets known to the ancients. In addition, asteroids seemed to fill a gap where the law predicted another planet. For about three-quarters of a century, these successes overcame doubts stemming from the fact that the law had no theoretical basis and provided only an approximate fit to the planetary orbits. Neptune did not fit the pattern at all (being 21 percent closer to the Sun than predicted), nor did Pluto, and now Bode's law is of only historical significance.

After the discovery in 1781, Herschel continued to observe the planet with larger and better telescopes and eventually discovered the outer two satellites, Titania and Oberon, in 1787. Two more satellites, Ariel and Umbriel, were discovered by the British astronomer William Lassell in 1851. The names of the four satellites come from English literature, three taken from Shakespeare, and were proposed by Herschel's son, John Herschel. A fifth satellite, Miranda, was discovered by Gerard P. Kuiper in 1948. The tradition of naming the satellites after characters in Shakespeare's plays continues to the present.

Discovery of major satellites

Since the 1860s the spectrum of Uranus has been known to contain deep absorption bands in the red region of the electromagnetic spectrum. In 1932 the German-American astronomer Rupert Wildt showed that these must be due to methane in the planet's atmosphere. The Canadian physicist Gerhard Herzberg first detected hydrogen in the atmospheres of both Uranus and Neptune in 1952. The rings were discovered by James L. Elliot of the United States in 1977 while he was observing the planet pass in front of a bright star. They showed up as places where the starlight briefly faded at some considerable distance above the atmosphere. The somewhat cumbersome nomenclature (Table 19) arose as subsequent observations

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

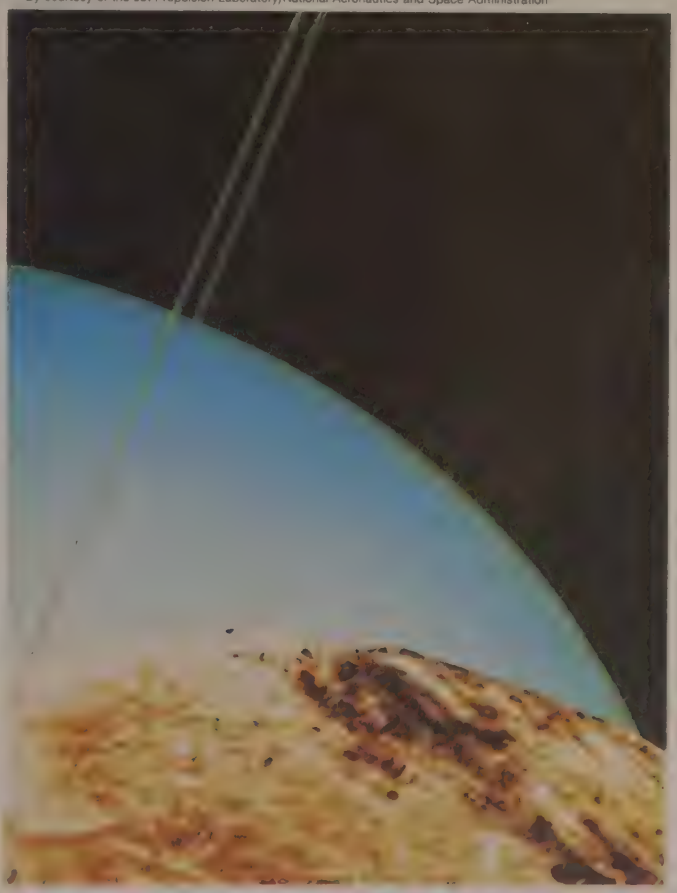

Figure 53: Montage of Voyager 2 photographs taken in January 1986 that simulates a view of Uranus and rings as if seen over the horizon of Miranda, one of the satellites of Uranus.

revealed new rings in places that did not fit the original nomenclature.

The Voyager 2 spacecraft flew by Uranus on Jan. 24, 1986. It was the first man-made object to visit the planet, and it revealed much about the Uranian system. A montage of Voyager 2 photographs (Figure 53) shows Uranus and its rings in a simulated view as if seen from the horizon of Miranda. Voyager provided an accurate determination of the masses and radii of the planet and its major satellites. It detected the magnetic field and determined its strength and orientation. Voyager instruments measured the rotation rate of the field and hence of the planet itself. Images from Voyager revealed for the first time the weather patterns in the atmosphere and the surface morphology of the satellites. Voyager discovered 10 new satellites, a narrow ring, and dust bands between the narrow rings. It provided details of ring structure at scales unachievable from the Earth. Yet, despite these advances, many unanswered questions remain that can be answered only by another spacecraft or by a major advance in Earth-based observations. (A.P.I.)

Neptune

Neptune, the eighth planet in average distance from the Sun, was named for the Roman god of the sea. The sea-god's three-pronged trident (Ψ) serves as its astronomical symbol. Neptune's distance from the Sun varies between 29.8 and 30.4 astronomical units (AUs). Its diameter is nearly four times that of the Earth, but because of its great distance Neptune cannot be seen from the Earth without the aid of a telescope. Neptune's deep blue colour is due to the absorption of red light by methane gas in its atmosphere. It receives less than half as much sunlight as Uranus, but heat escaping from its interior makes Neptune slightly warmer than the latter. The heat liberated may also be responsible for Neptune's stormier atmosphere, which exhibits the fastest winds seen on any planet in the solar system.

PRINCIPAL CHARACTERISTICS

Neptune's orbital period is 164.8 Earth years. It has not completely circled the Sun since its discovery in 1846, so some refinements in its orbital size and shape are still expected. Voyager 2's encounter with Neptune in 1989 resulted in an upward revision of about 0.17 percent in its estimated mean distance from the Sun, which is now thought to be 4,504,300,000 kilometres. Its orbital eccentricity of 0.009 means that Neptune's orbit is very nearly circular; among the nine planets in the solar system, only Venus has a smaller eccentricity. Neptune's seasons (and the seasons of its moons) are therefore of nearly equal length, each more than 41 Earth years in duration. The tilt of Neptune's equator relative to its orbit is 29.6°, somewhat larger than the Earth's 23.4°.

41-year seasons

The length of Neptune's day, as determined by Voyager 2, is 16.11 hours. Its equatorial diameter, measured at the one-bar pressure level (the pressure of the Earth's atmosphere at sea level), is 49,528 kilometres. Because of polar flattening, Neptune's polar diameter is only 48,680 kilometres. Neptune's volume is equivalent to 57.7 Earth volumes; Uranus is slightly larger with a value of 63 Earth volumes. Owing to its greater density (1.64 grams per cublic centimetre), however, Neptune's mass is 18 percent higher than the mass of Uranus. Neptune has a mass equivalent to that of 17.15 Earth masses.

Table 20: Physical Data for Neptune

Mean distance from the Sun	4,504,300,000 km (30.058 AU)
Eccentricity of orbit	0.009
Inclination of orbit to ecliptic	1.77°
Sidereal period of revolution	164.8 Earth years
Rotational period	16.11 hours
Radiometric bond albedo	0.29 ± 0.07
Effective temperature	59.3 K
Energy balance (emitted/absorbed)	2.7
Mean synodic period	367.49 days
Mean orbital velocity	5.43 km/s
Mean daily motion	0.005981°
Inclination of equator to orbit	29.6°
Mass	17.15 Earth masses
Equatorial radius at one bar	24,764 km
Polar radius at one bar	24,340 km
Mean density	1.64 g/cm³
Apparent magnitude	+7.8
Number of known satellites	8
Number of known rings	4
Magnetic dipole moment	0.133 gauss R^3_N
Magnetic dipole tilt	46.8
Magnetic dipole offset	0.55 R_N

THE ATMOSPHERE

As with the other giant planets of the outer solar system, Neptune's atmosphere is composed predominantly of hydrogen and helium. Near the one-bar pressure level in the atmosphere, these two gases contribute nearly 98 percent of the atmospheric molecules. Most of the remaining molecules consist of methane gas. Hydrogen and helium are nearly invisible, but methane strongly absorbs red light. Sunlight reflected off Neptune's clouds therefore exits the atmosphere with most of its red colours removed: this effect is responsible for Neptune's blue appearance (see Figure 54).

The temperature of Neptune's atmosphere varies with altitude. A minimum temperature of about 50 K occurs at pressure near 0.1 bar. The temperature increases with altitude to about 750 K at 2,000 kilometres (corresponding to a pressure of 10^{-11} bar) and remains uniform above that altitude. Temperatures increase with depth below the 0.1-bar level to about 7,000 K near the centre of the planet, where the pressure may reach 5,000,000 bars. The effective temperature of Neptune (the temperature of a perfect blackbody emitter of the same cross section) is 59.3 K.

Neptune is more than 50 percent farther from the Sun than is Uranus. Neptune consequently receives less than half as much sunlight as the latter. Yet the effective temperatures of these two giant gaseous planets are nearly equal. Uranus and Neptune each reflect (and hence also absorb) about the same proportion of the sunlight that reaches them. For reasons not fully understood, Neptune emits more than twice as much energy as it receives from the Sun. The added energy is generated in Neptune's interior. Uranus, by contrast, has little energy escaping from its interior.

At the reference level of one bar, the mean temperature of Neptune's atmosphere is roughly 74 K. Atmospheric temperatures are a few degrees warmer at the equator and poles than at mid-latitudes. This is probably an indication that air currents are rising near mid-latitudes and descending near the equator and poles. This vertical flow may extend to great heights within the atmosphere. A more vertically confined horizontal wind system exists near the cloud tops. As with the other giant planets of the outer solar system, the winds are constrained to blow generally along lines of constant latitude and are relatively invariable with time. Winds on Neptune vary from about 100 metres per second (m/s) in an easterly (prograde) direction near latitude 70° S to as high as 700 m/s in a westerly (retrograde) direction near latitude 20° S. These 700-m/s atmospheric winds are the highest measured anywhere in the solar system.

High atmospheric winds

The high winds and relatively large contribution of escaping internal heat may be responsible for the observed turbulence in Neptune's visible atmosphere. Two large dark ovals are clearly visible in images of Neptune's southern hemisphere (see Figure 54). The largest, called the "Great Dark Spot" because of its similarity in latitude and shape to Jupiter's Great Red Spot, is comparable to the entire Earth in size. It is near this Great Dark Spot that the highest wind speeds were measured. A somewhat smaller "Small Dark Spot" circles the planet near latitude 55° S. These two atmospheric storms may be centres where strong upwelling of gases from the interior takes place. A bright feature, dubbed the "Scooter," consists of a series of small streaks that vary in number and size over time, causing the Scooter to change in shape. Several other bright features, such as the bright white companions of the two dark spots, may be attributable to methane ice clouds created by strong upward motions of pockets of methane gas to higher, colder altitudes in the atmosphere.

Neptune is the only one of the giant planets of the solar

Figure 54: *Voyager 2 image of clouds in Neptune's atmosphere.*
The Great Dark Spot and its associated bright methane-ice clouds are shown slightly to the left of centre, the small dark spot is at the lower left, and the bright "Scooter" is just northward of the small dark spot.
Jet Propulsion Laboratory/National Aeronautics and Space Administration

system to display cloud shadows cast by high dispersed clouds on a lower, more continuous cloud bank. The higher clouds, probably composed of methane ice crystals, are generally located from 50 to 100 kilometres above the main cloud deck, which may be composed of ammonia or hydrogen sulfide ice crystals. As with the other gas giants, deeper cloud layers, invisible to the remote sensing instruments carried by the Voyager spacecraft, are thought to exist, but their composition is dependent on the relative amounts of gases composed of compounds of sulfur and nitrogen. Clouds of water ice are expected to occur at depths within Neptune's atmosphere where the pressure is in excess of 100 bars.

INTERIOR STRUCTURE AND COMPOSITION

Neptune's mean density is slightly less than 30 percent that of the Earth; nevertheless, it is the densest of the giant planets. Neptune's greater density implies that a larger percentage of its interior is composed of melted ices and molten rocky materials than is the case for the other gas giants.

The distribution of these heavier elements and compounds is poorly known at present. Voyager 2 data suggest, however, that the planet is unlikely to have a distinct inner core of molten rocky materials surrounded by an outer core of melted ices of methane, ammonia, and water. The relatively long rotational period of Neptune (16.11 hours) was about one hour longer than would be expected from such an interior model. Scientists have concluded that the heavier compounds and elements must not be centrally condensed; instead, they may be spread almost uniformly throughout the interior. In this respect, as in many others, Neptune resembles Uranus far more than the larger giants Jupiter and Saturn.

Distribution of rock and ice

The large fraction of Neptune's total heat budget derived from the planet's interior may not necessarily imply that Neptune is hotter at its centre than Uranus. Multiple stratified layers in the deep atmosphere of Uranus may serve to insulate the interior, trapping within Uranus the radiation that more readily escapes from Neptune.

MAGNETIC FIELD AND MAGNETOSPHERE

Neptune, like most of the planets in the solar system, possesses an internal magnetic field. The Earth's magnetic field is thought to be generated by electrical currents flowing in its liquid iron core, and electrical currents flowing within the outer cores of liquid metallic hydrogen in Jupiter and Saturn may similarly be the source of their magnetic fields. All three have magnetic fields relatively well centred within the planets and aligned within about 10° of their rotation axes. Uranus and Neptune, by contrast, have magnetic fields that are tilted with respect to their rotation axes by 59° and 47°, respectively. Furthermore, these magnetic fields are not well centred within their planets. Uranus' field is offset 30 percent of the distance from its centre to its cloud tops. Neptune's field, with an offset of 55 percent of Neptune's radius, originates in a portion of the interior that is actually closer to the cloud tops than to the centre. The unusual configurations of the magnetic fields of Uranus and Neptune have led scientists to speculate that these fields may be generated in processes occurring in the upper layers of the planetary interiors rather than near their centres.

Because of the high tilt of Neptune's magnetic field, charged particles (predominantly protons and electrons) trapped in the magnetosphere are repeatedly swept past the orbits of the satellites and rings. Many of these charged particles may be absorbed by the satellites and rings, effectively emptying from the magnetosphere a large fraction of its charged particle content. Neptune's magnetosphere is populated with fewer protons and electrons per unit volume than that of any of the other gas giant planets.

THE SATELLITES AND RINGS

Satellites. Prior to the Voyager 2 encounter in August 1989, Neptune's only known satellites were Triton and

Nereid. Triton is the lone large moon in the solar system to travel backward (in a direction opposite to the planet's rotation) around its primary. Among the largest satellites in the solar system, inclinations are less than about 5°; Triton's orbit, however, is tilted 157° to Neptune's equator. Nereid is very distant from the planet and has the most eccentric orbit of any known natural satellite. At its apoapsis (greatest distance), Nereid is nearly seven times as far from Neptune as at its periapsis (smallest distance). Even at its closest approach, Nereid is nearly four times the distance of Triton, Neptune's second most distant satellite.

Voyager 2 observations added six previously unknown satellites to Neptune's system. All are less than half Triton's distance from Neptune and travel in nearly circular orbits that are prograde and in or near Neptune's equatorial plane. The names of the satellites selected by the International Astronomical Union are all derived from Greek and Roman mythology and correspond to minor gods who served Neptune. These names, in order of increasing distance from Neptune, are Naiad, Thalassa, Despina, Galatea, Larissa, and Proteus. Physical data on the eight satellites are summarized in Table 21.

Table 21: Satellite Data

satellite name	radius (km)	density (g/cm³)	distance (km)*	inclination (°)	eccentricity	orbital period (days)
Naiad	29	—	48,230	4.74	0.0003	0.2944
Thalassa	40	—	50,070	0.21	0.0002	0.3115
Despina	74	—	52,530	0.07	0.0001	0.3347
Galatea	79	—	61,950	0.05	0.0001	0.4287
Larissa	96	—	73,550	0.20	0.0014	0.5547
Proteus	208	—	117,640	0.04	0.0004	1.1223
Triton	1,350	2.07	354,800	156.8	0.000	5.8768
Nereid	170	—	5,509,100	27.6	0.753	359.632

*From Neptune's centre.

Five of the six recently discovered satellites (all but Proteus) orbit Neptune in less time than the 16.11-hour rotational period of the planet. Hence, to an observer positioned near Neptune's cloud tops, these five would appear to rise in the west and set in the east. Only two of the six "new" satellites were seen from close enough range to detect both their size and approximate shape. Proteus and Larissa are irregular in shape and appear to have heavily cratered surfaces. The sizes of the other four are estimated from their integrated brightness by assuming that their surface reflectances are similar to those of Proteus and Larissa—namely, about 7 percent. Proteus, with a radius of approximately 208 kilometres, is slightly larger than Nereid (with a radius of about 170 kilometres). The other five new satellites are much smaller, each having an average radius of less than 100 kilometres.

Nereid was not observed from close range, but Voyager 2 data indicate a nearly spherical shape for the outermost of Neptune's satellites. Voyager detected no large variations in brightness as Nereid rotates. The highly elliptical orbit makes it unlikely that Nereid's rotational and orbital periods are equal, but Voyager 2 was not able to determine a rotational period. Rotational periods for all the other satellites (including Triton) are probably equal (or very nearly equal) to their orbital periods.

Pre-Voyager estimates of Triton's size made from the Earth were based on an erroneously high mass determination and assumption of low surface reflectivity. Triton's mass is now known to be only a small fraction of the previously accepted value, and the average surface reflectivity is high. Triton's radius as measured by Voyager 2 is 1,350 kilometres. Triton has a highly reflective icy surface, in contrast to the Moon's dark surface devoid of volatile components. Triton's low mass is likely a consequence of a predominantly water-ice interior surrounding a denser rocky core, while the Moon's composition is that of almost exclusively rocky materials. Nevertheless, Triton's mean density of 2.07 grams per cubic centimetre is higher than that measured for any of the satellites of Saturn or Uranus and is surpassed among large satellites only by the Moon and Jupiter's satellites Io and Europa.

Triton's visible surface is covered by methane and nitrogen ices. Evidence of trace amounts of carbon monoxide and carbon dioxide ices also has been revealed in spectroscopic studies conducted from the Earth. Even at the remarkably low 38 K surface temperature, sublimation of nitrogen ice is sufficient to form a tenuous atmosphere whose near-surface pressure is less than 0.00002 bar. A polar ice cap, presumably composed of nitrogen ice deposited in the prior winter, covered most of the southern hemisphere of Triton during Voyager 2's flyby in 1989. At that time Triton was nearly three-quarters of the way through its 41-year southern springtime. Equatorward of the polar cap, much of the terrain had the appearance of a cantaloupe rind, consisting of dimples crisscrossed with a network of fractures. This unique terrain is shown in Figure 55.

Within the polar cap region, numerous darker streaks provide evidence of surface winds. At least two of the streaks, and perhaps dozens, are the result of active, geyser-like plumes erupting during the Voyager 2 flyby. Nitrogen gas, escaping through vents in the overlying ice, carries entrained dust particles to heights of about 8 kilometres, where the dust is then transported downwind to distances of up to 150 kilometres. The energy sources and mechanisms for driving these plumes are not yet well understood, but their preference for latitudes illuminated vertically by the Sun has led to the conclusion that incident sunlight is an important factor in the process.

Triton's geyserlike plumes

Near the equator on the Neptune-facing side of Triton exist at least two and perhaps several frozen lakelike features with terraced edges. The terraced edges are probably the result of multiple epochs of melting, with each successive melt involving a somewhat smaller surface area of ice. The vertical extent of some of the cliffs (terrace edges) is more than one kilometre. Even at Triton's low surface temperature, nitrogen or methane ices are not strong enough to support a structure of that height without structural failure. It is assumed that the underlying material supporting these structures is water ice, although no direct evidence for water ice is seen in the spectra of Triton. A thin veneer of nitrogen or methane ice could effectively hide the spectral signature of water ice.

Triton is similar in size, density, and surface composition to the planet Pluto. It is thought to be a captured satellite, perhaps formed originally as an independent planet in the outer solar system. At some point in Neptune's early history, Triton's orbit may have carried it too near the gas giant. Gas drag in Neptune's extended atmosphere, or a collision with an existing satellite of Neptune, slowed Triton enough to place it in an elongated orbit, backward and tilted with respect to the orbits of the previously existing satellites. As Triton raised tides in Neptune's atmosphere, these tides in turn selectively retarded Triton in the closer portions of its orbit, eventually circularizing its path around Neptune. This process from capture to circular orbit may have taken more than one billion years, during which time the enormous tidal forces most likely melted the entire interior of Triton. The molten body would have undergone differentiation, with the denser material sinking into a core region and the more volatile materials rising to the surface.

It is thought that Triton's surface cooled faster than its interior and formed a thick layer of predominantly water ice. As subsurface water froze, it expanded, fracturing the outer ice layer and flowing through and filling the cracks. The intersecting fractures visible in Voyager images of Triton's surface provide strong corroborating evidence for the existence of water ice inside this satellite, since no other compositional candidates for Triton's subsurface expand as they freeze.

The process of capture and circularization of Triton's orbit would have severely disrupted any previously existing satellite system formed at the same time as Neptune. Nereid's radical orbit may be one consequence of this process. Satellites orbiting between Nereid and the six satellites discovered by Voyager 2 would have been ejected from the Neptune system, thrown into Neptune itself, or absorbed by the molten Triton. Those satellites orbiting at a distance of less than half Triton's present distance from

Figure 55: *Voyager 2 image of Triton.*
This 14-frame composite image shows the satellite's near-equatorial cantaloupe terrain and fracture network, the remnant southern hemisphere ice coverage, and the dark wind streaks within the ice-cap region.
Jet Propulsion Laboratory/National Aeronautics and Space Administration

Neptune would not have been close enough to the planet to avoid some disruption. Thus, the present orbits of the six small inner satellites are probably very different from their original orbits, and they may only be fragments of original satellites formed along with Neptune. Subsequent bombardment of these satellites by Neptune-orbiting debris and by meteorites may have further altered their sizes, shapes, and orbits.

Rings. Neptune's system of narrow rings (Figure 56), which may be a relatively new addition to the planet's family, displays a quite unusual feature. Although narrow rings have been seen around each of the other three gas giants, none have displayed the striking nonuniformity of particle density of Neptune's outermost ring, provisionally called 1989N1R. Material is clumped in at least five brighter regions, called arcs, that are found within a 45° segment of the ring. They range in length from about 1,000 kilometres to more than 10,000 kilometres. Although Galatea may gravitationally interact with 1989N1R to temporarily trap ring particles in such arclike regions, collisions between ring particles should eventually spread the constituent material relatively uniformly around the circumference of 1989N1R. Azimuthal uniformity is characteristic of almost all the known planetary rings, although some of the elliptical rings of Uranus exhibit smooth variations in width. 1989N1R's enigmatic arcs may be the

Ring arcs

Jet Propulsion Laboratory/National Aeronautics and Space Administration

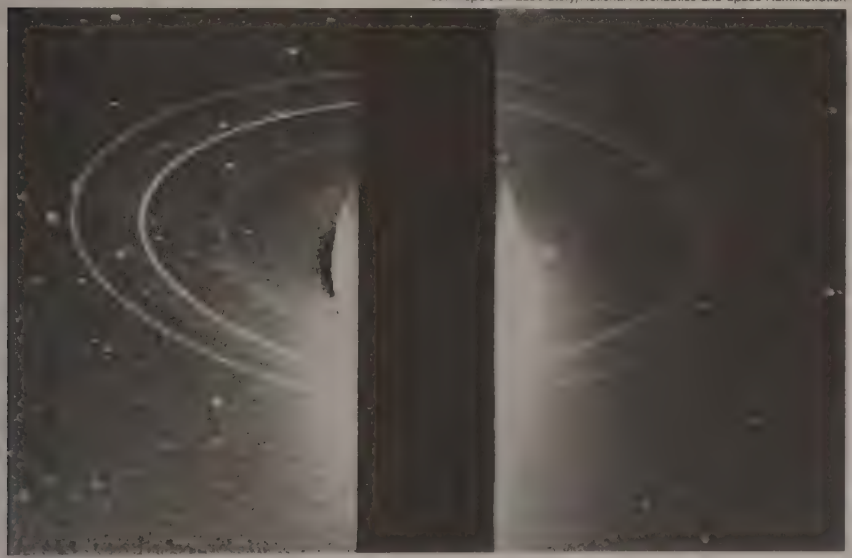

Figure 56: *Neptune's ring system.*
Two long-exposure images obtained by Voyager 2 a few hours after the spacecraft's closest approach to the planet show the main features of Neptune's rings. (The bright arcs of the outer ring are not visible here because they were on the opposite side of the planet when each photograph was taken.) The overexposed image of Neptune's southern polar crescent is near the centre.

result of the breakup of a small satellite within the past few thousand years.

The inner rings of Neptune (1989N2R, 1989N3R, and 1989N4R) lack the unusual azimuthal nonuniformity exhibited by 1989N1R. 1989N2R is narrow—less than 15 kilometres in radial width—and closely resembles the nonarc regions of 1989N1R. The small satellites Galatea and Despina orbit Neptune just planetward of 1989N1R and 1989N2R, respectively, and may gravitationally repel particles near the inner edges of these rings. 1989N3R is much broader and fainter than either 1989N1R or 1989N2R, possibly owing to the absence of any strong particle-shepherding action from a nearby satellite. 1989N4R consists of a faint plateau of ring material that extends outward in radial distance from 1989N2R about halfway to 1989N1R.

None of Neptune's rings were detected at radio wavelengths, indicating that they are nearly devoid of particles in the centimetre or larger size range. The fact that the rings are most visible when backlighted by sunlight implies that they are largely populated by dust-sized particles. Their chemical makeup is not known, but, like the rings of Uranus, the ring-particle surfaces (and possibly the particles in their entirety) may be composed of radiation-darkened methane ices. Physical data on the rings are summarized in Table 22.

Table 22: Ring Data

ring designation	common name	distance (km)*	comments
1989N3R	Galle	41,900	about 1,700 km wide with indistinct edges
1989N2R	Le Verrier	53,200	radial width not resolved; flanked by Despina
1989N4R	"Plateau"	56,100	about 5,800 km wide with inner edge at 1989N2R
1989N1R	Adams	62,900	15 km wide; bright arcs; flanked by Galatea

*From Neptune's centre.

HISTORY OF OBSERVATION

Brightness of Neptune

Neptune is the only giant gaseous planet that is not visible without a telescope. With an apparent brightness of +7.8 in stellar magnitudes, it is approximately one-fifth as bright as the faintest stars visible to the naked eye. Hence, it is relatively certain that there were no observations of Neptune prior to the use of telescopes. Galileo is credited as the first to view the heavens with a telescope in 1609. His sketches made a few years later suggest that he may have seen Neptune when it passed near Jupiter. He failed, however, to recognize it as a planet and therefore cannot be credited with its discovery.

Prior to the discovery of Uranus by William Herschel in 1781, the consensus among astronomers and philosophers alike was that all the planets in the solar system were those six that had been observed since ancient times. The discovery of a seventh planet almost immediately led astronomers and others to suspect the existence of still more planetary bodies. Additional impetus was given by a mathematical curiosity that has come to be known as Bode's law or the Titius-Bode law. In 1766 Johann Daniel Titius of Germany noted that the then-known planets formed an orderly progression in distance from the Sun that could be expressed as a simple mathematical equation. In astronomical units (AU), Mercury's distance is very nearly 0.4; the distances of Venus, the Earth, Mars, Jupiter, and Saturn are approximately $0.4 + (0.3 \times 2^n)$, where n is 0, 1, 2, 4, and 5, respectively, for the five planets. The astronomer Johann Elert Bode, also of Germany, published the law in 1772 in a popular introductory astronomy book, proposing that the missing 3 in the progression might indicate that a planet between Mars and Jupiter remained to be discovered.

The suggestion was met with little enthusiasm until it was discovered that Uranus was at a distance (19.2 AU) very nearly equal to that predicted by Bode's law (19.6 AU) for $n = 6$. It was found, however, that a group of asteroids orbiting between Mars and Jupiter, rather than a new planet, satisfied the $n = 3$ case of the equation (see below *Other constituents of the solar system: Asteroids: Historical survey of major asteroid discoveries*).

Some astronomers were so impressed by the seeming success of Bode's law that they proposed the name Ophion for a large planet predicted to lie beyond Uranus at a distance of 38.8 AU. In addition to the scientifically unfounded prediction from Bode's law, observations of Uranus provided more direct evidence for the existence of another planet. Uranus was not following the path predicted by the laws of motion and the gravitational forces exerted by the Sun and the known planets. Furthermore, more than 20 prediscovery sightings of Uranus dating back as far as 1690 also disagreed with the calculated positions of Uranus for the respective time at which each observation was made.

In 1843 the British mathematician John Couch Adams began a serious study to see if he could predict the location of a more distant planet that could account for the strange motions of Uranus. Adams succeeded and communicated the results of his study to the astronomer royal, Sir George B. Airy, but Airy did not take them seriously. In 1846 Urbain-Jean-Joseph Le Verrier of France, unaware of Adams' efforts in Britain, began a similar study of his own.

By mid-1846 the astronomer John Herschel, son of William Herschel, expressed his opinion that the mathematical studies under way could well lead to the discovery of a new planet. Airy, convinced by Herschel's arguments, sent Adams' calculations to James Challis at the Cambridge Observatory. Challis began a systematic search of a large area of sky surrounding Adams' predicted location. The search was slow and tedious, because Challis had no detailed maps of the dim stars in the area where the new planet was predicted. He would draw charts of the stars he observed and then compare them with the same region several nights later to see if any of the "stars" had moved.

Le Verrier also had difficulty convincing astronomers in his country that a telescopic search of the skies in the area he predicted for the new planet was not a waste of time. On Sept. 23, 1846, he communicated his results to the Berlin astronomer Johann Gottfried Galle. Galle and his assistant Heinrich Louis d'Arrest had access to detailed star maps of the sky painstakingly constructed to aid in the search for new asteroids. Galle and d'Arrest identified Neptune as a noncharted star that same night and verified the next night that it had moved relative to the background stars.

Neptune's identification in the sky

Although Galle and d'Arrest have the distinction of being the first individuals to identify Neptune in the night sky, credit for its "discovery" more properly belongs to Adams and Le Verrier for their accurate calculations of Neptune's position. At first the French attempted to proclaim Le Verrier as the sole discoverer of the new planet, suggesting that the planet be called Le Verrier in his honour. The suggestion was not favourably received outside France, both because of the studies by Adams and because of the general reluctance to name a major planet after a living individual. Neptune's discovery was eventually credited to both Adams and Le Verrier, and the more traditional practice of using names from ancient mythology for planets eventually prevailed.

It is interesting to note that Bode's law, which played a significant role in the search for additional planets, was finally laid to rest by the discovery of Neptune. Instead of being near the predicted 38.8 AU, Neptune was found to be only 30.1 AU from the Sun. This discrepancy, combined with the lack of any scientific foundation, discredited the law. The subsequent discovery of Pluto at a distance of 39.6 AU was even more at variance with the formula's prediction of 77.2 AU for $n = 8$. Not even the proximity of Pluto's mean distance to the 38.8 AU predicted for $n = 7$ could resurrect the credibility of Bode's law.

Pre-Voyager observations of Neptune often suffered greatly as a consequence of the planet's enormous distance from both the Earth and the Sun. Its distance of 30.1 AU from the Sun means that the brightness of sunlight incident upon its satellites and upon its upper atmosphere is barely 0.1 percent of that at the Earth. Telescopic viewing of Neptune from the bottom of the Earth's atmosphere cannot resolve features smaller than about one-tenth of Neptune's diameter, even under the best observ-

ing conditions. Most of the early telescopic observations concentrated on determining Neptune's size and orbital parameters and searching for satellites.

Following the successful detection of rings around Uranus in 1977, similar attempts were made to use stellar occultations to find rings around Neptune. These met with limited success in the mid-1980s. About 10 percent of the observed stellar occultations showed starlight blockage on one side of Neptune or the other, but never on both sides. This gave rise to the speculation that Neptune had a series of partial rings (ring arcs) occupying 10 percent or less of their orbit(s). Voyager 2 showed these ring arcs to be denser collections of ring particles in Neptune's continuous outermost ring, as discussed above. (E.D.M.)

Pluto

Pluto, designated ♇ in astronomy, is normally the outermost planet of the solar system and, by far, the smallest in size and mass. It is also the most recently discovered planet, having been found in 1930. It is not visible in the night sky to the unaided eye. Pluto's single moon, Charon, is close enough in size to Pluto that it has become common to refer to the two bodies as a double planetary system.

Pluto is named for the god of the underworld in Roman mythology (the Greek equivalent is Hades). Because of the planet's remoteness and small size, the best telescopes on Earth and in Earth orbit have been able to resolve little detail on its surface. Most of what is known about it has been learned since the late 1970s as an outcome of the discovery of Charon. In the 1990s, Pluto's very status as a planet was debated when new discoveries showed it to be a giant leftover of the process that built the solar system's other outer planets.

BASIC ASTRONOMICAL DATA

Pluto's mean distance from the Sun, about 5.9 billion kilometres (39.5 astronomical units), gives it the largest orbit among the planets. (One astronomical unit [AU] is the average Earth–Sun distance—about 150 million kilometres.)

Orbital eccentricity

Its orbit is atypical in several ways. It is the most elongated, or eccentric, of all the planetary orbits and the most inclined (at 17.1°) to the ecliptic, the plane of Earth's orbit, near which the orbits of most of the other planets lie. In traveling its eccentric path around the Sun, Pluto varies in distance from 29.7 AU (perihelion) to 49.5 AU (aphelion). Because Neptune, the next planet inward from Pluto, orbits in a nearly circular path at 30.1 AU, Pluto is for a small part of each revolution actually closer to the Sun than is Neptune. Nevertheless, the two planets will never collide, because Pluto is locked in a stabilizing 3:2 resonance with Neptune—*i.e.*, it completes two orbits around the Sun in exactly the time it takes Neptune to complete three. This gravitational interaction affects their orbits such that they can never pass closer than about 17 AU. The last time Pluto reached perihelion occurred in 1989; for about 10 years prior and again afterward, Neptune held the title of the most distant planet.

Eliot Young, Southwest Research Institute, NASA's Planetary Astronomy Program

Figure 57: Two-colour image of Pluto, created from telescopic data collected between 1985 and 1990 during a period of mutual eclipses of Pluto and its moon, Charon. Pluto's slightly reddish hue indicates that its surface does not comprise pure ices, though the nature of the coloured material remains to be determined.

Observations from Earth have revealed that Pluto's brightness varies with a period of 6.3873 Earth days, now well established as its rotation period. Only Mercury, with almost 59 days, and Venus, with 243 days, turn more slowly. Pluto's spin axis is tilted by 120° from the perpendicular to the plane of its orbit, so that the planet's north pole actually points 30° below the plane. (By convention, *above the plane* is taken to mean in the direction of Earth's and the Sun's north poles; *below*, in the opposite direction.) Pluto thus rotates nearly on its side in a retrograde direction (opposite the direction of rotation of the Sun and most of the planets); an observer on its surface would see the Sun rise in the west and set in the east.

Tilt of spin axis

The planet's anomalies also extend to its physical characteristics. Pluto's radius is only about two-thirds that of Earth's Moon. Next to the other outer planets—the giants Jupiter, Saturn, Uranus, and Neptune—it is strikingly tiny. When these characteristics are combined with what is known about its density and composition, Pluto appears to have more in common with the large icy moons of the outer planets than with any of the planets themselves. Its closest twin is Neptune's moon Triton, which suggests a similar origin for these two bodies (see below *Origin of Pluto and Charon*). For additional orbital and physical data about Pluto and Charon, see Table 23.

Table 23: Data for Pluto and Charon

Mean distance from Sun	5.91×10^9 km (39.5 AU)
Plutonian year (sidereal period of revolution)	247.69 Earth years
Eccentricity of orbit	0.251
Inclination of orbit to ecliptic	17.1°
Radius	1,172 km
Mass	1.2×10^{22} kg
Mean density	about 2 g/cm³
Rotation period (Plutonian sidereal day)	6.3873 Earth days
Mean synodic period	366.74 Earth days
Inclination of equator to orbit (obliquity)	120°
Moon	Charon
Mean distance from centre of Pluto (orbital radius)	19,640 km
Orbital period (sidereal period)	6.3873 Earth days
Rotation period	same as orbital period (synchronous)
Radius	625 km
Mass	1.8×10^{21} kg
Mean density	about 1.7 g/cm³

THE ATMOSPHERE

Although the detection of methane ice on Pluto's surface in the 1970s (see below *The surface and interior*) gave scientists confidence that the planet had an atmosphere, direct observation of it had to wait until the next decade. This confirmation was made in 1988 when Pluto passed in front of (occulted) a star as observed from Earth. The star's light gradually dimmed just before it disappeared behind the planet, demonstrating the presence of a thin, greatly distended atmosphere. Because Pluto's atmosphere must consist of vapours in equilibrium with their ices, small changes in temperature should have a large effect on the amount of gas in the atmosphere. During the years surrounding Pluto's perihelion (as in the period centred on 1989), when the planet is slightly less cold than average, more of its frozen gases will vapourize; the atmosphere should then be near or at its thickest. Astronomers in the year 2000 estimated a surface pressure in the range of a few to several tens of microbars (millionths of sea-level pressure on Earth). At aphelion, when Pluto is receiving the least sunlight, its atmosphere may not be detectable at all.

Variation of atmospheric pressure with solar distance

Drawing from occultation data and making reasonable assumptions about the atmospheric temperature, scientists have calculated that each particle—*i.e.*, each atom or mol-

ecule—of Pluto's atmosphere has a mean molecular weight of about 25 atomic mass units. This implies that significant amounts of gases heavier than methane (molecular weight 16) must also be present. Molecular nitrogen (molecular weight 28) must in fact be the dominant constituent, because nitrogen ice was discovered on the surface (see below *The surface and interior*) and is more volatile than methane ice. Nitrogen is also the main component of the atmospheres of both Triton and Saturn's largest satellite, Titan, as well as of Earth.

Although ongoing Earth-based observations will add to knowledge about the atmosphere and other aspects of the planet, major new insights will likely require a spacecraft visit. In the first years of the 21st century, scientists looked to the U.S. New Horizons spacecraft mission to Pluto, Charon, and the solar system beyond to provide much of the needed data. The mission plan called for a nine-year flight to the Pluto-Charon system followed by a 150-day flyby for investigation of the surfaces, atmospheres, interiors, and space environment of the two bodies.

THE SURFACE AND INTERIOR

Observations of Pluto show that its colour is slightly reddish, although much less red than Mars or Jupiter's moon Io. Thus the surface of Pluto cannot be composed simply of pure ices, a conclusion supported by the observed variation in brightness caused by the planet's rotation. Its average reflectivity, or albedo, is 0.55 (*i.e.*, it returns 55 percent of the light that strikes it), compared with 0.1 for the Moon and 0.8 for Triton.

Surface constituents

The first crude infrared spectroscopic measurements, made in 1976, revealed the presence of solid methane on Pluto's surface. Using new Earth-based instrumentation available in the early 1990s, observers discovered ices of water, carbon monoxide, and molecular nitrogen. Although nitrogen's spectral signature is intrinsically very weak, it is now clear that this substance must be the dominant surface constituent. The nature of the dark, reddish material remains to be determined; some mixture of organic compounds produced by photochemical reactions in atmospheric gases or surface ices seems a likely possibility. Brightness fluctuations observed during periods when Pluto and Charon mutually eclipse one another (see below *Pluto's moon*) reveal that the planet's south polar region is unusually bright. Brightness maps based on observations with the Earth-orbiting Hubble Space Telescope also reveal some of this heterogeneity, but only visiting spacecraft can provide the spatial resolution needed to make associations between brightness and surface composition or topography.

The same Pluto-Charon eclipses have allowed astronomers to estimate the masses and radii of the two bodies. From this information their densities have been calculated to fall between 1.92 and 2.06 grams per cubic centimetre for Pluto and between 1.51 and 1.81 grams per cubic centimetre for Charon. These values suggest that a significant fraction of each body consists of materials such as silicate rock and organic compounds denser than water ice (density of 1 gram per cubic centimetre). In analogy with the icy moons of Jupiter and Saturn, it is customary to assume that Pluto has a rocky core surrounded by a thick mantle of water ice. The frozen nitrogen, carbon monoxide, and methane observed on its surface are expected to be in the form of a relatively thin layer.

The surface temperature of Pluto has proved very difficult to measure. Observations made in 1983 from the Earth-orbiting Infrared Astronomical Satellite (IRAS) suggest values in the range of 45 to 58 K (−379° to −355° F, −228° to −215° C), whereas measurements from Earth's surface imply a slightly lower range of 35 to 50 K (−397° to −370° F, −238° to −223° C). The temperature certainly must vary over the surface, depending on the reflectivity at a given location and the angle of the noon Sun there. The solar energy falling on Pluto is also expected to decrease by a factor of roughly three as the planet moves from perihelion to aphelion.

Photo AURA/STScI/NASA/JPL

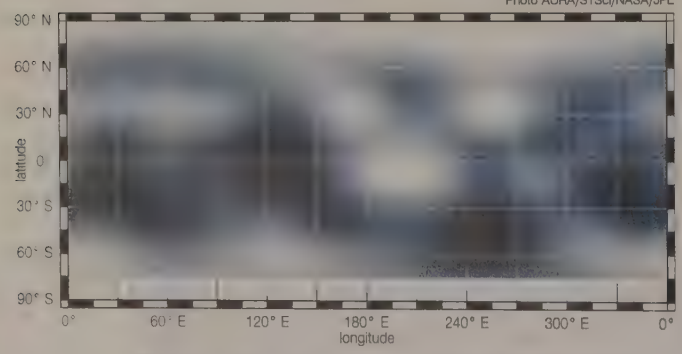

Figure 58: Map of Pluto's surface, a Mercator projection based on images made by the Hubble Space Telescope in June and July 1994. The north polar region generally comprises bright areas, while the equatorial region, particularly to the south, has more dark patches. The variations in brightness may indicate topographic features such as basins or craters; ground cover such as frost, rock, or dust; or a combination. Blue tint has been added in reproduction.

PLUTO'S MOON

Charon, which is fully half the size of Pluto, is the largest moon with respect to its primary planet in the solar system. It revolves around Pluto—more accurately, the two bodies revolve around a common centre of mass—at a distance of about 19,640 kilometres. Charon's period of revolution is exactly equal to the rotation period of the planet itself. In other words, Charon is in synchronous orbit around Pluto, the only moon in the solar system to have that distinction. As a result, Charon remains above the same location on Pluto's surface, never rising or setting (just as do communication satellites in geostationary orbits over Earth). In addition, as with most moons in the solar system, Charon is in a state of synchronous rotation—*i.e.*, it always presents the same face to its primary planet.

Charon is somewhat less reflective (has a lower albedo—about 0.35) than Pluto and is more neutral in colour. Its spectrum reveals the presence of water ice, which appears to be the dominant surface constituent. There is no hint of the solid methane that is so obvious on its larger neighbour. As discussed above, Charon's density implies that the moon contains materials such as silicates and organic compounds that are denser than water ice. Through an extraordinary coincidence, in 1985—just seven years after Charon was discovered—it began a five-year period of mutual eclipse events with Pluto in which the moon alternately crossed the disk of and was hidden by Pluto, as seen from Earth, every 6.4 days (see Figure 59). These events occur when Earth passes through Charon's orbital plane around Pluto, which happens only twice in Pluto's 248-year orbit. Careful observations of these events allowed more precise determinations of the radii and masses of Pluto and Charon than heretofore possible. They also permitted astronomers to estimate individual overall albedos of the two bodies and even to create surface maps depicting brightness differences.

Pluto-Charon mutual eclipse events

DISCOVERIES OF PLUTO AND CHARON

Pluto was the third planet to be discovered, after Uranus and Neptune, as opposed to the six planets that have been visible to the naked eye since ancient times. Its existence had been postulated since the late 19th century on the basis of apparent perturbations of the orbital motion of Uranus, which suggested that a more distant planet was gravitationally disturbing it. Astronomers later realized that these perturbations were spurious—Pluto's mass is too small to have caused the suspected disturbances. Thus, Pluto's discovery was a remarkable coincidence attributable to careful observations rather than to accurate prediction of the existence of a hypothetical planet.

The search for the expected ninth planet was supported most actively at the Lowell Observatory in Flagstaff, Arizona, U.S., in the early 20th century. It was initiated by the observatory's founder, Percival Lowell, an American astronomer who had achieved notoriety through his highly publicized claims of canal sightings on Mars. After two attempts to find the planet prior to Lowell's death in 1916, an astronomical camera built for the purpose and capable

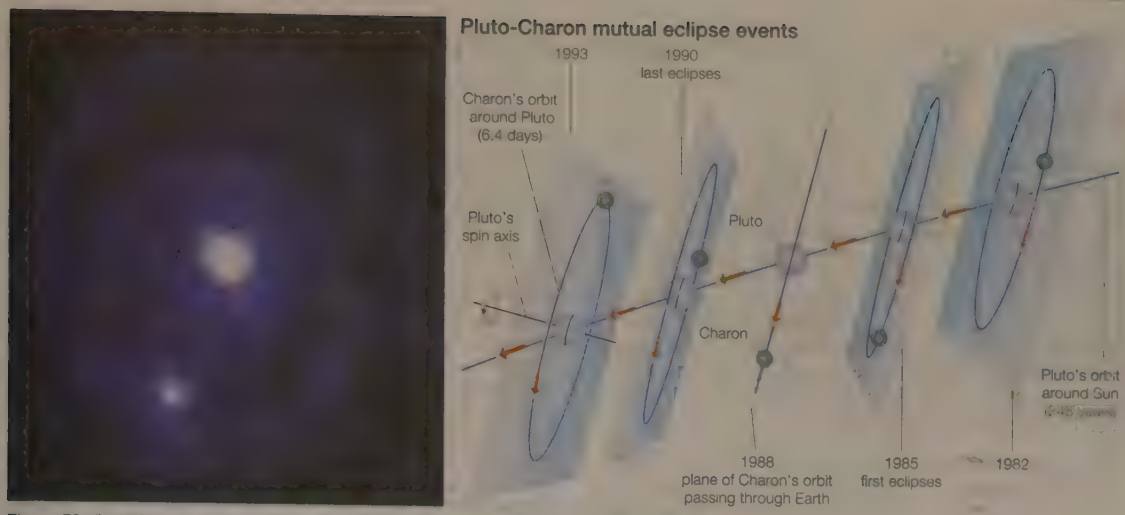

Figure 59: (Left) Pluto and Charon (centre and lower left, respectively) in an image made in 1990 by the Hubble Space Telescope. (Right) Charon's orbit around Pluto as viewed from Earth, 1982–93. Between 1985 and 1990, Pluto and Charon were in a period of mutual eclipses. During each 6.4-day revolution around Pluto, Charon passed in front of the planet, partially blocking it from view, and then disappeared behind the planet.
(Left) From NASA/European Space Agency; (right) Encyclopædia Britannica, Inc

of collecting light from a wide field of sky was put into service in 1929, and a young amateur astronomer, Clyde Tombaugh, was hired to carry out the search. On Feb. 18, 1930, less than a year after he began his work, Tombaugh found Pluto in the constellation Gemini. The object appeared as a dim 15th-magnitude "star" that slowly changed position against the fixed background stars as it pursued its 248-year orbit around the Sun. The symbol invented for it, ♇, stands both for the first two letters of Pluto and for the initials of Percival Lowell.

Charon's discovery

Charon was discovered in 1978 in images of Pluto that had been recorded photographically at the U.S. Naval Observatory station in Flagstaff, only a short distance from the site of Pluto's discovery. These images were being made by James W. Christy and Robert S. Harrington in an attempt to obtain more accurate measurements of Pluto's orbit. The new moon was named after the boatman in Greek mythology who ferries dead souls to Hades' realm in the underworld.

Prior to the discovery of Charon, Pluto was thought to be larger and more massive than it actually is. Even in the discovery images, Charon appears as an unresolved bump on the side of Pluto, an indication of the observational difficulties involved. Only near the end of the 20th century, with the availability of the Hubble Space Telescope and Earth-based instruments equipped with adaptive optics that compensate for atmospheric turbulence, did astronomers first resolve Pluto and Charon into separate bodies.

ORIGIN OF PLUTO AND CHARON

Before the discovery of Charon, it was popular to assume that Pluto was a former moon of Neptune that had somehow escaped its orbit. This idea gained support from the apparent similarity of the dimensions of Pluto and Triton and the near coincidence in Triton's orbital period (5.9 days) and Pluto's rotation period (6.4 days). It was suggested that a close encounter between these two bodies when they were both moons led to the ejection of Pluto from the Neptunian system and caused Triton to assume the retrograde orbit that is presently observed.

Astronomers found it difficult to establish the likelihood that all these events would have occurred, and the discovery of Charon provided information that further refuted the theory. Because the revised mass of Pluto is only half that of Triton, Pluto clearly could not have caused the reversal of Triton's orbit. Also, the fact that Pluto has a proportionally large moon of its own makes the escape idea implausible. Current thinking favours the idea that Pluto and Charon formed as two independent bodies in the solar nebula, the gaseous cloud from which the solar system condensed (see above *An overview of the solar system: Origin of the solar system*). A collision between Pluto and a proto-Charon could have produced a debris ring around Pluto that accreted by gravitational attraction to form the present moon. This scenario is similar to the currently favoured model for the formation of Earth's Moon (see above *The Moon: Origin and evolution*).

This scenario implies that at the time the Pluto-Charon system formed, about 4.6 billion years ago, the outer solar nebula contained many icy bodies of about the same size as these two. The bodies themselves are thought to have been built up from smaller entities that today would be recognized as the nuclei of comets. Triton is presumably another of these large icy planetesimals, captured into orbit by Neptune in the planet's early history.

Pluto as a Kuiper belt object

Most of these icy planetesimals were incorporated into the cores of the giant planets during their formation. Many others, however, are thought to have remained as unconsolidated debris to make up the Kuiper belt—a disk-shaped region that lies beyond Neptune's orbit and, significantly, includes the outer part of Pluto's orbit. After hundreds of Kuiper belt objects (KBOs) were directly observed starting in the early 1990s, astronomers came to suspect that Pluto (with Charon) is the largest known member of the Kuiper belt and that bodies such as Triton and some other icy moons of the outer planets originated as KBOs. In fact, like Pluto, one group of KBOs have highly eccentric orbits inclined to the plane of the solar system, and they exhibit the same 3:2 orbital resonance with Neptune. In recognition of this affinity, these objects have been dubbed Plutinos ("little Plutos").

PLUTO'S STATUS AS A PLANET

If Pluto had been discovered in the context of the Kuiper belt, rather than as an isolated entity, it might not have been ranked with the other eight planets. Furthermore, it may be only a matter of time before a body even larger than Pluto is detected lurking farther out in the Kuiper belt. In fact, within just a few years surrounding the turn of the 21st century, several KBOs each the size of Charon were discovered, including one that is well outside the gravitational influence of Neptune.

Nonetheless, since the early 1990s the major scientific discussions over Pluto's status have concluded with most of the participants agreeing that Pluto should remain a planet. One of these took place in 2000 at the General Assembly of the International Astronomical Union, the organization charged with classifying astronomical objects and that originally classified Pluto. Pluto's planetary status has been accepted by scientists and the general public for the greater part of a century. A demotion does not appear likely to be in its future. (T.C.O.)

OTHER CONSTITUENTS OF THE SOLAR SYSTEM

Asteroids

Asteroids are rocky bodies about 1,000 kilometres or less in diameter that orbit the Sun primarily between the orbits of Mars and Jupiter. Because of their small size and large numbers relative to the nine major planets, asteroids are also called minor planets. The two designations are frequently used interchangeably, though dynamicists, astronomers who study individual objects with dynamically interesting orbits or groups of objects with similar orbital characteristics, generally use the term minor planet, whereas those who study the physical properties of such objects usually refer to them as asteroids. The term planetoid is sometimes used as well.

Nomenclature

HISTORICAL SURVEY OF MAJOR ASTEROID DISCOVERIES

Early observations. The first asteroid was discovered on Jan. 1, 1801, by Giuseppe Piazzi at Palermo, Italy. At first Piazzi thought that he had discovered a comet; however, after the orbital elements of the object had been computed it became clear that the object moved in a planetlike orbit between the orbits of Mars and Jupiter. Owing to illness, Piazzi was able to observe the object only until February 11, and, as no one else was aware of its existence, it was not reobserved before it moved into the daytime sky. The short arc of observations did not allow computation of an orbit of sufficient accuracy to predict where the object would reappear when it moved back into the night sky, and so it was "lost." There matters might have stood were it not for the fact that this object was located at the heliocentric distance predicted by Bode's law of planetary distances proposed in 1766 by the German astronomer Johann D. Titius and popularized by his compatriot Johann E. Bode, who used the scheme to advance the notion of a "missing" planet between Mars and Jupiter. The discovery of Uranus in 1781 by the British astronomer William Herschel at a distance that closely fit the distance predicted by Bode's law was taken as strong evidence of its correctness. Some astronomers were so convinced that during an astronomical conference in 1796 they agreed to undertake a systematic search. Ironically, Piazzi was not a party to this attempt to locate the missing planet. Nonetheless, Bode and others, on the basis of the preliminary orbit, believed that Piazzi had found and then lost it. This led the German mathematician Carl Friedrich Gauss to develop in 1801 a method for computing the orbit of an asteroid from only a few observations, a technique that has not been significantly improved since. Using Gauss's predictions, the German astronomer Franz von Zach rediscovered Ceres on Jan. 1, 1802. Piazzi named this object Ceres after the ancient Roman grain goddess and patron goddess of Sicily, thereby initiating a tradition that continues to the present day: asteroids are named by their discoverers (in contrast to comets, which are named for their discoverers).

Identification of Ceres

The discovery of three more faint (compared with Mars and Jupiter) objects in similar orbits over the next six years (Pallas, Juno, and Vesta, respectively) complicated this elegant solution to the missing-planet problem and gave rise to the surprisingly long-lived, though no longer generally accepted, idea that the asteroids were remnants of a planet that had exploded.

Following this flurry of activity, the search for the planet appears to have been abandoned until 1830, when Karl L. Hencke renewed it. In 1845 he discovered the fifth asteroid, which he named Astraea.

Modern research. There were 88 known asteroids by 1866, when the next major discovery was made: Daniel Kirkwood, an American astronomer, noted that there were gaps in the distribution of asteroid distances from the Sun (see below *Distribution and Kirkwood gaps*). The introduction of photography to the search for new asteroids by the German astronomer Max Wolf in 1891, by which time 322 asteroids had been identified, accelerated the discovery rate. By the end of the 19th century, 464 had been found. The asteroid designated 323 Brucia, detected by Wolf in 1891, was the first to be discovered by means of photography.

Application of photography

The first measurements of the sizes of asteroids were made in 1894 and 1895 by the American astronomer Edward E. Barnard, who used a filar micrometer (an instrument normally employed for visual measurement of the separations of double stars) to estimate the diameters of the first four asteroids. Barnard's results established that Ceres was the largest asteroid, with an estimated diameter of nearly 800 kilometres. These values remained the best available until new techniques were introduced during the early 1970s (see below *Size and albedo*). The first four asteroids came to be known as "the big four," and, because all other asteroids were much fainter, they were believed to be considerably smaller as well.

In 1918 the Japanese astronomer Kiyotsugu Hirayama recognized clustering in three of the orbital elements of various asteroids (semimajor axis, eccentricity, and inclination). He speculated that objects sharing these elements had been formed by explosions of larger parent asteroids and called such groups of asteroids "families."

The idea that Jupiter was responsible for interrupting the formation of a planet from the swarm of planetesimals accreting near a heliocentric distance of 2.8 AU was introduced in 1944 by O.J. Schmidt. In 1951 the Estonian astronomer Ernest J. Öpik calculated the lifetimes of asteroids with orbits that passed close to those of the major planets and showed that most such asteroids were destined to collide with a planet or be ejected from the solar system on time scales of a few hundred thousand to a few million years. Since the age of the solar system is approximately 4.6 billion years, this meant that the asteroids seen today in such orbits must have entered them recently and implied that there was a source for the asteroids. Öpik believed this source to be comets that had been captured by the planets and that had lost their volatile material through repeated passages inside the orbit of Mars.

The mass of Vesta was deduced by the German-born American astronomer Hans G. Hertz in 1966 from measurements of its perturbations on the orbit of 197 Arete. The first mineralogical determination of the surface composition of an asteroid was made in 1969 by Thomas McCord, John B. Adams, and Torrence V. Johnson of the United States, who used spectrophotometry to identify the mineral pyroxene in the surface material of 4 Vesta. In 1970 the first reliable albedos (reflectivities) and diameters of asteroids were determined by two groups of American astronomers—Joseph F. Veverka, Benjamin H. Zellner, and their colleagues, who used a technique based on polarization measurements, and David A. Allen and Dennis L. Matson, who employed infrared radiometry.

Development of classification systems. In 1975 Zellner, together with Clark R. Chapman and David D. Morrison, grouped the asteroids into three broad taxonomic classes, which they designated C, S, and M (see below *Composition*). They estimated that about 75 percent belonged to class C, 15 percent to class S, and 5 percent to class M. The remaining 5 percent were unclassifiable in their system owing to either poor data or genuinely unusual properties. Furthermore, they noted that the S class dominated the population at the inner edge of the asteroid belt, whereas the C class was dominant in the middle and outer regions of the belt. In 1982 other American astronomers, Jonathan C. Gradie and Edward F. Tedesco, expanded this taxonomic system and recognized that the asteroid belt consisted of rings of differing taxonomic classes with the S, C, P, and D classes dominating the populations at heliocentric distances of approximately 2, 3, 4, and 5 AU, respectively (see below *Composition;* see also Figure 57). As more data became available from further observations, additional minor classes were recognized by the American astronomer David J. Tholen in 1984, by the Italian astronomer Antonietta Barucci and colleagues in 1987, and by Tedesco and colleagues in 1989.

ORBITS OF ASTEROIDS

Asteroid designations

Because of their large numbers, asteroids are assigned numbers as well as names. The numbers are assigned consecutively after accurate orbital elements have been determined. (For example, Ceres is officially known as 1 Ceres, Pallas as 2 Pallas, and so forth.) By mid-1991, more than 7,000 asteroids had been observed at two or more oppositions, and 5,000 of these were numbered. The discoverers have the right to choose a name for their discoveries as soon as they are numbered. Now the names selected are submitted to the International Astronomical Union for approval.

Prior to the mid-20th century, asteroids were sometimes assigned numbers before accurate orbital elements had been determined, and so some numbered asteroids could not later be located. These objects are referred to as "lost" asteroids. As of 1991 only asteroid 719 Albert remained lost.

The Minor Planet Center at the Harvard-Smithsonian Center for Astrophysics in Cambridge, Mass., U.S., maintains computer files for all measurements of asteroid positions. The Institute for Theoretical Astronomy in St. Petersburg, Russia, publishes each year the *Ephemerides of Minor Planets,* which contains the orbital elements of all numbered asteroids, together with their opposition dates and ephemerides.

Although most asteroids travel in fairly circular orbits, there are some notable exceptions. One of the most extreme of these is 3200 Phaethon, discovered by the Infrared Astronomical Satellite (IRAS) in 1983. (It was the first asteroid to be discovered by a spacecraft.) Phaethon approaches to within 0.14 AU of the Sun, well within Mercury's perihelion distance of 0.31 AU. Phaethon's aphelion (2.4 AU) is in the main asteroid belt. This object is the parent body of the Geminid meteor stream and, since the parent bodies of all other meteor streams identified to date are comets, it is considered by some to be a defunct comet. Another asteroid, 944 Hidalgo, is also thought by some to be a defunct comet because of its unusual orbit. This object, discovered in 1920 by Walter Baade at the Bergedorf Observatory near Hamburg, Ger., has a perihelion distance of 2.02 AU at the inner edge of the main asteroid belt and an aphelion distance of 9.68 AU just beyond the orbit of Saturn at 9.54 AU. Finally, there is the case of 2060 Chiron, discovered in 1977 by Charles Kowal at the Palomar Observatory near San Diego, Calif., U.S. This object was originally classified as an asteroid, but in 1989 the American astronomers Karen J. Meech and Michael J. Belton observed a dusty coma surrounding it, and in 1991 Schelte J. Bus, also of the United States, and his colleagues detected the presence of cyanogen radicals, a known constituent of the gas comas of comets. Chiron travels in an orbit that lies wholly outside of the asteroid belt, having a perihelion distance of 8.43 AU (between the orbits of Jupiter and Saturn) and an aphelion distance of 18.8 AU, which nearly reaches the orbit of Uranus at 19.2 AU. Because Chiron moves in a chaotic, planet-orbit-crossing orbit, astronomers believe that it will eventually collide with a planet or be permanently ejected from the solar system (see also below *Groups of comets and other unusual cometary objects*).

Distribution and Kirkwood gaps. About 95 percent of the known asteroids move in orbits between those of Mars and Jupiter. These orbits, however, are not uniformly distributed but, as shown in Figure 60, exhibit "gaps" in the distribution of their semimajor axes. These so-called Kirkwood gaps are due to resonances with Jupiter's orbital period. An asteroid with a semimajor axis of 3.3 AU, for example, makes two circuits around the Sun in the time it takes Jupiter to make one and is thus said to be in a two-to-one (written 2:1) resonance orbit with Jupiter. Consequently, once every two orbits Jupiter and an asteroid in such an orbit would be in the same relative positions, and such an asteroid would experience a force in a fixed direction. Repeated applications of this force would eventually change the semimajor axes of asteroids in such orbits, thus creating a gap at that distance. Gaps occur at 4:1, 7:2, 3:1, 5:2, 7:3, and 2:1 resonances, while concentrations occur at the 3:2 (Hilda group), 4:3 (Thule), and 1:1 (Trojan group) resonances. The presence of secular resonances complicates the situation, particularly at the inner edges of the belt. An adequate explanation of why some resonances produce gaps and others produce concentrations has yet to be found.

Cause of the Kirkwood gaps

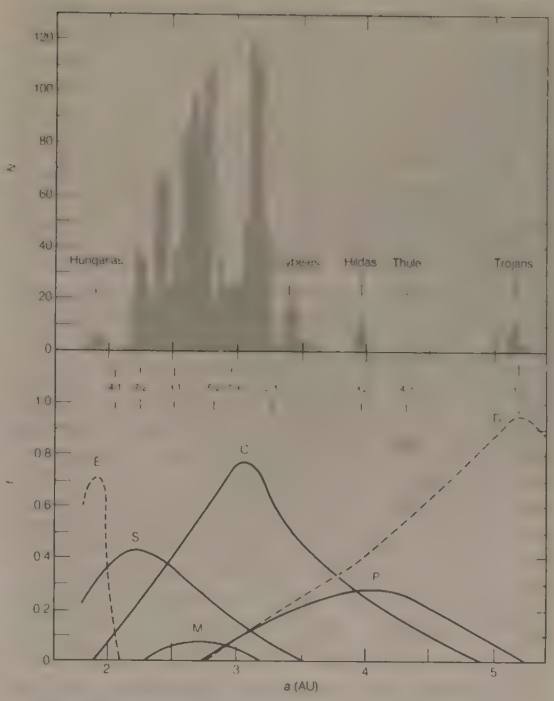

Figure 60: (Top) Number distribution (*N*) in semimajor axis (*a*) for asteroids with diameters greater than about 50 kilometres. The fractions below the centre indicate the locations of the major orbital period resonances with Jupiter. The deep Kirkwood gaps occur within the main belt near the 3:1, 5:2, and 7:3 resonances, whereas the concentrations are found at the 3:2, 4:3, and 1:1 resonances. The main belt is confined to the region between the 4:1 and 2:1 resonances. The Kirkwood gap at the 7:2 resonance is too narrow to be displayed at the scale plotted. (Bottom) Fractional number distribution (*f*) of the major asteroid classes from Table 24. The sum of the various classes found at any given semimajor axis must equal 1. The other classes in Table 24 do not appear because none of them constitute more than 2 percent of the total number of asteroids found at any given semimajor axis.

Families. Within the main asteroid belt are groups of asteroids that cluster in certain orbital elements (semimajor axis, eccentricity, and inclination). Such groups are called families and assigned the name of the lowest numbered asteroid in the family. Asteroid families are thought to be formed when an asteroid is disrupted in a catastrophic collision. Theoretical studies indicate that such catastrophic collisions between asteroids are common enough to account for the number of families observed. About 40 percent of all known asteroids belong to such families.

The three largest families (Eos, Koronis, and Themis) have been determined to be compositionally homogeneous. If the asteroids belonging to them are considered to be fragments of a single parent body, then their parent bodies must have had diameters of 200, 90, and 300 kilometres, respectively. The smaller families have not been as well studied because their numbered members are fewer and smaller (and hence fainter). Nevertheless, it is known that some of the smaller families are compositionally inhomogeneous and that, at least in some cases, what are observed are pieces of a geochemically differentiated parent body. It is theorized that some of the Earth-crossing asteroids and meteorites reaching the terrestrial surface are fragments produced in collisions similar to those that produced the asteroid families.

Outer-belt asteroids. The vast majority of asteroids have orbital periods between three years and six years—*i.e.*, between one-fourth and one-half of Jupiter's orbital period (see Figure 60). These asteroids are said to be

Asteroid groups that fall outside the main belt

main-belt asteroids. Besides the few asteroids in highly unusual orbits, some of which were noted above, there are a number of groups that fall outside the main belt. Those that have orbital periods greater than one-half that of Jupiter are called outer-belt asteroids. There are four such groups: the Cybeles, Hildas, and Thule, named after the lowest numbered asteroid in each group, as well as the Trojan group, so called because all its members are named after characters from Homer's epic work about the Trojan War, the *Iliad*. As of mid-1991, 86 Cybeles, 66 Hildas, 1 Thule, and 153 Trojans had been observed at two or more oppositions.

Trojan asteroids. In 1772 the French mathematician and astronomer Joseph-Louis Lagrange predicted the existence and location of two groups of asteroids located near the (L_4 and L_5) equilateral triangular stability points of a three-body system formed by the Sun, Jupiter, and the asteroids. These are two of the five stable points in the circular, restricted three-body problem. (The other three stable points are located along a line passing through the Sun and Jupiter. Because of the presence of other planets, principally Saturn, the Sun-Jupiter-Trojan asteroid system is not a true three-body system, and so these other three points are not stable and no asteroids have been found near them. In fact, most of Jupiter's Trojan asteroids do not move in the plane of its orbit but rather in orbits inclined by up to 40° and at longitudes that differ by as much as 70° from the longitudes of the true Lagrangian points.)

In 1906 Max Wolf discovered 588 Achilles near the Lagrangian point preceding Jupiter in its orbit. Within a year August Kopff had discovered two more: 617 Patroclus, located near the following Lagrangian point, and 624 Hector near the preceding Lagrangian point. It was later decided to name such asteroids after the participants in the Trojan War as given in the *Iliad* and, furthermore, to name those near the preceding point after Greek warriors and those near the following point after Trojan warriors. With the exception of the two previously named "spies" (Hector, the lone Trojan in the Greek camp, and Patroclus, the lone Greek in the Trojan camp), this tradition has been maintained.

The term Trojan has since been applied to any object occupying the equilateral Lagrangian points of other pairs of bodies. Searches have been made for Trojans of the Earth, Saturn, and Neptune, as well as of the Earth-Moon system, but so far none have been found. It was long considered doubtful whether truly stable orbits could exist near these Lagrangian points because of perturbations by the major planets. However, in 1990 an asteroid librating about the following Lagrangian point of Mars was discovered by the American astronomers David H. Levy and Henry E. Holt, thus reopening this question.

Although only about 65 Trojans have been numbered, photographic surveys have shown that there are about $2{,}300 \pm 500$ such asteroids with diameters greater than 15 kilometres. About 1,300 of these are located near the preceding Lagrangian point and 1,000 near the following Lagrangian point.

The Hungaria group

Inner-belt asteroids. There is only one known group of inner-belt asteroids—namely, the Hungarias. The Hungaria asteroids, about 100 of which are known, have a mean semimajor axis of 1.91 AU; thus, their orbital periods are less than one-fourth that of Jupiter (see Figure 57). Hungarias have nearly circular orbits (the mean eccentricity is 0.08) but large inclinations, the mean inclination being 22.7°. At least one dynamical family, the Hungaria family, exists within the Hungaria group. Because of the low eccentricities of their orbits, the mean perihelion distance of a Hungaria asteroid is 1.76 AU. Accordingly, a typical Hungaria cannot pass close to Mars, whose aphelion distance is 1.67 AU. A few Hungarias, however, have perihelion distances a few hundredths of 1 AU less than Mars's aphelion distance and so are shallow "Mars crossers" (see below) as well.

Classes of near-Earth asteroids

Near-Earth asteroids. Asteroids that can pass inside the orbit of Mars are said to be near-Earth asteroids. The near-Earth asteroids are subdivided into several classes. The most distant—those that can cross the orbit of Mars but that have perihelion distances (q) greater than 1.3 AU—are dubbed Mars crossers. This group is further subdivided into two groups: shallow Mars crossers ($1.58 \leq q < 1.67$ AU) and deep Mars crossers ($1.3 < q < 1.58$ AU).

The next most distant group of near-Earth asteroids are the Amors ($1.017 < q \leq 1.3$ AU). Amor asteroids have perihelion distances greater than the Earth's present aphelion distance (Q) of 1.017 AU and therefore do not at present cross the planet's orbit. Because of strong gravitational perturbations produced by their close approaches to the Earth, however, the orbital elements of all the Earth-approaching asteroids, except the shallow Mars crossers, change appreciably on a time scale of a few years or tens of years. For this reason about half the known Amors, including 1221 Amor, are part-time Earth crossers. Only asteroids that cross the orbits of planets, such as the Earth-approaching asteroids and objects like 944 Hidalgo and 2060 Chiron, suffer significant changes in their orbital elements on time scales shorter than many millions of years. Hence, the outer-belt asteroid groups (Cybeles, Hildas, Thule, and the Trojans) do not interchange members.

There are two groups of near-Earth asteroids that deeply cross the Earth's orbit on an almost continuous basis. The first of these to be discovered were the Apollo asteroids, 1862 Apollo being detected by the German astronomer Karl Wilhelm Reinmuth in 1932 but lost shortly thereafter and not rediscovered until 1978. Apollo asteroids have semimajor axes (a) that are greater than or equal to 1 AU and perihelion distances that are less than or equal to 1.017 AU; thus, they cross the Earth's orbit when near the perihelia of their orbits. For the other group of Earth-crossing asteroids—named Atens after 2062 Aten, which was discovered in 1976 by Eleanor F. Helin of the United States—$a < 1.0$ AU and $Q \geq 0.983$ AU, the present perihelion distance of the Earth. These asteroids cross the Earth's orbit when near the aphelia of their orbits.

By mid-1991 the number of known Aten, Apollo, and Amor asteroids were 11, 91, and 81, respectively. Most of these were discovered since 1970, when dedicated searches for this type of asteroid were begun: 25 were discovered during the 1970s, 80 during the 1980s, and 49 during the first 20 months of the 1990s. It is estimated that there are roughly 100 Atens, 700 Apollos, and 1,000 Amors that have diameters larger than about one kilometre. Because these asteroids travel in orbits that cross the Earth's orbit, close approaches to the Earth occur, as well as occasional collisions. For example, in January 1991, an Apollo asteroid with an estimated diameter of 10 metres passed by the Earth within less than half the distance to the Moon.

THE NATURE OF ASTEROIDS

Rotation and shape. Asteroid rotational periods and shapes are determined primarily by monitoring their changing brightness on time scales of hours to days. Short-period fluctuations in brightness caused by the rotation of an irregularly shaped or spotted body (a spotted body being a spherical object with albedo differences) give rise to a light curve (a graph of brightness versus time) that repeats at regular intervals corresponding to an asteroid's rotation period. The range of brightness variation is more difficult to interpret but is closely related to an asteroid's shape or spottedness.

Rotational periods have been determined for more than 400 asteroids. They range from 2.3 hours to 48 days, but the majority (more than 80 percent) lie between 4 hours and 20 hours. Periods longer than a few days may actually be due to precession caused by an unseen satellite. The mean rotational period is roughly 10 hours for the entire sample. The largest asteroids (those with diameters greater than about 175 kilometres), however, have a mean rotational period close to 7 hours, whereas this value is about 10 hours for smaller asteroids. The largest asteroids may have preserved their primordial rotation rates, but the smaller ones have almost certainly had theirs modified by subsequent collisions. The difference in rotation rates between the larger and the smaller asteroids is believed to stem from the fact that large asteroids retain all of their collisional debris from minor collisions, whereas smaller asteroids retain more of the debris ejected in the direction

opposite to that of their spins, causing a loss of angular momentum and thus a reduction in speed of rotation.

Major collisions can completely disrupt smaller asteroids. The debris from such collisions makes still smaller asteroids, which can have virtually any shape or spin rate. Thus, the fact that no rotational periods shorter than about 2.5 hours have been observed implies that the material of which asteroids are made is not strong enough to withstand the centripetal forces that such rapid spins would produce.

For mathematical reasons it is impossible to distinguish between the rotation of a spotted sphere and an irregular shape of uniform reflectivity on the basis of observed brightness changes alone. Nevertheless, the fact that opposite hemispheres of most asteroids appear to have albedos differing by no more than a few percent suggests that their brightness variations are due mainly to changes in their projected, illuminated, visible, cross-sectional areas. Hence, in the absence of evidence to the contrary, it is generally accepted that variations in reflectivity contribute little to the observed rotational light-curve amplitude. Asteroid 4 Vesta is a notable exception to this generalization because it is known that the difference in reflectivity between its opposite hemispheres is sufficient to account for much of its light-curve amplitude.

Asteroid light-curve amplitudes range from zero to a factor of 6.5 in the case of the Apollo asteroid 1620 Geographos. A light-curve amplitude of zero is caused by viewing an asteroid along one of its rotational poles, while the 6.5 to 1 variation in brightness is believed to result from either of two possibilities: Geographos is a cigar-shaped object that is viewed along a line perpendicular to its rotational axis, or it is a pair of objects nearly in contact that orbit each other around their centre of mass.

The mean rotational amplitude for asteroids is about a factor of 1.3. These data, together with the assumptions mentioned above, allow astronomers to estimate asteroid shapes, which occur in a wide range (see Figure 61). Some asteroids, such as 1 Ceres, 2 Pallas, and 4 Vesta, are nearly spherical, whereas others, like 15 Eunomia, 107 Camilla, and 511 Davida, are quite elongated. Still others, as, for example, 624 Hektor, 1580 Betulia (not shown in Figure 58 but whose proposed shape is that of a kidney bean), and 4769 Castalia (which appears in radar observations by the American astronomer Steven J. Ostro to resolve as two spheres in contact), apparently have bizarre shapes.

Size and albedo. The most widely used technique for determining the sizes of asteroids is that of thermal radiometry. This technique makes use of the fact that the infrared radiation (heat) emitted by an asteroid must balance the solar radiation it absorbs. By using a so-called thermal model to balance the intensity of infrared radiation with the intensity at visual wavelengths, investigators are able to arrive at the diameter of the asteroid. Several other techniques—polarimetry, speckle interferometry, and radar—also are used, but they are limited to brighter, larger, and/or closer asteroids.

Application of thermal radiometry

From K. Beatty, B. O'Leary, and A. Chaikin (eds.), *The New Solar System*, 2nd ed.

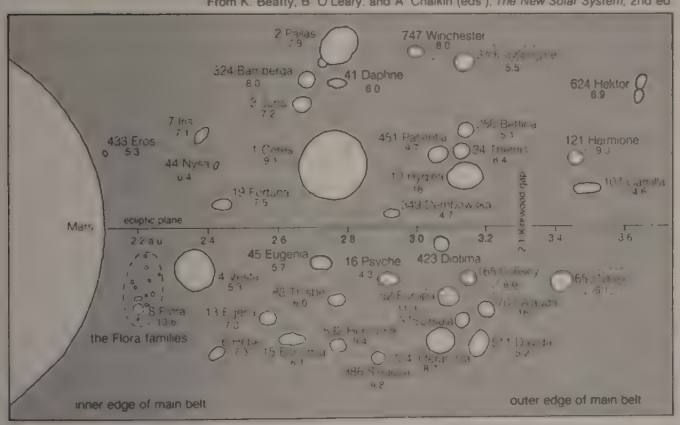

Figure 61: This representation of notable asteroids includes all those exceeding 200 kilometres in diameter. The asteroids are depicted in their correct relative sizes and shapes (the limb of Mars is included for comparison), and their rotational pole orientations (if known) are indicated. They are positioned at their correct relative distances from the Sun. Asteroids located near the top or bottom of the diagram travel in relatively eccentric and/or inclined orbits, whereas those near the ecliptic move in fairly circular, noninclined orbits. Rotational periods (in hours) are indicated beneath the names of the asteroids. Among the special smaller asteroids shown are the members of the Flora families larger than 15 kilometres across.

The only technique that measures the diameter directly (*i.e.*, without having to "model" the actual observations) is that of stellar occultation. In this method, investigators measure the length of time that a star disappears owing to the passage of an asteroid between the Earth and the star. Then, using the known distance and the rate of motion of the asteroid, they are able to determine the latter's diameter uniquely. The results of this method have made it possible to reliably calibrate the indirect techniques, thermal radiometry in particular. As a consequence, asteroid diameters obtained by means of such techniques are now thought to have uncertainties of less than 10 percent. Because passages of asteroids in front of stars are rare and best applied to fairly spherical asteroids and because only one cross section is measured, the majority of asteroid sizes have been obtained using indirect techniques.

By mid-1991 the diameters of about 21 asteroids, including 1 Ceres, 2 Pallas, 3 Juno, and 4 Vesta, had been accurately determined by means of the stellar-occultation method, whereas about 2,000 had been measured with the indirect techniques, principally thermal radiometry.

Asteroid 1 Ceres, with a diameter of about 930 kilometres (km), is the largest, followed by 2 Pallas at 535 km and 4 Vesta at 520 km. The fourth largest asteroid, 10 Hygiea, has a diameter of about 410 km. There are two asteroids with diameters between 300 and 400 km and about 24 with diameters between 200 and 300 km. In total, there are about 30 asteroids with diameters greater than 200 km. The smallest known asteroids are members of the Earth-approaching groups, since these asteroids can approach the Earth to within a few hundredths of 1 AU. The smallest routinely observed Earth-approaching asteroids measure less than 0.5 km across. It has been estimated that there are 250 asteroids larger than 100 km in diameter and perhaps 1,000,000 with diameters greater than 1 km.

Albedo

A parameter closely related to size is albedo, or reflectivity. This property also provides compositional information. Albedo is the ratio between the amount of light actually reflected and that which would be reflected by a uniformly scattering disk of the same size. Snow has an albedo of approximately 1 and coal an albedo of about 0.05.

An asteroid's apparent brightness depends on both its albedo and diameter as well as on its distance. For example, if 1 Ceres and 4 Vesta could both be observed at the same distance, Vesta would be the brighter of the two by about 15 percent. Vesta's diameter, however, is only about 55 percent that of Ceres. It appears brighter because its albedo is around 0.35, compared with 0.09 for Ceres.

Asteroid visual geometric albedos range from just under 0.02 to over 0.5 and may be divided into four albedo groups: low (0.02–0.07), intermediate (0.08–0.12), moderate (0.13–0.28), and high (greater than 0.28). About 78 percent of the known asteroids are low-albedo objects, and most of them are located in the outer half of the main asteroid belt and among the outer-belt populations. More than 95 percent of outer-belt asteroids belong to this group. Roughly 18 percent of all known asteroids belong to the moderate-albedo group, the vast majority of which are found in the inner half of the main belt. The high-albedo asteroids make up the remaining 4 percent of the asteroid population. For the most part, they occupy the same regions of the main asteroid belt as the moderate-albedo objects.

Mass and density. Asteroid masses are low and have little effect on the orbits of the major planets. In the past, the masses of several have been measured by noting their effect on the orbits of other asteroids that they approach closely at regular intervals. In 1989 the American scientists E. Myles Standish and Ronald W. Hellings used radio-ranging measurements that were transmitted from

the surface of Mars between June 1976 and August 1980 by the two Viking landers to determine distances to Mars with an accuracy of about 10 metres. Because the largest asteroids (Ceres, Pallas, and Vesta) cause perturbations in Mars's orbit in excess of 50 metres on time scales of 10 years or less, they were able to use the measured departures of Mars from its predicted orbit to estimate the masses (given below) of these three asteroids. Since the diameters of these three largest asteroids also have been determined and since their shapes are either spherical or ellipsoidal, their volumes are known as well. Knowledge of the mass and volume of an asteroid allows its density to be computed.

The mass of the largest asteroid, Ceres, is 1.0×10^{24} grams (0.0002 the mass of the Earth). The masses of the second and third largest asteroids, Pallas and Vesta, are only 0.28 and 0.30 times the mass of Ceres. The mass of the entire asteroid belt is roughly three times that of Ceres. Most of the mass in the asteroid belt is concentrated in the larger asteroids. The 10th largest asteroid has only 1/60 the mass of the largest, and about 90 percent of the total mass is contained in asteroids with diameters exceeding 100 kilometres. Ninety percent of the total mass of the asteroids is located in the main belt, 9 percent is in the outer belt and Jupiter Trojan asteroids, and the remainder is distributed among the inner belt and planet-crossing asteroid populations.

The densities of the largest asteroids as compared with those of the inner planets

The densities of Ceres, Pallas, and Vesta are 2.3, 3.4, and 4.0 grams per cubic centimetre, respectively. These compare with 5.4, 5.2, and 5.5 g/cm^3 for Mercury, Venus, and the Earth, respectively; 3.9 g/cm^3 for Mars; and 3.3 g/cm^3 for the Moon. The density of Ceres is similar to that of a class of meteorites known as carbonaceous chondrites, which contain a larger fraction of volatile material than do ordinary terrestrial rocks and hence have a somewhat lower density (see below *Specific asteroidal source regions for recovered meteorites*). The density of Vesta is similar to those of the rocky planets. Insofar as Ceres, Pallas, and Vesta are typical of asteroids in general, it can be concluded that asteroids are rocky bodies.

Composition. The combination of spectral reflectance measurements (measures of the amount of reflected sunlight at various wavelengths between about 0.3 and 2.6 micrometres) and albedos is used to classify asteroids into various taxonomic groups. If sufficient spectral resolution is available, these measurements also can be used to infer the composition of the surface reflecting the light. This can be done by comparing the asteroid data with that obtained in the laboratory using meteorites or terrestrial rocks or minerals.

By the end of the 1980s, spectral reflectance measurements at visual wavelengths between 0.3 and 1.1 micrometres were available for about 6,000 asteroids, while albedos were determined for roughly 2,000. Both types of data were available for approximately 400 asteroids. Table 24 summarizes the 15 taxonomic classes into which the asteroids can be divided on the basis of such data.

Asteroids of the B, C, F, and G classes have low albedos and spectral reflectances similar to those of carbonaceous chondritic meteorites and assemblages produced by hydrothermal alteration and/or metamorphism of carbonaceous precursor materials. Some C-class asteroids are known to have hydrated minerals on their surfaces, whereas Ceres (a G-class) probably has water present as a layer of permafrost. K- and S-class asteroids have moderate albedos and spectral reflectances similar to the stony-iron meteorites, and they are known to contain significant amounts of silicates and metals, including the minerals olivine and pyroxene on their surfaces. M-class asteroids are moderate-albedo objects, may have significant amounts of nickel-iron metal in their surface material, and exhibit spectral reflectances similar to the nickel-iron meteorites. P-, D-, and T-class asteroids have low albedos and no known meteorite or naturally occurring mineralogical counterparts, but they may contain a large fraction of carbon polymers or organic-rich silicates or both in their surface material. R-class asteroids are very rare; only one (the high-albedo asteroid 349 Dembowska) has been identified with certainty. The surface material of Dembowska has been identified as being most consistent with a pyroxene and olivine-rich composition analogous to the pyroxene-olivine achondrite meteorites. The E-class asteroids have the highest albedos and spectral reflectances that match those of the enstatite achondrite meteorites. V-class asteroids have reflectance properties closely matching those of one particular type of basaltic achondritic meteorite, the eucrite. The match is so good that some believe that the eucrites exhibited in museums are chips from the surface of a V-class asteroid that were knocked off during a major cratering event. The V class is confined to the large asteroid Vesta and a few very small Earth-approaching asteroids. (For additional information about achondrite meteorites, see below *Types of meteorites*.)

Among the larger asteroids (those with diameters greater than 100 kilometres), the C-class asteroids are the most common (accounting for about 65 percent by number) followed, in decreasing order, by the S (15 percent), D (8 percent), P (4 percent), and M (4 percent) classes. The remaining classes constitute less than 4 percent of the population by number. In fact, there are no A-, E-, or Q-class asteroids in this size range, only one member of the R and V classes, and between two and five members of each of the B, F, G, K, and T classes.

The distribution of the taxonomic classes throughout the asteroid belt is highly structured, as can be seen from Figure 60. Some believe this variation with distance from the Sun means that the asteroids formed at or near their present locations and that a detailed comparison of the chemical composition of the asteroids in each region will provide constraints on models for the conditions that may

Table 24: Summary of Asteroid Taxonomic Classes

class	mean albedo	spectral reflectivity (0.3–1.1 micrometres)
C	0.05	neutral, slight absorption at wavelengths of 0.4 micrometre or shorter
D	0.04	very red at wavelengths of 0.7 micrometre or longer
F	0.05	flat
P	0.04	featureless, sloping up into red*
G	0.09	similar to C class but with a deeper absorption at wavelengths of 0.4 micrometre or shorter
K	0.12	similar to S class but with lower slopes
T	0.08	moderately sloped with weak ultraviolet and infrared absorption bands
B	0.14	similar to C class but with shallower slope toward longer wavelengths
M	0.14	featureless, sloping up into red*
Q	0.21	strong absorption features shortward and longward of 0.7 micrometre
S	0.18	very red at wavelengths of less than 0.7 micrometre, typically with an absorption band between 0.9 and 1.0 micrometre
A	0.42	extremely red at wavelengths shorter than 0.7 micrometre and a deep absorption longward of 0.7 micrometre
E	0.44	featureless, sloping up into red*
R	0.35	similar to A class but with slightly weaker absorption bands
V	0.34	very red at wavelengths of less than 0.7 micrometre and a deep absorption and centred near 0.95 micrometre
Other	any	any object not falling into one of the above classes

*Classes E, M, and P are spectrally indistinguishable at these wavelengths and require an independent albedo measurement for unambiguous classification.

have existed within the contracting solar nebula at the time the asteroids were formed.

THE ORIGIN AND EVOLUTION OF THE ASTEROIDS

Available evidence indicates that the asteroids are the remnants of a "stillborn" planet. It is thought that at the time the planets were forming from the low-velocity collisions among asteroid-size planetesimals, one of them grew at a high rate and to a size larger than the others. In the final stages of its formation this planet, Jupiter, gravitationally scattered large planetesimals, some of which may have been as massive as the Earth is today. These planetesimals were eventually either captured by Jupiter or another of the trans-Jovian planets or ejected from the solar system. While they were passing through the inner solar system, however, such large planetesimals strongly perturbed the orbits of the planetesimals in the region of the asteroid belt, raising their mutual velocities to the average five kilometres per second they exhibit today. These high-velocity collisions ended the accretionary collisions by transforming them into catastrophic disruptions. Only objects larger than about 500 kilometres in diameter could have survived collisions with objects of comparable size at collisional velocities of five kilometres per second. Since that time, the asteroids have been collisionally evolving so that, with the exception of the very largest, most present-day asteroids are either remnants or fragments of past collisions.

While breaking down larger asteroids into smaller ones, collisions expose deeper layers of asteroidal material. If asteroids were compositionally homogeneous, this would have no noticeable result. Some of them, however, have become differentiated since their formation. This means that some asteroids, originally formed from so-called primitive material (*i.e.*, material of nonvolatile solar composition), were heated, perhaps by short-lived radionuclides or solar magnetic induction, to the point where their interiors melted and geochemical processes occurred. In certain cases, temperatures became high enough for iron to form. Being denser than other materials, the iron then sank to the centre, forming an iron core and forcing basaltic lavas onto the surface. At least one asteroid with a basaltic surface, Vesta, survives to this day. Other differentiated asteroids were disrupted by collisions that stripped away their crusts and mantles and exposed their iron cores. Still others may have had only their crusts partially stripped away, which exposed surfaces such as those visible today on the A-, E-, and R-class asteroids.

Evidence of differentiation

Collisions were responsible for the formation of the Hirayama families and at least some of the planet-crossing asteroids. A number of the latter enter the Earth's atmosphere, giving rise to sporadic meteors. Larger pieces survive passage through the atmosphere, and some of these end up in museums and laboratories as meteorites (see below *Relationship of meteoroids to asteroids and comets* and *Meteorites, asteroids, and the early solar system*). The very largest produce craters such as Meteor Crater in Arizona in the southwestern United States, and one may even have been responsible for the extinction of the dinosaurs some 65 million years ago. This extinction may have been triggered by an explosion resulting from the impact of an asteroid measuring roughly 10 kilometres in diameter. (Some investigators believe that a cometary body rather than an asteroid may have caused such an explosion.) Fortunately, collisions of this sort are rare. According to current estimates, a few asteroids of 1-kilometre diameter collide with the Earth every 1 million years. (E.F.T.)

Comets

GENERAL CONSIDERATIONS

Basic features. The traditional definition of a comet is a nebulous body with a "hairy" tail that makes a transient appearance in the sky. The word comet comes from the Greek *komētēs,* meaning "hairy one," a description that fits the bright comets noticed by the ancients. Many comets, however, do not develop tails. Moreover, comets are not surrounded by any nebulosity during most of their lifetime. The only permanent feature of a comet is its nucleus, which is a small body that may be seen as a stellar image in large telescopes when tail and nebulosity do not exist, particularly when the comet is still far away from the Sun. Two characteristics differentiate the cometary nucleus from a very small asteroid—namely, its orbit and its chemical nature. A comet's orbit is more eccentric; therefore, its distance to the Sun varies considerably. Its material is more volatile. When far from the Sun, however, a comet remains in its pristine state for eons without losing any volatile components because of the deep cold of space. For this reason, astronomers believe that pristine cometary nuclei may represent the oldest and best-preserved material in the solar system.

Differences between cometary nuclei and asteroids

During a close passage near the Sun, the nucleus of a comet loses water vapour and other more volatile compounds, as well as dust dragged away by the sublimating gases. It is then surrounded by a transient dusty "atmosphere" that is steadily lost to space. This feature is the coma, which gives a comet its nebulous appearance. The nucleus surrounded by the coma makes up the head of the comet. When it is even closer to the Sun, solar radiation usually blows the dust of the coma away from the head and produces a dust tail, which is often rather wide, featureless, and yellowish. The solar wind, on the other hand, drags ionized gas away in a slightly different direction and produces a plasma tail, which is usually narrow with nods and twists and has a bluish appearance.

Designations. In order to classify the chronological appearance of comets, the *Astronomische Nachrichten* ("Astronomical Reports") introduced in 1870 a system of preliminary and final designations that is still used today with only minor modifications. The preliminary designation classifies comets according to their order of discovery, using the year of discovery followed by a lowercase letter in alphabetical order, as in 1987a, 1987b, 1987c, and so forth. Comets are reclassified as soon as possible—usually a few years later—according to their chronological order of passage at perihelion (closest distance to the Sun); a Roman numeral is used in this case, as in 1987 I, 1987 II, 1987 III, and so on. Since the discovery may have taken place at any time either before or after perihelion passage, the two chronologies are not necessarily in the same order, and even the year may change in the final designation. The official designation generally includes the name(s) of its discoverer(s)—with a maximum of three names—preceded by a P/ if the comet is on a periodic orbit. If a person discovers several comets, an Arabic numeral is used after his name, as in 1867 II Tempel 1 and 1873 II Tempel 2. The discoverer's rule has not always been strictly applied: comets P/Halley, P/Lexell, P/Encke, and P/Crommelin have been named after the astronomers who proved their periodic character. Some comets become bright so fast that they are discovered by a large number of persons at almost the same time. They are given an arbitrary impersonal designation such as Brilliant Comet (1882 II), Southern Comet (1947 XII), or Eclipse Comet (1948 XI). Finally, comets may be discovered by an unusual instrument without direct intervention of a specific observer, as in the case of the Earth-orbiting Infrared Astronomical Satellite (IRAS). Its initials are used as if it were a human observer, as in 1983 VII IRAS-Araki-Alcock.

HISTORICAL SURVEY OF COMET OBSERVATIONS AND STUDIES

Early observations. In ancient times, without interference from streetlights or urban pollution, comets could be seen by everyone. Their sudden appearance—their erratic behaviour against the harmonious order of the heavenly motions—was interpreted as an omen of nature that awed people and was used by astrologers to predict flood, famine, pestilence, or the death of kings. The Greek philosopher Aristotle (4th century BC) thought that the heavens were perfect and incorruptible. The very transient nature of comets seemed to imply that they were not part of the heavens but were merely earthly exhalations ignited and transported by heat to the upper atmosphere. Although the Roman philosopher Seneca (1st century AD) had proposed that comets could be heavenly bodies like the planets, Aristotle's ideas prevailed until the 14th century AD. Finally, during the 16th century the Danish no-

The studies of Tycho Brahe

bleman Tycho Brahe established critical proof that comets are heavenly bodies. He compared the lack of diurnal parallax of the comet of 1577 with the well-known parallax of the Moon (the diurnal parallax is the apparent change of position in the sky relative to the distant stars due to the rotation of the Earth). Tycho deduced that the comet was at least four times farther away than the Moon, establishing for the first time that comets were heavenly bodies.

The impact of Newton's work. The German astronomer Johannes Kepler still believed in 1619 that comets travel across the sky in a straight line. It was the English physicist and mathematician Isaac Newton who demonstrated in his *Principia* (1687) that, if heavenly bodies are attracted by a central body (the Sun) in proportion to the inverse square of its distance, they must move along a conic section (circle, ellipse, parabola, or hyperbola). Using the observed positions of the Great Comet of 1680, he identified its orbit as being nearly parabolic.

Newton's friend, the astronomer Edmond Halley, endeavoured to compute the orbits of 24 comets for which he had found accurate enough historical documents. Applying Newton's method, he presupposed a parabola as an approximation for each orbit. Among the 24 parabolas, 3 were identical in size and superimposed in space. The three relevant cometary passages (1531, 1607, and 1682) were separated by two time intervals of 76 and 75 years. Halley concluded that the parabolas were actually the end of an extremely elongated ellipse. Instead of three curves open to infinity, the orbit is closed and brings the same comet periodically back to the Earth. As a consequence, it would return in 1758, he predicted. Observed on Christmas night, 1758, by Johann Georg Palitzsch, a German amateur astronomer, the comet passed at perihelion in March 1759 and at perigee (closest to the Earth) in April 1759. The perihelion date of 1759 had been predicted with an accuracy of one month by Alexis-Claude Clairaut, a French astronomer and physicist. Clairaut's work contributed much to the acceptance of Newton's theory on the Continent. With this, the until-then anonymous comet came to be called Halley's comet (or, in modern nomenclature, Comet P/Halley).

Passages of Comet P/Halley. Since 1759, Comet Halley has reappeared three more times—in 1835, 1910, and 1986. Its trajectory has been computed backward, and all of its 30 previous passages described in historical documents over 22 centuries have been authenticated. Comet Halley's period has irregularly varied between 74.4 years (from 1835 to 1910) and 79.6 years (from AD 451 to 530). These variations, which have been accurately predicted, result from the changing positions of the giant planets, mainly Jupiter and Saturn, whose variable attractions perturb the trajectory of the comet. The space orientation of the orbit has been practically constant, at least for several centuries. Since its returns are not separated by an integer number of years, however, the comet encounters the Earth each time on a different point of its orbit around the Sun; thus, the geometry of each passage is different and its shortest distance to the planet varies considerably. The closest known passage to the Earth, 0.033 AU, occurred on April 9, AD 837.

The 1986 passage of Comet Halley

The perigee distance of most of Comet Halley's historical passages has been between 0.20 and 0.50 AU. The last perigee, on April 11, 1986, took place at 0.42 AU from the Earth (Figure 62). By contrast, the comet passed at only 0.14 AU from the Earth in 1910. Seen from closer range, it was brighter and had a longer tail than on its return in 1986. This is one reason why the 1986 passage proved so disappointing to most lay observers. Yet, a far more important factor had to do with geometry: in the latitudes of the major Western countries, the comet was hidden by the southern horizon during the few weeks in April 1986 when it was at its brightest. Moreover, the night sky of most Western countries is brightly and constantly illuminated by public and private lights. Even in the absence of moonlight, the nighttime sky is pervaded by a milky glare that easily hides the tail of a comet.

Each century, a score of comets brighter than Comet Halley have been discovered. Yet, they appear without warning and will not be seen again. Many are periodic comets like Comet Halley, but their periods are extremely long (millennia or even scores or hundreds of millennia), and they have not left any identifiable trace in prehistory. Bright Comet Bennett 1970 II (Figure 63) will return in 17 centuries, whereas the spectacular Comet West 1976 VI will reappear in about 500,000 years. Among the comets that can easily be seen with the unaided eye, Comet Halley is the only one that returns in a single lifetime. Approximately 100 comets whose periods are between 3 and 200 years are known, however. Unfortunately they are or have become too faint to be readily seen without the aid of telescopes (see below *Periodic comets*).

Modern cometary research. During the 19th century it was shown that the radiant (*i.e.*, spatial direction) of the spectacular meteor showers of 1866, 1872, and 1885 coincided well with three known cometary orbits that happened by chance to cross the Earth's orbit at the dates of the observed showers. The apparent relationship between

Figure 63: Comet Bennett, taken at Cerro Tololo Interamerican Observatory, Chile, March 16, 1970.

comets and meteor showers was interpreted by assuming that the cometary nucleus was an aggregate of dust or sand grains without any cohesion. (This conception of the cometary nucleus became known as the "sandbank" model [see below *Cometary models*].) Meteor showers were explained by the spontaneous scattering of the dust grains along a comet's orbit, and the cometary nucleus began to be regarded only as the densest part of a meteor stream. At the end of the 19th and the beginning of the 20th century, spectroscopy revealed that the reflection of sunlight by the dust was not the only source of light in the tail; it showed the discontinuous emission that constitutes the signature of gaseous compounds. More specifically, it revealed the existence in the coma of several radicals—molecular fragments such as cyanogen (CN) and the carbon forms C_2 and C_3, which are chemically unstable in the laboratory because they are very reactive in molecular collisions. Spectroscopy also enabled investigators to detect the existence of a plasma component in the cometary tail by the presence of molecular ions, as, for example, those of carbon monoxide (CO^+), nitrogen (N_2^+), and carbon dioxide (CO_2^+). The radicals and ions are built up by the three light elements carbon (C), nitrogen (N), and oxygen (O). Hydrogen (H) was added when the radical CH was discovered belatedly on spectrograms of Comet Halley taken in 1910. The identification of CH was proposed by the American astronomer Nicholas Bobrovnikoff in 1931 and confirmed in 1938 by Marcel Nicolet of Belgium. In 1941 another Belgian astronomer, Pol Swings, and his coworkers identified three new ions: CH^+, OH^+, and CO_2^+. The emissions of the light elements hydrogen, carbon, oxygen, and sulfur and of carbon monoxide were finally detected when the far ultraviolet spectrum (which is absorbed by the Earth's atmosphere) was explored during the 1970s with the help of rockets and satellites. This included the very large halo (10^7 kilometres) of atomic hydrogen (the Lyman-alpha emission line) first observed in Comets Tago-Sato-Kosaka 1969 IX and Bennett 1970 II.

Spectroscopic discoveries

Although the sandbank model was still seriously considered until the 1960s and '70s by a small minority (most notably the British astronomer Raymond A. Lyttleton), the presence of large amounts of gaseous fragments of volatile molecules in the coma suggested to Bobrovnikoff the release by the nucleus of a bulk of unobserved "parent" molecules such as H_2O, CO_2, and NH_3 (ammonia). In 1948, Swings proposed that these molecules should be present in the nucleus in the solid state as ices.

In a fundamental paper, the American astronomer Fred L. Whipple set forth in 1950 the so-called dirty snowball model, according to which the nucleus is a lumpy piece of icy conglomerate wherein dust is cemented by a large amount of ices—not only water ice but also ices of more volatile molecules. This amount must be substantial enough to sustain the vaporizations for a large number of revolutions. Whipple noted that the nuclei of some comets at least are solid enough to graze the Sun without experiencing total destruction, since they apparently survive unharmed. (Some but not all Sun-grazing nuclei split under solar tidal forces.) Finally, argued Whipple, the asymmetric vaporization of the nuclear ices sunward produces a jet action opposite to the Sun on the solid cometary nucleus. When the nucleus is rotating, the jet action is not exactly radial. This explained the theretofore mysterious nongravitational force identified as acting on cometary orbits. In particular, the orbital period of P/Encke mysteriously decreased by one to three hours per revolution (of 3.3 years), whereas that of P/Halley increased by some three days per revolution (of 76 years). For Whipple, a prograde rotation of the nucleus of P/Encke and a retrograde rotation of that of P/Halley could explain these observations. In each case, a similar amount of some 0.5 to 0.25 percent of the ices had to be lost per revolution to explain the amount of the nongravitational force. Thus, all comets decay in a matter of a few hundred revolutions. This duration is only at most a few centuries for Encke and a few millennia for Halley. At any rate, it is millions of times shorter than the age of the solar system.

Dirty snowball model

The observed comets, however, have obviously survived until now. If they have existed for billions of years, they must have been stored in an extremely cold place far away from the Sun before recently coming into the inner solar system where they could be seen from the Earth. A reply to such a suggestion had already been anticipated in 1932 by the Estonian-born astronomer Ernest J. Öpik, who proposed the possible existence of a large cloud of unobservable comets surrounding the solar system. Nearly 20 years later, the Dutch astronomer Jan Hendrick Oort established the existence of such a cloud of comets by indirect reasoning based on observations. Since the appearance of his theory in 1950, this enormous cloud of comets has come to be called the Oort cloud.

The Oort cloud

Oort showed by statistical arguments that a steady flux of a few "new" comets are observed per year (those that had never been through the solar system before). This flux comes from the fringe of the Oort cloud. He identified it by looking at the distribution of the original values of the total energies of cometary orbits (see discussion of total energy below in *Motion and discovery of comets: Types of orbits*). These energies are in proportion to a^{-1}, with a being the semimajor axis of the cometary orbit. The original value of a refers to the orbit when the comet was still outside of the solar system, as opposed to the osculating orbit, which refers to the arc observed from the Earth after it has been modified by the perturbations of the giant planets. Passages through the solar system produce a rather wide diffusion in orbital energies (in a^{-1}). In 1950 Oort accounted for only 19 accurate original orbits of long-period comets. The fact that 10 of the 19 orbits were concentrated in a very narrow range of a^{-1} established that most of them had never been through this diffusion process due to the planets. The mean value of a for these new comets suggested the distance they were coming from—about 10^5 AU. This distance is also the place where perturbations resulting from the passage of nearby stars begin to be felt. The distance coincidence suggested to Oort that stellar perturbations were the mechanism by which comets were sent into the planetary system.

Subsequent work by the American astronomer Brian G. Marsden and his coworkers confirmed the existence of the Oort cloud. Their list of approximately 90 original orbits crammed within an extremely narrow range of a^{-1} corroborated Oort's initial effort. The mean aphelion distance of this list of new comets implies, however, that the Oort cloud margin is only at some 40,000 to 50,000 AU, which makes the standard mechanism of stellar perturbations much less effective than Oort had believed. Comets must therefore come down from the Oort cloud in several steps, penetrating first into the outer solar system where the perturbations of Uranus and Neptune are weak enough not to remove them from the action of passing stars except after several revolutions.

During the late 1980s astronomers explored new ideas with which to determine how the outer perturbations on the Oort cloud could increase. Dark molecular clouds, for example, may be substituted for stars as major perturbing agents. The hypothesis that there exists some extra undetected matter (like black dwarfs) in the disk of the Milky Way Galaxy also has been used. Then, the total mass distribution in the galactic disk may be large enough to induce tidal forces in the Oort cloud that would change cometary orbits.

MOTION AND DISCOVERY OF COMETS

Types of orbits. In the absence of planetary perturbations and nongravitational forces, a comet will orbit the Sun on a trajectory that is a conic section with the Sun at one focus. The total energy E of the comet, which is a constant of motion, will determine whether the orbit is an ellipse, a parabola, or a hyperbola. The total energy E is the sum of the kinetic energy of the comet and of its gravitational potential energy in the gravitational field of the Sun. Per unit mass, it is given by $E = \frac{1}{2}v^2 - GMr^{-1}$, where v is the comet's velocity and r its distance to the Sun, with M denoting the mass of the Sun and G the gravitational constant. If E is negative, the comet is bound to the Sun and moves in an ellipse. If E is positive, the comet is unbound and moves in a hyperbola. If $E = 0$, the comet is unbound and moves in a parabola.

Total energy of a comet

In polar coordinates written in the plane of the orbit, the general equation for a conic section is

$$r = q(1 + e)(1 + e \cos \theta)^{-1},$$

where r is the distance from the comet to the Sun, q the perihelion distance, e the eccentricity of the orbit, and θ an angle measured from perihelion. When $0 \leq e < 1$, $E < 0$ and the orbit is an ellipse (the case $e = 0$ is a circle, which constitutes a particular ellipse); when $e = 1$, $E = 0$ and the orbit is a parabola; and when $e > 1$, $E > 0$ and the orbit is a hyperbola.

Orbital elements

In space a comet's orbit is completely specified by six quantities called its orbital elements. Among these are three angles that define the spatial orientation of the orbit: i, the inclination of the orbital plane to the plane of the ecliptic; Ω, the longitude of the ascending node measured eastward from the vernal equinox; and ω, the angular distance of perihelion from the ascending node (also called the argument of perihelion). The three most frequently used orbital elements within the plane of the orbit are q, the perihelion distance in astronomical units; e, the eccentricity; and T, the epoch of perihelion passage.

Identifying comets and determining their orbits. Up to the beginning of the 19th century, comets were discovered exclusively by visual means. Many discoveries are still made visually with moderate-size telescopes by amateur astronomers. Although comets can be present in any region of the sky, they are often discovered near the western horizon after sunset or near the eastern horizon before sunrise, since they are brightest when closest to the Sun. Because of the Earth's rotation and direction of motion in its orbit, discoveries before sunrise are more likely, as confirmed by discovery statistics. At discovery a comet may still be faint enough not to have developed a tail; therefore, it may look like any nebulous object—*e.g.*, an emission nebula, a globular star cluster, or a galaxy. The famous 18th-century French comet hunter Charles Messier (nicknamed "the ferret of comets" by Louis XV for his discovery of 21 comets) compiled his well-known catalog of "nebulous objects" so that such objects would not be mistaken for comets. The final criterion remains the apparent displacement of the comet after a few hours or a few days with respect to the distant stars; by contrast, the nebulous objects of Messier's catalog do not move. After such a displacement has been undisputably observed, any amateur wishing to have the comet named for himself must report his claim to the nearest observatory as soon as possible.

Photographic discovery of comets

Most comets are and remain extremely faint. Today, a larger and larger proportion of comet discoveries are thus made fortuitously from high-resolution photographs, as, for instance, those taken during sky surveys by professional astronomers engaged in other projects.

The faintest recorded comets are approaching the limit of detection of large telescopes (those that are two metres or more in diameter). That is to say, they are of the 22nd–23rd magnitude, or 10^6 to 10^7 times fainter than the limit of the naked eye. Several successive photographic observations of these faint moving objects are necessary to ensure identification and simultaneous calculation of a preliminary orbit. In order to determine a preliminary orbit as quickly as possible, the eccentricity $e = 1$ is assumed since some 90 percent of the observed eccentricities are close to one, and a parabolic motion is computed. This is generally sufficient to ensure against "losing" the comet in the sky.

The best conic section representing the path of the comet at a given instant is known as the osculating orbit. It is tangent to the true path of the chosen instant, and the velocity at that point is the same as the true instantaneous velocity of the comet. Nowadays, high-speed computers make it possible to produce a final ephemeris (table of positions) that is not only based on the definitive orbit but also includes the gravitational forces of the Sun and of all significant planets that constantly change the osculating orbit. In spite of this fact, the deviation between the observed and the predicted positions usually grows (imperceptibly) with the square of time. This is the signature of a "neglected" acceleration, which comes from a nongravitational force (see above). Formulas representing the smooth variation of the nongravitational force with heliocentric distance are now included for many orbits. The most successful formula assumes that water ice prevails and controls the vaporization of the nucleus.

COMETARY STATISTICS

The *Catalog of Cometary Orbits,* compiled by Marsden, remains the standard reference for orbital statistics. Its 1989 edition lists 1,292 computed orbits from 239 BC to AD 1989; only 91 of them were computed using the rare accurate historical data from before the 17th century. More than 1,200 are therefore derived from cometary passages during the last three centuries. The 1,292 cometary apparitions of Marsden's catalog involve only 810 individual comets; the remainder represents the repeated returns of periodic comets.

Periodic comets. The periodic comets are usually divided into short-period comets (those with periods of less than 200 years) and long-period comets (those with periods of more than 200 years). Of the 155 short-period comets, 93 have been observed at two or more perihelion passages. In 1989, four of these comets had been definitely lost, and three more were probably lost, presumably because of their decay in the solar heat. Some authors have found it advantageous to change the definition of short-period comets by diminishing their longest-period cutoff to 20 years. This leaves 135 short-period comets (new style) in the *Catalog;* the 20 others having periods between 20 and 200 years are called intermediate-period comets. These two new classes are separated by a small period gap. The average short-period comet has a seven-year period, a perihelion distance of 1.5 AU, and a small inclination (13°) on the ecliptic. All short-period comets (new style) revolve in the direct (prograde) sense around the Sun, just as the planets do. The intermediate-period comets have on average a larger inclination of the ecliptic, and five of them turn around the Sun in a retrograde direction. The most famous of the latter is P/Halley (30 appearances); the others are P/Tempel-Tuttle (4 appearances), P/Pons-Gambart, P/Hartley-IRAS, and P/Swift-Tuttle (the last three with only 1 appearance each). Eleven of the 20 intermediate-period comets have been observed during a single appearance.

Short- and intermediate-period comets

Long-period comets

The comets with long-period orbits are distributed at random in all directions of the sky, and roughly half of them turn in the retrograde direction. Of the 655 comets of long period contained in the *Catalog,* 192 have osculating elliptic orbits, and 122 have osculating orbits that are very slightly hyperbolic. Finally, 341 are listed as having parabolic orbits, but this is rather fallacious because either it has not been possible to detect unequivocal deviations from a parabola on the (sometimes very short) arc along which the comets have been observed or, more simply, the final calculations have never been made. The parabola is always assumed first in the preliminary computation as it is easier to deal with. If the osculating orbit is computed backward to when the comet was still far beyond the orbit of Neptune and if the orbit is then referred to the centre of mass of the solar system, the original orbits almost always prove to be elliptic. (The centre of mass of the solar system is different from the centre of the Sun primarily because of the position of massive Jupiter.) Twenty-two original orbits remain (nominally) slightly hyperbolic beyond the orbit of Neptune, but 19 remain not significantly different from a parabola. Even the three that are significantly different near 50 AU are likely to become elliptic when they are 50,000 or 100,000 AU from the Sun. The reason is that, though the mass of the Oort cloud remains uncertain, it should be added to the mass of the inner solar system to compute the orbits. The smallest possible mass of the Oort cloud is likely to transform the orbits into ellipses. It is thus reasonable to believe that all observed comets were initially in elliptic orbits bound to the solar system. Accordingly, all parabolic and nearly parabolic comets are thought to be comets of very long period.

The future orbit of a long-period comet is obtained when the osculating orbit is computed forward to when the comet will be leaving the planetary system (beyond the orbit of Neptune) and is referred to the centre of mass of

the solar system. Because of the planetary perturbations, slightly more than half of the future orbits become strongly elliptic, whereas slightly less than half become strongly hyperbolic. Roughly half of the long-period comets are thus "captured" by the solar system on more strongly bound orbits; the other half are permanently ejected out of the system.

"New" comets

Among the very-long-period comets, there is a particular class that Oort showed as having never passed through the planetary system before (see above), notwithstanding the fact that their original orbits were elliptic, which implies repeated passages. This paradox vanishes when it is understood that their perihelia were outside of the planetary system before their first appearance but that their orbits have been perturbed near aphelia (either by stellar or dark interstellar-cloud passages or by galactic tides) in such a way that their perihelia were lowered into the planetary system. The first passage of a "new" comet is usually brighter than an average passage (a large fraction of the famous bright historical comets were such new comets). This is possibly explained by the presence of more volatile gases and of a larger component of very fine dust. The most volatile gases may have disappeared during subsequent passages, and the finest dust may have agglomerated into larger dust grains that reflect less light for the same production rate. About 90 comets have been identified as new in long-period orbits. If the same proportion exists in the poorly computed parabolic orbits, the total must be close to 170 new comets in Marsden's catalog, but 80 of them have not been identified.

Groups of comets and other unusual cometary objects. Some comets travel in strikingly similar orbits, only the time of perihelion passages being appreciably different. Members of such a group of comets are thought to be fragments from a larger comet that was tidally disrupted earlier by the Sun or in some cases by the differential jet action of nongravitational forces on a fragile nucleus. Many such breakups have been observed historically. Slight differences in the resultant velocities—though they occur very gently—are sufficient to cause cometary fragments to separate along orbits close to but distinct from each other, particularly as far as their total energy is concerned. A very slight variation in a^{-1} introduces an orbital period that may vary by several years, and when the cometary fragments return they will go through perihelion at widely separated epochs. The best-known example is the famous group of "Sun-grazing" comets (also called the Kreutz group), which has 12 definite members (plus one probable) with perihelion distances between 0.002 and 0.009 AU (less than half a solar radius). Their periods are scattered from 400 to 2,000 years, and their last passages occurred between 1880 and 1970. The most famous fragment of the group is Comet Ikeya-Seki 1965 VIII.

Comet P/Schwassmann-Wachmann 1, which has a period of 15 years, is in a quasi-circular and somewhat unstable orbit between Jupiter and Saturn, with a perihelion q that equals 5.45 AU and an aphelion of 6.73 AU. It can be observed every year for several months when opposite to the Sun in the sky. Without any visible tail, it has irregular outbursts that make its coma grow in size for a few weeks and become up to 1,000 times as bright as normal.

Unusual comets

Another unusual object is the so-called asteroid 2060 Chiron, which has a similar orbit between Saturn and Uranus. Though first classified as an asteroid, its icy nucleus of some 300 kilometres suggests that it is a giant comet provisionally parked on a quasi-circular but unstable orbit. Indeed, Chiron develops weak, sporadic outbursts, and in 1989 a transient nebulosity surrounding it (a "coma") was reported for the first time. Within a few thousand years, Chiron might be perturbed enough by Saturn to come closer to the Sun and become a spectacular comet.

For faraway objects that contain volatile ices, the distinction between asteroids and comets becomes a matter of semantics because many orbits are unstable; an asteroid that comes closer to the Sun than usual may become a comet by producing a transient atmosphere that gives it a fuzzy appearance and that may develop into a tail. Some objects have been reclassified as a result of such occurrences. For example, asteroid 1990 UL3, which crosses the orbit of Jupiter, was reclassified as Comet P/Shoemaker-Levy 2 late in 1990. Conversely, it is suspected that some of the Earth-approaching asteroids (Amors, Apollos, and Atens) could be the extinct nuclei of comets that have now lost most of their volatile ices (see above *Orbits of asteroids; Near-Earth asteroids*).

Two bright comets, Morehouse 1908 III and Humason 1962 VIII, exhibited a peculiar tail spectrum in which the ion CO^+ prevailed in a spectacular way, possibly because of an anomalous abundance of a parent molecule (carbon monoxide, carbon dioxide, or possibly formaldehyde [CH_2O]) vaporizing from the nucleus. Finally, Comet Halley is the brightest and therefore the most famous of all short- and intermediate-period comets as the only one that returns in a single lifetime and can be seen with the naked eye.

THE NATURE OF COMETS

The nucleus. As previously noted, the traditional picture of a comet with a hazy head and a spectacular tail applies only to a transient phenomenon produced by the decay in the solar heat of a tiny object known as the cometary nucleus. In the largest telescopes, the nucleus is never more than a bright point of light at the centre of the cometary head. At substantial distances from the Sun, the comet seems to be reduced to its starlike nucleus. The nucleus is the essential part of a comet because it is the only permanent feature that survives during the entire lifetime of the comet. In particular, it is the source of the gases and dust that are released to build up the coma and tail when a comet approaches the Sun. The coma and tail are enormous: typically the coma measures 100,000 kilometres or more in diameter, and the tail may extend about 100,000,000 kilometres in length. They scatter and continuously dissipate into space but are steadily rebuilt by the decay of the nucleus, whose size is usually in the range of 10 kilometres.

The evidence on the nature of the cometary nucleus remained completely circumstantial until March 1986, when the first close-up photographs of the nucleus of Comet Halley were taken during a flyby by the *Giotto* spacecraft of the European Space Agency (Figure 64). Whipple's basic idea that the cometary nucleus was a monolithic piece of icy conglomerate (see above) had been already

Figure 64: Composite image of the nucleus of Comet Halley produced from 68 original photographs taken by the Halley Multicolour Camera on board the *Giotto* spacecraft on March 13 and 14, 1986.

well supported by indirect deductions in the 1960s and '70s and had become the dominant though not universal view. The final proof of the existence of such a "dirty snowball," however, was provided by the photographs of Comet Halley's nucleus.

If there was any surprise, it was not over its irregular shape (variously described as a potato or a peanut), which had been expected for a body with such small gravity (10^{-4} *g*, where *g* is the gravity of the Earth). Rather, it was over the very black colour of the nucleus, which suggests that the snows or ices are indeed mixed together with a large amount of sootlike materials (*i.e.,* carbon and tar in fine dust form). The very low geometric albedo (2 to 4 percent) of the cometary nucleus puts it among the darkest objects of the solar system. Its size is thus somewhat larger than anticipated: the roughly elongated body measures 15 by 8 kilometres and has a total volume of some 500 cubic kilometres. Its mass is rather uncertain, estimated in the vicinity of 10^{17} grams, and its bulk density is very small, ranging anywhere from 0.1 to 0.8 gram per cubic centimetre. The infrared spectrometer on board the Soviet Vega 2 spacecraft estimated a surface temperature of 300 to 400 K for the inactive "crust" that seems to cover 90 percent of the nucleus. Whether this crust is only a warmer layer of outgassed dust or whether the dust particles are really fused together by vacuum welding under contact is still open to speculation.

The 10 percent of the surface of Halley's nucleus that shows signs of activity seems to correspond to two large and a few smaller circular features resembling volcanic vents. Large sunward jets of dust originate from the vents; they are clearly dragged away by the gases vaporizing from the nucleus. This vaporization has to be a sublimation of the ices that cools them down to no more than 200 K in the open vents. The chemical composition of the vaporizing gases, as expected, is dominated by water vapour (about 80 percent of the total production rate). The next most abundant volatile (close to 10 percent) appears to be carbon monoxide (CO), though it could come from the dissociation of another parent molecule (*e.g.,* carbon dioxide [CO_2] or formaldehyde [CH_2O]). Following CO in abundance is CO_2 (close to 4 percent). Methane (CH_4) and ammonia (NH_3), on the other hand, seem to be close to the 0.5 to 1 percent level, and the percentage of carbon disulfide (CS_2) is even lower; at that level, there also must be unsaturated hydrocarbons and amino compounds responsible for the molecular fragments observed in the coma. This is not identical to—though definitely reminiscent of—the composition of the volcanic gases on the Earth, which also are dominated by water vapour, but their CO_2:CO, CO_2:CH_4, and SO_2:S_2 ratios are all larger than in Comet Halley, meaning that the volcanic gases are more oxidized. The major difference may stem from the different temperature involved—often near 1,300 K in terrestrial volcanoes, as opposed to 200 K for cometary vaporizations. This may make the terrestrial gases closer to thermodynamic equilibrium. The dust-to-gas mass ratio is uncertain but is possibly in the vicinity of 0.4 to 1.1.

Chemical composition of Comet Halley's nucleus

The dust grains are predominantly silicates. Mass spectrometric analysis by the *Giotto* spacecraft revealed that they contain as much as 20–30 percent carbon, which explains why they are so black. There also are grains composed almost entirely of organic material (molecules made of atoms of hydrogen, carbon, nitrogen, and oxygen).

There is some uncertainty concerning the rotation of Halley's nucleus. Two different rotation rates of 2.2 days and 7.3 days have been deduced by different methods. Both may exist, one of them involving a tumbling motion, or nutation, that results from the irregular shape of the nucleus, which has two quite different moments of inertia along perpendicular axes.

Scientific knowledge of the internal structure of the cometary nucleus was not enhanced by the flyby of Comet Halley, and so it rests on weak circumstantial evidence from the study of other comets. Earlier investigations had established that the outer layers of old comets were processed by solar heat. These layers must have lost most of their volatiles and developed a kind of outgassed crust, which probably measures a few metres in thickness. Inside the crust there is thought to exist an internal structure that is radially the same at any depth. Arguments supporting this view are based on the fact that cometary comas and tails do not become essentially different when comets decay. Since they lose more and more of their outer layers, however, the observed phenomena come from material from increasingly greater depths. These arguments are specifically concerned with the dust-to-gas mass ratio, the atomic and molecular spectra, the splitting rate, and the vaporization pattern during fragmentation.

Before the *Giotto* flyby of Comet Halley, other cometary nuclei had never been resolved optically. For this reason, their albedos had to be assumed first in order to compute their sizes. Techniques proposed to deduce the albedo yielded only that of the dusty nuclear region made artificially brighter by light scattering in the dust. In 1986 the albedo of Comet Halley's nucleus was found to be very low (A = 2 to 4 percent). If this value is typical for other comets, then 11 of 18 short-period comets studied would be between 6 and 10 kilometres in diameter; only 7 of them would be somewhat outside these limits. Comet Schwassmann-Wachmann 1 (see above) would be a giant with a diameter of 96 kilometres; 10 long-period comets would all have diameters close to 16 kilometres (within 10 percent). Since short-period comets have remained much longer in the solar system than comets having very long periods, the smaller size of the short-period comets might result from the steady fragmentation of the nucleus by splitting. Yet, the albedo may also diminish with aging. At the beginning, if the albedo were close to that of slightly less dirty snow (A = 10 percent), the nuclear diameter of long-period comets would come very close to that of the largest of the short-period comets. The diameters of new comets also have been shown to be rather constant and most likely measure close to 10 kilometres. Of course, these are mean "effective" diameters of unseen bodies that are all likely to be very irregular.

Variation in size of nuclei

The region around the nucleus, up to 10 or 20 times its diameter, contains an amount of dust large enough to be partially and irregularly opaque or at least optically thick. It scatters substantially more solar light than is reflected by the black nucleus. Dust jets develop mainly sunward, activated by the solar heat on the sunlit side of the nucleus. They act as a fountain that displaces somewhat the centre of light from the centre of mass of the nucleus. This region also is likely to contain large clusters of grains that have not yet completely decayed into finer dust; the grains are cemented together by ice.

The gaseous coma. The coma, which produces the nebulous appearance of the cometary head, is a short-lived, rarefied, and dusty atmosphere escaping from the nucleus. It is seen as a spherical volume having a diameter of 10^5 to 10^6 kilometres, centred on the nucleus. The coma gases expand at a velocity of about 0.6 kilometre per second. This velocity can be measured from the motion of expanding "halos" triggered by outbursts in the nucleus, from the speed required to produce the Greenstein effect (see below), and from the fluid dynamics required to drag dust particles away at those places where they are observed in the dust tails. This expansion velocity, *v*, varies somewhat with heliocentric distance *r*: $v = 0.58r^{-0.5}$ (in kilometres per second, when *r* is in astronomical units). The light of the spherical coma comes mainly from molecular fragments that have been produced by the dissociation of unobserved "parent molecules" in a zone on the order of 10^4 kilometres around the nucleus. This also is the approximate size of the zone where molecular collisions continue to occur; beyond that zone, the gas becomes too rarefied for such interaction to occur. The zone simply expands radially without molecular collisions into the vacuum of space. The parent molecules (*e.g.,* those of water vapour, carbon dioxide, and hydrogen cyanide [HCN]) are generally not observed because they do not fluoresce in visible light. So far, only a few have been observed at millimetre or centimetre wavelengths by radio telescopes; many more are needed if they are to be regarded as the source of the various radicals and ions that have been detected (Table 25).

Molecular collision zone

If the mixture of original parent molecules has been frozen out of thermodynamic equilibrium in the nuclear

ices, many chemical reactions can still take place in the molecular collision zone. At the usually cold temperature of vaporization, the kinetics of fast ion-molecular reactions would prevail. The reactions might reshuffle the original molecules present in the nucleus into new parent species, which would be the ones subsequently photodissociated into observed fragments by solar light. (This complex situation is still far from being completely understood.) In turn, the observed fragments, after having absorbed and reemitted photons from the solar light several times, would photodissociate or photoionize, which make them disappear from sight at the fuzzy limit of the light-emitting coma (typically $2–5 \times 10^5$ kilometres). A composite list of all observed species in cometary comas and tails is given in Table 25. It is based mainly on observations of the bright comets of the 1960s, '70s, and '80s, including spacecraft results from Comet Halley.

The organic radicals given in Table 25 were seen in cometary heads as visual or ultraviolet emission lines or bands. The exceptions were water vapour, along with hydrogen cyanide and methyl cyanide (CH_3CN); these species, which could be called parent molecules, were observed as pure rotation lines at radio frequencies. The metals—except for sodium (Na), which is observed in many comets—were seen as visual lines in Sun-grazing comets alone. They are assumed to result from the vaporization of dust grains by solar heat. Sodium is a volatile metal that is not unlikely to vaporize easily from dust grains at large distances from the Sun (more than 1 AU). The ions were seen in the visual or ultraviolet emission lines or bands at the onset of the plasma tail or detected by spacecraft. The silicate signature was found in infrared emission bands at the onset of dust tails. The occurrence of the silicate elements, as well as the presence of a rather large amount of organic compounds, was confirmed by the mass spectrometric analysis of dust grains during the *Giotto* flyby of Comet Halley.

An extremely weak coma appeared in 1984 when Comet Halley still was 6 AU from the Sun. In February 1991, the Belgian astronomers Olivier Hainaut and Alain Smette detected a giant outburst from Comet Halley, which was already at a distance of 14.5 AU from the Sun and had the form of a fanlike structure in the direction of the Sun; this is the best case study to date. Rarely have comas been detected beyond 3 or 4 AU, where they are still quite small; they grow to a maximum near 1.5 AU and seem to contract as they approach closer to the Sun. This effect comes from the more rapid decay in solar light (by photoionization or photodissociation) of the visible radicals that emit the coma light. The discrete emission of light by cometary atoms, radicals, or ions is due to the selective absorption of sunlight followed by its reemission either at the same wavelength (resonance) or at a different wavelength (fluorescence). In 1941, Pol Swings explained the peculiar appearance of some of the molecular bands in comets by the irregular spectral distribution of the exciting solar radiation owing to the presence of Fraunhofer lines (dark, or absorption, lines) in this radiation. The temporal variations that occur in the molecular bands as a comet approaches the Sun were explained quantitatively by the variable shift in the apparent wavelengths of the solar Fraunhofer lines due to the variable radial velocity of the comet. This is the so-called Swings effect. Later, the American astronomer Jesse Greenstein explained, by a differential Swings effect, the observed differences in the molecular bands in front of and behind the nucleus: the radial expansion velocity of the coma introduces a different shift forward and backward. This differential Swings effect is often referred to as the Greenstein effect (Figure 65).

Swings effect

Exceptions to the resonance-fluorescence mechanism are known and are exemplified by the case of the emission

Table 25: Observed Chemical Species in Comets

Organic	C, C_2, C_3, CH, CN, CO, CO_2, CS, HCN, CH_3CN, HCO, H_2CO
Inorganic	H, NH, NH_2, O, OH, H_2O, S, S_2, NH_3, NH_4
Metals	Na, K, Ca, V, Mn, Fe, Co, Ni, Cu
Ions	C^+, CH^+, CO^+, CO_2^+, N_2^+, O^+, OH^+, H_2O^+, H_3O^+, S^+, S_2^+, H_2S^+, CS_2^+
Dust	silicates, organic compounds

of the "forbidden" red doublet of atomic oxygen at wavelengths of 6300 and 6364 angstroms. Such an emission cannot be excited by direct absorption of sunlight but is produced directly by the photodissociation of H_2O into $H_2 + O$ (in the ^1D state) and, in an accessorial manner, of CO_2 into $CO + O$ (in the ^1D state). The ^1D state is an excited state of the oxygen atom that decays spontaneously into the ground (lowest energy) state by emitting the forbidden red doublet, provided that it had not been quenched earlier by molecular collisions.

The large atomic hydrogen halo detected up to 10^7 kilometres from the nucleus is simply a large coma visible in ultraviolet (Lyman-alpha line). It is two orders of magnitude larger than the comas that can be seen in visible light only because the hydrogen atoms, being lighter, move radially away 10 times faster and are ionized 10 times more slowly than the other radicals.

Halo of atomic hydrogen

Cometary tails. The tails of comets are generally directed away from the Sun. They rarely appear beyond 1.5 or 2 AU but develop rapidly with shorter heliocentric distance. The onset of the tail near the nucleus is first directed toward the Sun and shows jets curving backward like a fountain, as if they were pushed by a force emanating from the Sun. The German astronomer Friedrich Wilhelm Bessel began to study this phenomenon in 1836, and Fyodor A. Bredikhin of Russia developed, in 1903, tail kinematics based on precisely such a repulsive force that varies as the inverse square of the distance to the Sun. Bredikhin introduced a scheme for classifying cometary tails into three types, depending on whether the repulsive force was more than 100 times the gravity of the Sun (Type I) or less than one solar gravity (Types II and III). Subsequent research showed that Type-I tails are plasma tails (containing observed molecular ions as well as electrons not visible from ground-based observatories), and Types II and III are dust tails, the differences between them being attributable to a minor difference in the size distribution of the dust grains. As a result of these findings, the traditional classification formulated by Bredikhin is no longer considered viable and is seldom used. Most comets (but not all) simultaneously show both types of tail: a bluish plasma tail, straight and narrow with twists and nods, and a yellowish dust tail, wide and curved, which is often featureless (see Figure 66).

The plasma tail has its onset in a region extremely close

Plasma tail

to the nucleus. The ion source lies deep in the collision zone (typically 1,000 kilometres). It is likely that charge-exchange reactions compete with the photoionization of parent molecules, but the mechanism that produces ions is not yet quantitatively understood. In 1951 the German astronomer Ludwig Biermann predicted the existence of the solar wind (see above) in order to account for the rapid accelerations observed in plasma tails as well as their aberration (*i.e.,* deviation from the direction directly opposite the Sun). The cometary plasma is blown away by the magnetic field of the solar wind until it reaches its own velocity—nearly 400 kilometres per second. This action explains the origin of the large forces postulated by the Bessel-Bredikhin theory. Spectacular changes observed in the plasma tail, such as its sudden total disconnection, have been explained by discontinuous changes in the solar wind flow (*e.g.,* the passage of magnetic sector boundaries).

In 1957 the Swedish physicist Hannes Alfven predicted the draping of the magnetic lines of the solar wind around the cometary ionosphere. This phenomenon was detected by the International Cometary Explorer spacecraft, launched by the U.S. National Aeronautics and Space Administration (NASA), when it passed through the onset of the plasma tail of Comet P/Giacobini-Zinner on Sept. 11, 1985. Two magnetic lobes separated by a current-carrying neutral sheet were observed as expected. A related feature known as the ionopause was detected by the *Giotto* space probe during its flyby of Comet Halley in 1986. The ionopause is a cavity without a magnetic field that contains only cometary ions and is separated from the solar wind by a sharp discontinuity. Halley's ionopause lies about 4,000 to 5,000 kilometres from the nucleus of the comet. An analysis of all the encounter data indicates that a complete understanding of cometary interaction with the solar wind has not yet been achieved. It is well understood, however, that the neutral coma remains practically spherical. The solar wind is so rarefied that there are no direct collisions of its particles with the neutral particles of the coma, and, as these particles are electrically neutral, they do not "feel" the magnetic field.

Dust tail

The source of the dust tail is the dust dragged away by the vaporizing gases that emanate from the active zones of the nucleus, presumably from vents like those observed on Comet Halley's nucleus (Figure 64). The dust jets are first directed sunward but are progressively pushed back by the radiation pressure of sunlight. The repulsive acceleration of a particle varies as $(sd)^{-1}$ (with linear size s and density d). For a given density, it thus varies as s^{-1}, separating widely the particles of different sizes in different parts of the tail. Studying the dust tail isophotes of varying brightnesses therefore yields the dust grain distribution. This distribution may peak for very fine particles near 0.5 micrometre (μm), assuming a density of two, as in the case of Comet Bennett; however, it falls off with s^{-n} (with n ranging from three to five) for larger particles. This mechanism neglects particles much smaller than the mean wavelength of sunlight. Because such particles do not reflect light, they do not feel its radiation pressure. (They are not detected from ground-based observations anyway.)

One of the major results of the *Giotto* flyby of Halley's nucleus was the detection of abundant particles much smaller than the wavelength of light, indicating that the size distribution does not peak near 0.5 μm but seems rather to grow indefinitely with a slope close to a^{-2} for finer and finer particles down to possibly 0.05 μm (10^{-17} gram). The dust composition analyzers on board the *Giotto* and Vega spacecraft revealed the presence of at least three broad classes of grains. Class 1 contains the light elements hydrogen, carbon, nitrogen, and oxygen only (in the form of either ices or polymers of organic compounds). The particles of class 2 are analogous to the meteorites known as CI carbonaceous chondrites but are possibly slightly enriched in carbon and sulfur. Class 3 particles are even more enriched in carbon, nitrogen, and sulfur; they could be regarded as carbonaceous silicate cores (like those of class 2) covered by a mantle of organic material (similar to that of class 1) that has been radiation-processed. Most of the encounter data were excellent for elemental analyses but poor for determining molecular composition, because most molecules were destroyed by impact at high encounter velocity. Hence, there still remains much ambiguity regarding the chemical nature of the organic fraction present in the grains.

Meteors are extraterrestrial particles of sand-grain or small-pebble size that become luminous upon entering the upper atmosphere at very high speeds. Meteor streams have well-defined orbits in space. More than a dozen of these orbits have practically the same orbital elements as the orbits of the identical number of short-period comets (see below *Orbits of meteoroids and meteor showers*). Fine cometary dust consists primarily of micrometre- or sub-micrometre-size particles that are much too small to become visible meteors (they are more like cigarette smoke than dust). Moreover, they are scattered in the cometary tail at great distance from the comet orbit. The size distribution of cometary dust grains, however, covers many orders of magnitude; a small fraction of them may reach 0.1 millimetre to even a few centimetres. Because of their large size, these dust grains are almost not accelerated by the radiation pressure of sunlight. They remain in the plane of the cometary orbit and in the immediate vicinity of the orbit itself, even though they separate steadily from the nucleus. They sometimes become visible as an anti-tail—*i.e.,* as a bright spike extending from the coma

Anti-tail

sunward in a direction opposite to the tail (Figure 67). This phenomenon occurs as a matter of geometry: it takes place for only a few days when the Earth crosses the plane of the cometary orbit. At such a time, this plane is viewed through the edge, and all large grains are seen accumulated along a line. The same grains scatter farther and farther away from the nucleus until some are along the entire cometary orbit. When the Earth's orbit intersects such an orbit (an event that occurs year after year at the same calendar date), these large grains produce meteor showers.

Extremely fine cometary grains also may penetrate the Earth's atmosphere, but they can be slowed down gently without burning up. Some have been collected by NASA's U-2 aircraft at very high altitudes. Grains of this kind are known as Brownlee particles and are believed to be of cometary origin (Figure 68). Their composition is chondritic, though they show somewhat more carbon and sulfur than the CI carbonaceous chondrites, and their structure is fluffy with many pores. Similar grains were found in space during the space probe exploration of Comet Halley.

COMETARY MODELS

As previously noted, the sandbank model of the cometary nucleus fell into disregard by the late 1950s and early 1960s and was supplanted by the dirty snowball (or icy conglomerate) concept. Much circumstantial evidence supported the latter, but confirmation was lacking until 1986, when the *Giotto* spacecraft returned detailed, close-up photographs of Comet Halley's nucleus. Yet, while these photographs corroborated the general idea of the model, they revealed that "dirty snowball" was in fact a misnomer because snow (even when dirty) is suggestive of something white or at least gray in colour. In actuality, the cometary nucleus proved to be pitch black owing to the large amount of very fine, black sootlike particles intermixed with the volatile ices (see above).

Many variations of the icy conglomerate model have been proposed since the early 1980s, as, for example, the fractal model, rubble-pile model, and icy-glue model. These names, however, suggest only slightly different types of accretion of primordial particles; they all share common features—namely, irregular shape, heterogeneous mixture, and very low density because of cavities and pores. The existence of a crust or dust mantle of a different nature had already been proposed before the 1986 spacecraft encounter with Comet Halley for two reasons. First, cosmic-ray processing of the outer layers had been described by Leonid M. Shul'man of the Soviet Union (1972) and later advocated by Fred Whipple and Bertram Donn of the United States, while the outgassing of the outer layers by solar heat had also been assumed since the proposal of Whipple's model (1950). Second, detailed models of the formation and disruption of such mantles due to solar-radiation processing of the upper layers had been studied by Devamitta Asoka Mendis of the United States (1979) and M. Horanyi of Hungary (1984).

Elemental abundances of the cometary nucleus

An average heuristic model for the elemental abundances of the cometary nucleus was developed by the American astronomer Armand H. Delsemme in 1982. Delsemme computed the H:C:N:O:S ratios from ultraviolet and visual observations of atomic and molecular species in bright comets detected during the 1970s and deduced the abundances of metals from the chondritic composition of cometary dust. In this model, hydrogen was depleted by a factor of 1,000 with respect to solar or cosmic abundances, and carbon was depleted by a factor of 4 in the gaseous fraction. The results of the 1986 study of Comet Halley confirmed the average chemical model and showed that the carbon missing in the gas was actually present in the dust. Except for hydrogen (and presumably helium), it appears that all elements are roughly in cosmic proportions in comets in spite of their extremely low gravity (10^{-4} times that of the Earth). This emphasizes the pristine nature of comets. Unlike most bodies of the solar system, comets obviously have never been severely processed by any heating episode since their formation. If the accretion of comets occurred at very low temperatures, near absolute zero, the water ice in a newly formed comet must be amorphous. Idealized models show that the transition to cubic ice might be the cause of sudden flare-ups between 3 and 6 AU.

ORIGIN AND EVOLUTION OF COMETS

Evolution of orbits

All observed comets make up an essentially transient system that decays and disappears almost completely in less than one million years. Since they all pass through the solar system, planetary perturbations eject a fraction of them into deep space on hyperbolic orbits and capture another fraction on short-period orbits. In turn, those that have been captured decay rapidly in the solar heat. Fortunately, there is a permanent source of new comets that maintains the steady state—namely, the outer margin of the Oort cloud. As explained above, these so-called new comets are those Oort-cloud comets whose perihelia have been brought down into visibility—*i.e.*, into the inner planetary system where they display their spectacular decay through comas and tails. Comets within the bulk of the Oort cloud are unobservable, not only because they do not develop comas and tails but also because they are too far away.

Formation of the Oort cloud. Any modern theory about cometary origins must first explain the origin of the Oort cloud. None of the comets observed today left the Oort cloud more than three or four million years ago. The Oort cloud is, however, gravitationally bound to the solar system, which it follows in its orbit around the Milky Way Galaxy. Therefore, it is likely that the Oort cloud has existed for a long time. The most probable hypothesis is that it was formed at the same time as the giant planets by the very process that accreted them. The Soviet astronomer Viktor S. Safronov developed this accretionary theory of the planetary system mathematically in 1972. According to his model, the planets originated from a disk or a ring of dust around the Sun, and cometary nuclei are noth-

The Oort cloud as a by-product of the accretion of the giant planets

ing more than primordial planetesimals that accreted first and became the building blocks of the planets. From the accreted mass of the giant planets, Safronov predicted the correct order of magnitude of the mass of the Oort cloud, which was built up by those planetesimals that missed colliding with the planetary embryos and were thrust far away by their perturbations. In effect, the Oort cloud in this theory becomes the necessary consequence and the natural by-product of the accretion of the giant planets.

Later in the 1970s the American astronomer A.G.W. Cameron developed a much more massive model of the protostar nebula, in which the comets accreted in a circular ring at some 1,000 AU from the Sun, which is far beyond the present limits of the planetary system. The primeval circular orbits were then transformed into the elongated ellipses present in the Oort cloud by mass loss of the primitive solar nebula. Both the Cameron and Safronov models put the origin of comets together with that of the solar system some 4.6 billion years ago. Plausibility is given to the general idea of accretion from dust disks by the existence of such disks around many young stars—a fact established by infrared observations in the 1980s and confirmed visually in at least one case (β Pictoris). Further support is found in clues derived from meteorites.

Since the early 1980s, new ideas have been explored to determine whether the Oort cloud could be much younger than the solar system or at least periodically replenished. The role of the massive and dense molecular clouds that exist in interstellar space has been reexamined in different ways. Could comets have accreted in these clouds directly from interstellar grains? Mechanisms for later capturing them into the Oort cloud cannot be very effective, but the efficiency is not capital, and some possibilities have been proposed. Since the solar system itself was probably formed from the gravitational collapse of such a molecular cloud, it seems more likely that either comets or the interstellar grains that were going to accrete into comets followed suit during gaseous collapse and were put into the Oort cloud at the same time that the planets were being formed. Elemental isotopic ratios deduced from the Comet Halley flyby have not brought about any conspicuous anomalies that could be attributed to matter coming from outside the solar system. So far, observational clues all favour the idea of cometary matter deriving from the same primeval reservoir as the stuff of the solar system, but it must be recognized that the evidence remains weak.

Possible pre-solar-system origin of comets. Telltales based on the chemical constitution of cometary nuclei as well as on the evolution of their orbits suggest that the origin of comets goes back beyond that of the planets and their satellites. Two scenarios are among the likeliest possibilities. In the first, comets had already accreted in all dense molecular clouds of the Milky Way Galaxy by the agglomeration of interstellar grains covered by a frost of organic molecules that cemented them together. Later, such a cloud collapsed to form the solar system. In the second scenario, dense molecular clouds were not able to accrete their frosty interstellar grains into larger bodies. When one of these molecular clouds collapsed to form the future solar system, however, the interstellar grains did likewise and eventually formed a dusty disk around the central star—the proto-Sun. Accretion into objects of 10-kilometre diameter is more likely in dusty disks of this type. The outer grains of the disk had not lost their frost, and some of them were ejected into the Oort cloud during the accretion of planetesimals into giant planets after some very moderate processing by heat. It is hoped that one day, space probes will secure data that will make it possible to determine whether frosty interstellar grains have lost their identity or can still be recognized as pristine and unaltered objects in cometary dust.

Comets seem to be the most pristine objects of the solar system, containing intact the material from which it was formed. Included are the hydrogen, carbon, oxygen, nitrogen, and sulfur atoms needed to build the volatile molecules present in the terrestrial biosphere (including the oceans and the atmosphere). Comets also seem to be the link between interstellar molecules and the most primitive meteorites known—the carbonaceous chondrites (see below *Types of meteorites*). The molecules required to initiate prebiotic chemistry (*e.g.*, hydrogen cyanide, methyl cyanide, water, and formaldehyde) are present in interstellar space just as they are in comets; larger prebiotic chemistry molecules (*e.g.*, amino acids, purines, and pyrimidines) occur in some chondrites and possibly in comets. An early cometary bombardment of the Earth, predicted in some accretion models of the solar system, may have brought the oceans and the atmosphere, as well as a veneer of the molecules needed for life to develop on the Earth. Comets could well be the link between interstellar chemistry and life. (A.H.De.)

Meteoroids, meteors, and meteorites

METEOROIDS

General considerations. The solar system contains many small bodies that move in orbits sufficiently eccentric to cross over and intersect the orbit of the Earth. When their orbits do intersect that of the Earth, the probability of the objects colliding with the planet becomes quite high. A body of this kind entering the Earth's atmosphere is called a meteoroid. Such bodies range from small particles less than one micrometre in size (about 10^{-12} gram in mass) up through objects several centimetres or metres in diameter and grade into kilometre-size bodies large enough to be observed as astronomical objects through telescopes. They enter the upper atmosphere with velocities of 11 to 72 kilometres per second. Interaction with the atmosphere heats incoming objects that are larger than about 0.01 centimetre to temperatures high enough to cause them to become incandescent, vaporize, and heat the surrounding air. As a result of this sequence, such objects are observable from the ground as meteors or, in more popular language, "shooting stars" or "falling stars." Strictly speaking, the term meteor refers only to the phenomena associated with the collision of a meteoroid with the Earth's atmosphere. Scientific usage is not all that strict, however, and the body itself is often called a meteor. Unusually luminous meteors are termed fireballs or bolides.

Variations in size

Owing to its fairly low entry velocity, large mass, and physical strength, a meteoroid sometimes survives its passage through the atmosphere, falls to the ground, and may be recovered as a meteorite. Recovered meteorites, ranging in mass from a few grams to several tons, are often exhibited in museums. Most meteorites either consist of rocky—chiefly silicate—material (stony meteorites) or are composed primarily of nickel-iron alloy (iron meteorites; Figures 69 and 70). In stony-iron meteorites, massive nickel-iron alloy is intermixed with silicate material.

In addition to these relatively large meteorites, it is possible to recover much smaller objects about 0.001 centimetre in diameter called micrometeorites on filters attached to aircraft flying in the stratosphere. These micrometeorites (often referred to as interplanetary or cosmic dust) also accumulate on the bottom of the deep ocean. The larger ones can be identified and separated from cores drilled from the muddy deposits on the seafloor.

Micrometeorites

The largest meteoroidal bodies are observable through telescopes as astronomical objects. These include the Apollo objects, bodies of asteroidal appearance with diameters ranging from a few hundred metres to several kilometres that come closer to the Sun than to the Earth's orbit. There are about 700 of these larger than one kilometre in diameter. Because comets can strike the Earth, they, too, can be thought of as large meteoroidal bodies.

When meteoroids are sufficiently large (*i.e.*, 100 metres to several kilometres in diameter), they can pass through the atmosphere without slowing down appreciably. When they strike the Earth's surface at velocities of many kilometres per second, the kinetic energy released is sufficient to produce an impact crater. In many ways such craters resemble those produced by nuclear explosions. They are often called meteorite craters, in spite of the fact that the impacting meteoroids themselves are almost entirely vaporized during the explosion. High-velocity impact by objects of this kind on the Moon, Mercury, and Mars are in large part responsible for the heavily cratered appearance of the surface of these bodies. The cratering record

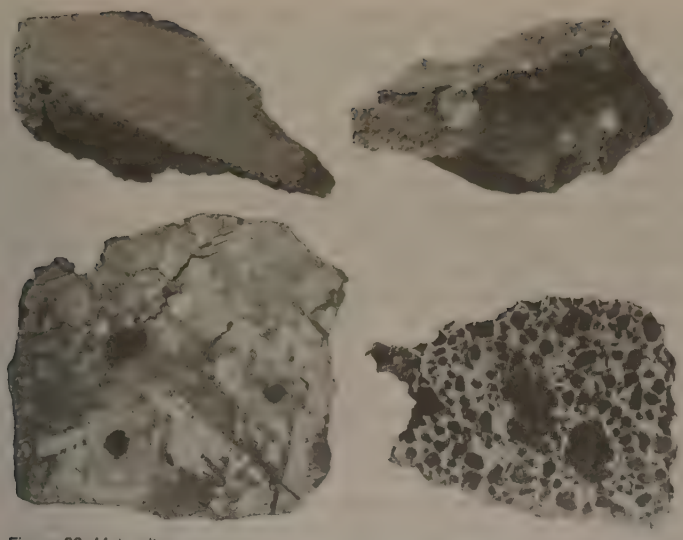

Figure 69: *Meteorites.*
(Top left) Ankober (Ethiopia) ordinary (H4 olivine-bronzite) chondrite (reduced). One surface has been sawed and polished, revealing the internal structure. The white spots are reflections from nickel-iron metal; the surrounding gray material is composed of silicate minerals. (Top right) Allende carbonaceous (CV3) chondrite (reduced 3.8×). The large white inclusions consist primarily of refractory aluminum- and calcium-bearing minerals, which are embedded in a dark gray matrix containing fine-grained minerals formed at much lower temperatures. (Bottom left) Sawed, polished, and acid-etched interior surface of the Osseo (Ontario) iron meteorite (coarsest octahedrite; reduced 4.2×). This treatment reveals the "Widmanstätten pattern" resulting from coarsely crystalline kamacite (α-iron-nickel alloy). (Bottom right) Polished and etched section of the Salta stony-iron (pallasite), composed of roughly equal amounts of olivine (magnesium-iron silicate in the form of dark grains) and nickel-iron alloy (the shiny crystals; reduced 4.1×).

on the Earth and Moon also shows that there are many meteoroids in the intermediate mass range between the larger recovered meteorites (a few metres in diameter) and the Apollo objects.

Relationship of meteoroids to asteroids and comets. Most of the mass of the solar system resides in its larger bodies, the Sun and the planets. The planets move about the Sun in stable and well-separated orbits. It is almost certain that these orbits and thus the positions of the planets have undergone only minor changes since the formation of the solar system some 4.6 billion years ago. In addition, the planets are large enough to retain on their surfaces nearly all the debris produced by impact craters.

On the other hand, a smaller fraction of the mass of the solar system is found in bodies of such small size or in orbits so eccentric that their physical survival or orbital stability has been in jeopardy throughout the history of the solar system. Most of these bodies are found in either of two regions of the solar system: the asteroid belt, between the orbits of Mars and Jupiter (mostly between 2.2 and 3.4 AU), and the cometary, or Oort, cloud extending far beyond the orbits of Neptune and Pluto to distances of more than 10,000 AU.

G. Kurat

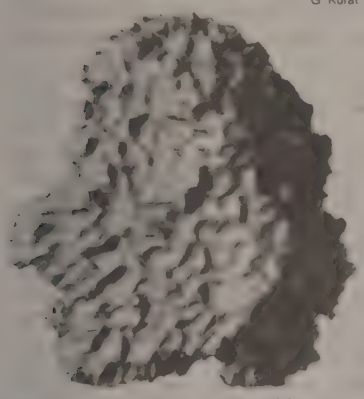

Figure 70: Cabin Creek (Arkansas) iron meteorite (medium octahedrite; reduced 8.1×). The dimpled appearance of the face of the meteorite was caused by melting of its surface upon entering the Earth's atmosphere.

The members of the asteroid belt have high enough eccentricities and inclinations that they collide with one another at velocities averaging about five kilometres per second. Because of this, it is unlikely that most asteroids larger than about 75 kilometres in diameter have survived collisional destruction over the entire 4.6 billion-year history of the solar system. The present-day smaller asteroids are debris formed by fragmentation of larger asteroids caused by this natural grinding process in the asteroid belt. The grinding extends down to bodies the size of meteorites exhibited in museums and even to much smaller particles in the form of fine dust.

Fragmentation of asteroids

Some of this collisional debris is orbitally unstable. The same collisions that produced the fragments propel a portion of them into chaotic orbits controlled by dynamical resonances with the motions of the planets. As a result of collisions and orbital instability, asteroidal material is injected into orbits that cross the Earth's orbit. Some of this matter collides with the atmosphere of the Earth and becomes visible meteors. A small number of the particles survive as meteorites.

The much more distant cometary bodies also are vulnerable to destruction. Their orbits extend to the threshold of interstellar space. Passing stars and interstellar molecular clouds gravitationally perturb some of these bodies into orbits with perihelia within several astronomical units of the Sun. A small fraction of the comets that are perturbed into orbits approaching the Sun experience close approaches to planets, particularly Jupiter, and this leads to further orbital perturbations. In some cases, this causes the orbital eccentricity and orbital period of a comet to be drastically reduced to periods from about three to several hundred years.

Comets are small bodies consisting of a mixture of ice and less volatile material, the latter mostly in the form of dust (see above *The nature of comets*). When a comet is perturbed into an orbit that comes within a few astronomical units of the Sun, the ice begins to evaporate, giving rise to the luminous object commonly thought of as a comet. Dust is swept away from the comet along

with the evaporating ice. Most of the fine dust escapes the Sun's gravitational field and is lost to interstellar space. Some of the dust, however, is in larger particles typically millimetres to centimetres in size. As compared with the finer particles of dust, these larger bodies have a smaller ratio of surface area to mass, and this renders them less susceptible to the solar radiation forces, proportional to the cross-sectional area, that drive the finest dust out of the solar system. Thus, these larger cometary particles can remain in short-period orbits and can intersect the orbit of the Earth. When they collide with the atmosphere, meteoroids of this kind also appear as meteors.

Association of meteor showers with meteoroids of cometary origin

The best evidence for the cometary origin of certain meteoroids is identification of the orbits of meteoroids with those of known periodic comets (see above *Modern cometary research*). It is possible to determine these orbits by photographing the meteors with special cameras as they pass through the Earth's atmosphere. This identification has been made for several of the meteors that produce meteor showers. In this way inferences can be made about the physical properties of particulate cometary material.

The asteroid belt and the outermost part of the solar system should be thought of as long-lived though somewhat leaky reservoirs of meteoroidal bodies. They are long-lived enough to retain a significant quantity of primordial solar system material but leaky enough to permit the escape of the observed quantity of Earth-crossing material. This quantity of Earth-crossing material represents an approximate steady-state balance between the input from the storage regions and the loss by ejection from the solar system, collision with the Earth, the Moon, and other planets, or vaporization by impact.

Evidence for meteoroids of asteroidal origin: radiometric ages of meteorites. The most meaningful way of describing and classifying meteoroids would be in terms of their various sources in the solar system. To do so, it is necessary to find criteria that discriminate among these sources.

Unlike the association of some meteoroids with the actual observed orbits of comets, direct orbital identification is not possible for meteoroids of asteroidal origin. The asteroids in the asteroid belt that are the ultimate parents of these meteoroids are not in Earth-crossing orbits. A meteoroid entering the atmosphere must be in an Earth-crossing orbit. Therefore, the observed meteoroid orbit cannot be the same as that of its source. The evolution of the asteroidal collision debris from the asteroid belt is complex, involving collisional fragmentation and major orbital changes caused by planetary gravitational perturbations. Although this evolution is quantitatively understandable in terms of known physical processes, the complex history destroys the information required to directly link the meteoroid with its source. Unlike cometary meteors, there is, for example, no good evidence that asteroidal meteors occur in streams, nor would such clustering of orbits be expected on theoretical grounds. The link between asteroidal meteoroids and their sources must be established in ways that are less direct.

This link is supplied by laboratory investigations of meteoroids that have survived passage through the atmosphere—namely, meteorites. As a result of these investigations, it is generally believed that nearly all recovered meteorites are fragments of asteroids. A small fraction, about 0.5 percent, may be of lunar or Martian origin. It is possible, but not at all firmly established, that some meteorites may be derived from comets.

The reasoning that leads to identification of most meteorites as asteroidal meteoroids is fairly complex but quite compelling. Perhaps the best starting point would be that based on studies of the daughter isotopes produced by the radioactive decay of radioactive parent isotopes of such elements as uranium, thorium, rubidium, potassium, and samarium. As is commonly done for terrestrial rocks, the ages of meteorites can be determined by isotopic measurements of this kind.

Isotopic measurements

When this is done, all but a very few meteorites show good evidence of having been formed, from the mineralogical point of view, some 4.6 billion years ago. Similar techniques have been used to infer, somewhat less directly, the age of the Earth and the Moon, with the same result. Within an uncertainty of less than about 100 million years, this age represents the time in the past when the Sun, the planets, and their natural satellites, along with the asteroids and comets, formed from interstellar dust and gas. Because of geologic processes that produced younger rocks on the Earth and Moon, their evidence for this primordial age of formation has been obscured but not erased. By contrast, the evidence for the age of the solar system is clearly preserved in meteorites.

Although present-day meteorites are the products of a long series of events that caused physical fragmentation, in most cases the mineral grains of which they are composed have undergone little chemical alteration since the early years of the solar system. As a consequence, the isotopic ratios from which the ages are calculated preserve the evidence for this very ancient time of formation.

If meteorites are asteroidal fragments, this is what would be expected. Theoretical calculations of the thermal evolution of bodies as small as asteroids predict that they would not exhibit the long-continuing history of igneous and metamorphic rock formation characteristic of large bodies such as the Earth and Moon. As in the case of the latter, however, the decay of radioactive isotopes produces heat in the interiors of asteroids. Yet, because of their small size, this heat is readily conducted to the surface and radiated to space. The internal temperature thus would never rise high enough to produce the metamorphism or melting that would chemically alter the ancient mineralogy. In the much larger Earth, on the other hand, the heat is not efficiently transported to the surface by convection until the temperature increases to near its melting point.

By itself, this preservation of ancient mineralogy does not, however, clearly indicate that the meteorites are of asteroidal rather than of cometary origin. Comets are even smaller bodies than asteroids and would be heated even less. If, in addition to the volatile material and fine dust emitted by comets as they approach the Sun, there exists ancient rocky material in their nuclei, one would expect the primordial isotopic age record to be preserved in cometary meteoroids as well.

Distinguishing between asteroidal and cometary sources

The clue to the distinction between asteroidal and cometary sources for at least the most common meteorites is provided by minor mineralogical disturbances that slightly alter the otherwise clear preservation of the primordial isotopic age record in meteorites. Such disturbances are attributable to metamorphism associated with evidence for collisional shocks preserved in the detailed mineralogy of meteorites. For example, many representatives of one very common type of chondritic meteorite, the hypersthene chondrite, display glass veins and other evidence of shock-induced metamorphism of the sort that would be expected to result from collisions between asteroids. (Chondrites, the most common type of stony meteorite, are so called because they contain small primordial silicate spherules known as chondrules.) Ages measured by the decay of potassium to argon show that this shock metamorphism took place quite late in the history of the solar system—about 500 million years ago. Ages measured by other isotopic decay systems on these same meteorites still display the more common value of 4.6 billion years (Figure 71). Furthermore, these shocked meteorites exhibit a very strong chemical and textural kinship to unshocked meteorites that record completely the isotopic age of the solar system. It is not plausible that such similar rocks should be provided by sources from regions as far removed from one another as the asteroid belt and the cometary cloud. Other evidence for impact events late in solar system history is provided by dating shocked fragments of meteoritic material embedded in meteorites of different types which are presumably a result of collisions in space. Quantitative comparison of the collisional history expected for the sparsely populated, low-relative-velocity source regions of comets with that expected for the more densely populated, higher-velocity asteroid belt argues strongly for the asteroid belt being the actual site of these collisions and thus the source region for the meteorites.

Such conclusions are supplemented by observational and theoretical dynamical studies of meteorite orbits. The results of these studies are in agreement with an asteroidal

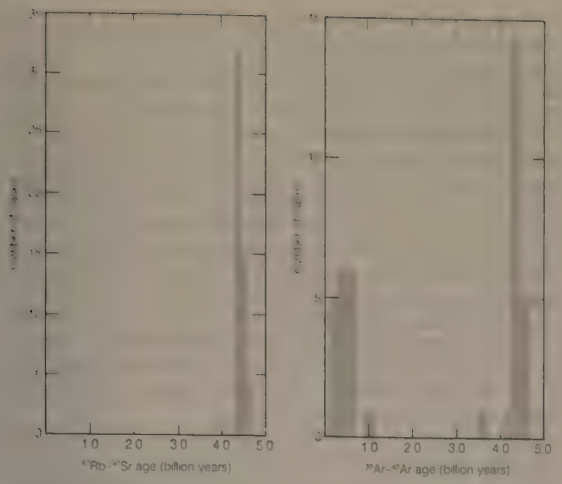

Figure 71: *Distribution of formation and metamorphism ages of ordinary chondrite meteorites.*
(Left) Ages measured by the decay of ^{87}Rb to ^{87}Sr. The "isotopic clocks" of these meteorites were set by heating events essentially at the beginning of solar system history. (Right) Ages based on the decay of ^{40}K to ^{40}Ar. Many of these ages also cluster around 4.6 billion years, but a significant number have been "reset" by collisionally induced shock metamorphism on the asteroid from which the meteorite was fragmented.

(Left) Based on data from J.F. Minster (1979) and a series of papers by K. Gopalan, S.K. Kaushal, and G.W. Wetherill in *Journal of Geophysical Research* (1968–71), copyright by the American Geophysical Union. (Right) Data compiled by J.T. Wasson (1985) based on data from D. Bogard, *Journal of Geophysical Research*, vol. 81, p. 5664, (1976), copyright by the American Geophysical Union; G. Turner, *Meteorite Research* (1969), and G. Turner *et al.*, *Proceedings of the Ninth Lunar Planetary Scientific Conference* (1979)

origin for at least the most abundant types of meteorites but are not in agreement with a cometary origin.

Meteoroids of less certain origin. Identification of many meteoroids with either asteroids or comets can be securely established. It is then possible to extend these identifications by extrapolation to cases where the distinction is less obvious. There are, for example, many shower meteors in meteor streams for which no comet is presently identifiable; however, the orbits and characteristics of their passage through the atmosphere are very similar to those of stream meteors that are associated with known comets. Even when such meteors are not in streams, their orbits with aphelia and physical characteristics similar to those of cometary stream meteors leave little room to question their cometary parentage. It also has been possible to identify a number of very bright meteors (fireballs) with asteroidal meteorites by comparing the details of their atmospheric flight with those of recovered meteorites (see below *Fireball networks*).

There are many meteoroids whose asteroidal or cometary nature remains highly uncertain. These include objects that are presently in orbits very similar to identifiably asteroidal meteoroids but that exhibit in their atmospheric flight the greater fragility associated with meteoroids known to be derived from comets. Are these fragments of comets that have been perturbed into orbits traditionally associated with asteroids, or do they represent a type of asteroidal material that is too weak to survive as a meteorite? Answers to such questions are needed if scientists are to use the information preserved in primitive bodies—comets and asteroids—in the most effective way. There is much more that can be learned from further observational studies of meteors, laboratory investigations of meteorites, Earth-based observations of comets and asteroids, and spacecraft missions to these small primitive bodies. Continuation of this work holds much promise for clarifying the processes by which both the Earth and the solar system came into existence.

In addition to cometary and asteroidal sources, a very minor but identifiable contribution to the meteoroidal population is derived from the Moon. Such particles are ejected from primary cratering of the lunar surface by large meteorites. By comparison with lunar rocks returned by the U.S. Apollo missions, several small meteorites collected on the Antarctic ice sheet have been positively identified as lunar meteorites. It also appears probable that certain relatively rare types of meteorites (shergottites, nakhlites, and chassignites) are fragments of igneous rocks from Mars. Some day evidence for meteoroids from Mercury, Venus, the Earth, and the interstellar medium may be identified.

METEORS

Characteristic observational effects. On any clear night in the countryside beyond the bright lights of cities, one can observe with the naked eye several meteors (or shooting stars) per hour as they streak through the sky, with durations ranging from a small fraction of a second up to several seconds. Quite often they vary in brightness along the path of their flight, appear to emit "sparks" or flares, and sometimes leave a luminous train that lingers after their flight has ended. These meteors are the result of the high-velocity collision of meteoroids with the Earth's atmosphere. Nearly all such interplanetary bodies are small fragments derived from comets or asteroids.

The observed apparent brightness of these easily observable meteors covers the same range of brightness as the stars visible to the unaided eye (*i.e.*, from about zero to fifth astronomical magnitude). They constitute a portion of an Earth-impacting interplanetary flux of similar bodies ranging in mass from less than one nanogram up to millions of tons. The smaller bodies are too faint to be seen with the naked eye but are observable with the aid of binoculars and telescopes or by radar reflection. Brighter meteors—of magnitudes ranging in brightness from that of Venus (−4 magnitude) to greater than that of the full Moon—are less common but are not really unusual. These are produced by meteoroids with masses ranging from several grams up to about one ton.

The brightest meteor (possibly of cometary origin) for which historical documentation exists struck on June 30, 1908, in the Tunguska region of central Siberia and rivaled the Sun in brightness. The energy delivered to the atmosphere by this impact was roughly equivalent to that of a 10-megaton thermonuclear explosion and caused the destruction of forest over an area of about 2,000 square kilometres. The geologic record of cratering attests to the impact of much more massive meteoroids, including objects with kinetic energies equivalent to 100 million megatons. Fortunately, impacts of this magnitude occur only once or twice every 100 million years. It is hypothesized that large impacts of this kind may have played a major role in determining the course of biological evolution by causing simultaneous mass extinctions of many species of organisms, possibly including the dinosaurs some 65 million years ago. If so, the replacement of reptiles by mammals as the dominant land animals, the eventual consequence of which was the rise of the human species, would be the result of a grand example of a phenomenon observable every clear night.

Heights and velocities

The visibility of meteors is a consequence of the high velocity of meteoroids in interplanetary space. Before entering the region of the Earth's gravitational influence, their velocities range from a few kilometres per second up to as high as 72 kilometres per second. As they approach the Earth, within a few Earth radii, they are accelerated to even higher velocities by the planet's gravitational field. As a consequence, the minimum velocity with which a meteoroid can enter the atmosphere is equal to the Earth's escape velocity of 11 kilometres per second. Even at this minimum velocity, the kinetic energy of a meteoroid would be 6×10^4 joules per gram of its mass. This can be compared with the energy of about 4×10^3 joules per gram produced by chemical explosives, such as TNT. As the meteoroid is slowed down by friction with atmospheric gas molecules, this kinetic energy is converted into heat. Even at the low atmospheric density at altitudes of 100 kilometres (6×10^{-10} gram per cubic centimetre compared with 10^{-3} gram per cubic centimetre at sea level), this heat is sufficient to vaporize and ionize the surface material of the meteoroid and dissociate and ionize the surrounding atmospheric gas as well. Electronic transitions effected by this excitation of atmospheric and meteoroidal atoms produce a luminous region, which travels with the meteoroid

and greatly exceeds its dimensions. At deeper levels in the atmosphere, a shock wave may be produced in the air ahead of the meteoroid. This shock wave interacts with the solid meteoroid and its vapour in a complex way. About 0.1 to 1 percent of the original kinetic energy of the meteoroid is transformed into visible light.

Ablation and fragmentation

This great release of energy destroys meteoroids of small mass—particularly those with relatively high velocities—very quickly. This destruction is the result both of ablation (the loss of mass from the surface of the meteoroid by vaporization or as molten droplets) and of fragmentation caused by aerodynamic pressure that exceeds the crushing strength of the meteoroid. For these reasons, numerous meteors end their observed flight at altitudes above 80 kilometres, and penetration to as low as 50 kilometres is unusual. Nevertheless, some meteoroids survive to much lower altitudes owing to a combination of relatively low entry velocity (< 25 kilometres per second), large mass (>100 grams), and fairly high crushing strength ($>10^7$ dynes per square centimetre). Those that are recoverable as meteorites lose their kinetic energy before the meteoroid is completely destroyed. They are effectively stopped by the atmosphere at altitudes of 5 to 25 kilometres. Following this atmospheric braking, they begin to cool, their luminosity fades, and they fall to the Earth at low terminal velocities of 100 to 200 metres per second. This "dark flight" of the meteoroid may be several minutes in duration, in contrast to the few seconds of visible flight.

The passage of meteoroids through the atmosphere produces atmospheric shock waves that penetrate to the ground. The penetration of a meteoroid in the kilogram range to altitudes of about 40 kilometres can thereby produce sounds on the ground similar to sonic booms or thunder. These sound waves can be intense enough to become coupled to the ground and recorded by seismometers.

The effect of the final impact with the ground of meteorites in the kilogram mass range could be considered an anticlimax. The fall can go unnoticed by those near the impact site, the impact being signaled only by a whistling sound and a thud. For this reason, many meteorites are recovered only because at least one fragment of the meteoroid strikes a house, drawing the attention of the residents to an unusual event.

Orbits of meteoroids and meteor showers. Prior to entering the gravitational field of the Earth, a meteoroidal body, like all bodies of the solar system, moves around the Sun in an elliptic Keplerian orbit. If this orbit can be determined, valuable information relevant to identifying the source—the parent body—of the meteoroid can be obtained.

When the coordinates in the sky of the trajectory of a meteor are observed from two or more well-separated stations, the direction in which the meteoroid was moving in space before it encountered the Earth can be estimated reasonably well by triangulation. This direction is called the radiant of the meteor. If the motion of the meteoroid is thought of as a velocity vector, such observations determine approximately the direction of this vector. To determine the meteoroid's orbit, however, requires ascertaining not only the direction but also the magnitude of the velocity vector. Although well-trained visual observers are able to estimate the coordinates of the meteor trajectories and thereby determine radiants fairly well, their velocity estimates have proved to be too uncertain to be useful for orbit determination.

This problem was overcome during the 1940s by the introduction of astronomical cameras specially designed for studying meteors. These wide-field cameras were equipped with a rotating shutter that periodically interrupted the light to the photographic plate. The shutter breaks permitted calculation of the speed of a meteor along its path. The position of the meteor's trajectory with respect to the stars photographed on the same plate also was measured accurately. Such observations made at two or more stations could then be used to calculate precisely the orbit of the meteoroid before it encountered the Earth. During the 1940s, special radar instruments also were applied to the study of meteors generally fainter than those observed photographically.

"Showers" of meteors have been known since ancient times. On rare occasions, these showers are very dramatic, with thousands of meteors falling per hour. More often, the background hourly rate of roughly 5 observed meteors increases up to about 10–50. Shower meteors characteristically have nearly the same radiant. This means they are all moving in the same direction in space. As a consequence, plots of meteoroid trajectories on a star map converge at a single point, the radiant, for the same reason that parallel railroad tracks appear to converge at a distance. The new photographic data fully confirmed the belief that meteors belonging to a particular shower had not only the same radiant but similar orbits as well. In other words, the meteoroids producing the meteor showers move in confined streams around the Sun. The introduction of radar observation led to the discovery of several new meteor streams that were totally invisible to cameras because they came from radiants in the daytime sky.

Radiants of shower meteors

A fact of great importance, fully confirmed by the photographic data, is the association of many meteor streams with the orbits of observed comets. A list of the more important meteor-stream orbits and associated comets is given in Table 26. The streams with cometary associations represent debris ejected from a comet along its orbit through space. A recently formed stream, the Leonids, tends to appear in great strength every 33 or 34 years, the same as the period of the parent comet, Temple-Tuttle. These meteoroids are clustered in a compact swarm moving in the orbit of the comet. With the passage of 1,000 years or so, the slightly different orbits of the meteoroids will cause them to disperse more uniformly along the orbit of the comet. In such cases, a shower, usually weaker, occurs annually when the Earth's orbit intersects the orbital plane of the meteor stream. After a still longer period, about 10,000 years, planetary perturbations will cause the orbits of the stream meteoroids to disperse into different orbits, and their identity as members of a stream will gradually disappear.

Meteors that do not appear to belong to streams are called sporadic. It is likely that in some sense all meteoroids are, or have been, stream members because the physical processes that release meteoroids from either comets or asteroids do so in great numbers. Sporadic meteors are therefore the result of streams too weak to be distinguished from one another or old streams so dispersed as to be no longer recognizable.

Sporadic meteors

There is one rather strange example of a major meteor shower that is clearly identifiable with an astronomical object that, at least at first glance, does not appear to be a comet: the Geminid shower and 3200 Phaeton, respectively. The latter (formerly designated 1983TB) exhibits none of the usual cometary features, a nebulous halo and tail; it simply looks like a small Earth-crossing asteroid. If the stream is cometary, it means that a comet that produced meteoroids prolifically only a few thousand years ago has now completely ceased its cometary activity and looks more like an asteroid. The orbits of 3200 Phaeton and the Geminids also are unlike those of comets in that their aphelia are at 2.4 AU, well within the orbit of Jupiter.

Table 26: Principal Visually Observable Meteor Showers

shower	average date of maximum	normal duration (days)	visual strength (Northern Hemisphere)	entry velocity (km/sec)	associated comet
Quadrantid	January 3	1	medium	41	not known
Lyrid	April 22	1	irregular	48	1861 I (Thatcher)
Eta Aquarid	May 3	5	weak	66	Halley
S. Delta Aquarid	July 29	8	medium	41	not known
Capricornid	July 30	3	medium	23	not known
Perseid	August 12	5	strong	59	Swift-Tuttle
Andromedid	October 3	11	weak	21	Biela
Draconid	October 9	1	irregular	20	Giacobini-Zinner
Orionid	October 21	2	medium	66	Halley
Taurid	November 8	30	weak	28	Encke
Leonid	November 17	<1	irregular	71	Temple-Tuttle
Geminid	December 14	4	strong	34	3200 Phaeton*

*This body exhibits no cometary activity and is possibly of asteroidal rather than of cometary origin.
Source: Data derived primarily from A.F. Cook in *NASA SP-319* (1973).

If 3200 Phaeton came from the Oort cloud of comets (see above *Comets*), it must at one time have crossed the orbit of Jupiter. Over a span of millions of years, it is not out of the question that close encounters with the Earth and Venus could gravitationally perturb a Jupiter-crossing orbit into an orbit of this kind. The observed rate at which matter is lost from comets, however, seems to indicate that their inventory is exhausted in only a few thousand years. Thus, the millions of years required for this orbital evolution does not appear to have been available.

It could be hypothesized that 3200 Phaeton was never a comet at all but simply an Apollo object that strayed from the asteroid belt by the reasonably well-understood resonant perturbations that can cause this to occur. The Geminid meteors would then be explained as fragments produced by an asteroidal collision while 3200 Phaeton is traversing the portion of its orbit that is in the asteroid belt. There are serious problems with this explanation. Quantitative calculations show that an asteroidal collision of the required magnitude during an interval of only a few thousand years is very unlikely. Studies of the historical orbital evolution of the Geminid stream suggest that its orbit is incompatible with a single outburst of meteoroids; it is more like one expected from a body that produced a series of outbursts. Finally, the orbit is not the kind one would expect for an Apollo object perturbed from the asteroid belt. Its perihelion is too close to the Sun. An understanding of the mystery of 3200 Phaeton and the Geminids is likely to contribute much to the understanding of comets, the origin of meteor streams, and the relationship between Apollo objects, comets, and asteroids.

Fireball networks. A very significant development in meteor science occurred during the 1960s. This was the establishment of large-scale networks for photographing very bright meteors, or fireballs. These networks were designed to provide all-sky coverage of meteors over areas of about a million square kilometres. Three such networks were developed: the Prairie Network in the central United States, the MORP (Meteorite Observation and Recovery Project) network in the prairie provinces of Canada, and the European Network with stations in Germany and Czechoslovakia. The most complete set of published data is that of the Prairie Network, which was operated by the Smithsonian Astrophysical Observatory from 1964 to 1974.

Principal objectives of the networks

An original goal of these networks was to recover a larger number of meteorites for laboratory studies. Other objectives were to determine the orbits of the recovered meteorites and to compare the inferences of meteor theory regarding the density and strength of meteoroids with "ground truth" provided by the study of the same meteoroids in the laboratory. The goal of recovering meteorites had only limited success. Three meteorites were recovered, one by each of the networks. All three meteorites were ordinary chondrites, the most abundant type of stony meteorite. During the operation of the networks, many more meteorites were actually recovered by chance collisions with the roofs of houses.

In spite of this meagre record for meteorite recovery, the networks compiled data that became the basis for a new outlook on meteor science and meteoroid sources. Prior to this effort, there was a tendency to regard the study of meteors and meteorites as independent scientific fields that had little to contribute to each other. Meteors were studied by astronomers and were thought to be associated almost entirely with fragile and low-density "dust balls." On the other hand, meteorites were dense rocks studied by geochemists in the laboratory as samples of the primordial solar system. Little thought was given to why meteor astronomers did not concern themselves with meteorites.

Straightforward application of conventional meteor physics to determine the density of the three recovered meteorites led to the incorrect conclusion that these dense rocks were also low-density objects. This clearly showed that there was something wrong with meteor physics as traditionally applied. A likely, but still not proven, explanation was that the value of luminous efficiency, conventionally used to relate the mass of a meteoroid to the brightness of a meteor, was too low. As a result, the mass of the meteoroid calculated from the luminosity of the meteor was too high. When this large "photometric" mass was combined to measure the cross-sectional area of the meteoroid (using the rate at which it was observed to slow down by atmospheric gas drag) and thereby its radius and volume, a spuriously low density was obtained.

Impact of photographic data on meteor studies

The photographic data from the three fireballs recovered by the networks permitted a more direct empirical approach to the analysis of meteor data. It was found that the atmospheric trajectories of the recovered meteorites, including the end height at which they ceased to be luminous, could be accurately reproduced if the "dynamic mass," determined by the deceleration of the meteor, were used in the theory instead of the photometric mass. It also was found that the ratio of the photometric mass to the dynamic mass was a constant. Laboratory measurements of cosmic-ray effects on the recovered meteorites led to a calculation of the "true mass," which was intermediate between the photometric mass and the dynamic mass. Finally, the light curve (the plot of brightness versus altitude) was similar for the three meteorites.

These results, obtained from the recovered meteorites, could then be used to identify similar objects in the other fireball photographs. Their presence certainly could be expected, because meteorites are produced by fragmentation processes in space similar to those studied in the laboratory. Both experimental and theoretical studies of these processes demonstrate that for every large fragment there must be many small ones.

The recovered fireballs were among the very brightest observed by the photographic networks. Accordingly, there were among the fireball data many objects physically identical to the recovered meteorites. In short, the problem of determining which fireballs were meteorites no longer was dependent on uncertain first principle measurements of density. The empirical data obtained from the recovered meteorites could be used to check the record of each individual fireball, testing quantitatively whether or not the object "looked like a meteorite."

To date, about 30 fireballs have been identified as stony meteorites in this way. The adoption of this approach has increased scientific knowledge of the distribution of meteorite orbits by an order of magnitude.

Application of the same method of analysis shows that fireballs from the Taurid shower, associated with Comet Encke, do not look like meteorites, or at least not like ordinary chondrites. On the other hand, they do not resemble dust balls either but appear to have significant physical strength. The stronger objects of this group have a strength comparable to that of ordinary dirt clods. These physical properties overlap with those of some carbonaceous meteorites. Further analysis of existing data can be expected to shed new light on important questions regarding the relationships between meteoroids of various kinds and their sources. If some way could be found to increase the rate at which fireball networks recover meteorites by about an order of magnitude, the empirical approach, proved valuable for identifying ordinary chondrite sources, could be extended to include less abundant types of meteorites.

METEORITES

As noted above, meteorites are meteoroids that survive passage through the Earth's atmosphere. Any source that can eject such material into interplanetary space should therefore, at least in principle, be thought of as a candidate source of meteorites. There is no fundamental reason why all meteorites must come from similar sources.

It turns out, however, that in practice there are some regions in the solar system that are much more effective in introducing material of substantial strength into Earth-crossing orbits than others. Recent laboratory and theoretical studies fully confirm the older belief that most meteorites are fragments of asteroids. These same studies show that a small fraction, less than 1 percent of the meteorites, come from nonasteroidal sources. The lunar origin of several meteorites is well-established, and it is probable that at least eight others come from Mars. There is evidence from fireball data that a small part of the material in cometary orbits (*i.e.*, with aphelia beyond Jupiter)

Asteroidal origin of most meteorites

Table 27: Classification of Undifferentiated Meteorites (Chondrites)

class	group	percentage of observed chondrite falls	total iron (weight %)	Fe—metal / Fe—total (%)	FeO / FeO + Mg (mole %)	chondrules (%)	carbon (weight %)
Ordinary	H	38.1	25–31	58–65	17	80	0.1
	L	46.3	21–23	30–39	22	80	0.1
	LL	8.5	20–23	6–25	27	80	0.1
Enstatite	E	1.8	22–35	70–88	0.05	20	0.4

may possess sufficient strength to successfully penetrate the atmosphere. It is not known if any of this material is present in existing meteorite collections. If it is, the best candidate material would be carbonaceous stony meteorites, probably those of type CI (see below), of which five separate falls have been recovered.

With these few exceptions, it is safe to regard all meteorites as samples broken from outcrops of rock or metal, which until fairly recently in solar-system history were part of asteroidal bodies, mostly in the inner region of the asteroid belt (between about 2.2 and 2.6 AU). Like rocks from the Moon, the Earth, or any other similar planetary body, their present state is determined by the total effect of events that occurred on the body throughout the entire history of the solar system. There is no a priori reason why such samples must be pristine samples of a primordial solar nebula from which the present solar system evolved. On the other hand, the principal driving force behind asteroid studies has been the plausible belief that small "primitive" bodies such as asteroids and comets are those most likely to preserve evidence of events that took place in the early solar system. Insofar as this belief is correct, meteorites, samples of these bodies, share this property. Evidence derived from the study of meteorites themselves supports this conclusion.

Types of meteorites. The most fundamental distinction between the various meteorites—no two of which are exactly alike—is the division between chemically undifferentiated and differentiated meteorites. This concept arises from the fact that there is an average chemical composition of the solar system. This average composition must be very close to the composition of the Sun, because the Sun contains most of the mass of the solar system. Spectroscopic comparison of the Sun's chemical makeup with those of other stars shows that its composition in turn is closely related to a cosmic average of the relative abundances of the elements. Important deviations from such average abundances are observed, but these do not invalidate the view that they are deviations from normal abundance ratios determined by the processes by which the chemical elements are formed in stars at various stages of their evolution, returned to the interstellar medium where they are mixed, and then incorporated into new stars and their planetary systems when they are formed.

Since the late 1940s, important advances have been made in the chemical analysis of both meteorites and the Sun. A remarkable result has emerged from this work. Although at one time there appeared to be major differences between the Sun and typical meteorites in the ratios of elements to one another (*e.g.*, iron to silicon), these differences tended to disappear as the accuracy of the measurements improved. It turned out that, for most meteorites and most elements, the solar and meteoritic values of the element ratios relative to silicon (taken as a standard) agreed to within better than a factor of two.

Basic agreement between the meteoritic and solar abundances of the elements

Two kinds of exceptions to this rule were found. Relative to the Sun, the meteorites were deficient in the more volatile elements. For the most volatile elements, hydrogen and the noble gases, the deficiencies were gross—more than a factor of 10,000. For less volatile elements, the deficiencies were smaller; and for the nonvolatile elements, or "refractory" elements, such as iron, magnesium, aluminum, and calcium, the meteoritic and solar abundance ratios were identical within the accuracy of the data.

The other kind of exception to the rule relates to differences between meteorites. For some meteorites, as, for example, those consisting primarily of metallic iron, the similarity between meteoritic and solar abundance ratios fails completely. This also is true for basaltic meteorites, those that appear to have been at one time volcanic magmas and have undergone chemical fractionation of the sort observed in terrestrial igneous rocks.

Undifferentiated meteorites. The meteorites that do obey the rule prove to be of a kind that had already been grouped together on textural grounds—namely, the chondrites. From observed fall rates, this is the most abundant type of meteorite (Table 27). The designation chondrite is based on the occurrence in these meteorites of small (about one millimetre in diameter) spherules called chondrules (Figure 72). In many chondrites, the composition of the chondrules is quite heterogeneous, and the space between

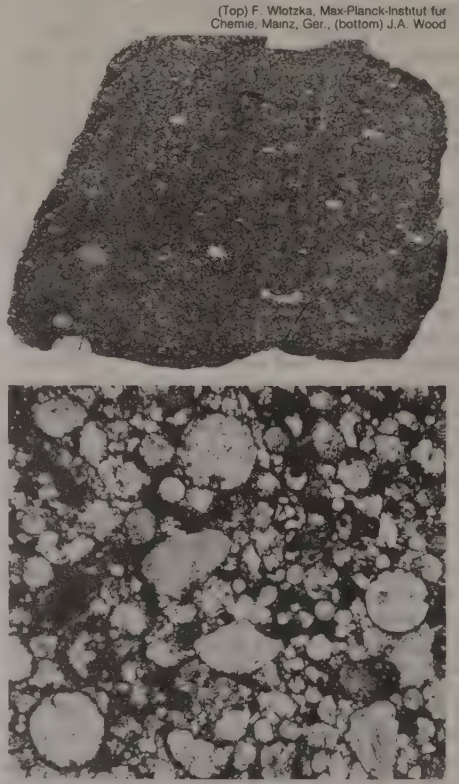

Figure 72: (Top) Sawed and polished section of the Leoville carbonaceous chondrite (CV3; reduced 2.3×). The small, rounded gray objects are chondrules. The larger, whitish objects are refractory inclusions, similar to those seen in Allende (Figure 67, top right). (Bottom) Microscopic view of a thin section of the Tieschitz (Czechoslovakia) ordinary chondrite (olivine-bronzite H3). The round objects are chondrules, some of which have been fractured by collisions after their formation.

the chondrules is filled with a fine-grained matrix material that is richer in volatile elements. In terms of terrestrial rocks, these meteorites seem more akin to sedimentary conglomerates composed of a mechanical mixture of a jumble of components rather than to rocks formed by a process of igneous differentiation.

Not all chondrites contain chondrules of heterogeneous composition. More often, the mixture of heterogeneous chondrules and matrix appears to have undergone a thermal metamorphism that caused the chemical components of the chondrules to come into equilibrium with one another and with the matrix material. This metamorphism was accompanied by the loss of relatively volatile elements. All of these chondrites share one common property. They do not appear to have ever experienced chemical differentiation associated with igneous melting. This shared property is the basis for grouping them all as undifferentiated meteorites even though they clearly differ from one another in the degree to which they have retained volatiles and in various other ways.

Undifferentiated meteorites are classified in two complementary ways. Based on their major element concentrations (Fe, Mg, O), carbon content, and abundance of chondrules, these meteorites naturally cluster into the distinct classes shown in Table 27. In addition, within each of these classes, the meteorites differ according to the degree that they have been thermally metamorphosed or experienced loss of volatile elements. This difference is referred to as the petrologic type (Table 28). For example, the Allende carbonaceous chondrite (Figure 66, top right) is classified CV3, indicating that it belongs to group CV (Table 27) and petrologic type 3 (Table 28).

Differences between chondrite types

Chondrites obviously differ from one another in several important respects. As has been pointed out, they vary in the extent to which they have undergone thermal metamorphism. Another important distinction is between the more abundant ordinary chondrites (of which there are three principal kinds) and the rarer chondritic meteorites that exhibit significant chemical differences. One of these types is the enstatite chondrite, which is, among other things, chemically more reduced than the ordinary chondrites. Almost all the iron in these meteorites, for example, is in metallic form. As a result, most of the abundant silicate mineral, pyroxene, is present as nearly pure enstatite ($MgSiO_3$) rather than in magnesium-iron solid solution minerals, such as bronzite and hypersthene, found in the ordinary chondrites. In enstatite chondrites, the readily oxidized element silicon is even found in the reduced state, and calcium occurs as the sulfide mineral oldhamite (CaS) rather than in its more usual silicate forms.

Other very important varieties of chondrites are grouped together as the carbonaceous chondrites. As their name implies, they characteristically contain more carbon (0.5 to 5 percent) than the ordinary chondrites (only about 0.1 percent). The mineral constituents of the carbonaceous chondrites are less chemically equilibrated with one another than even the unequilibrated ordinary chondrites. In many cases, one finds in the same meteorite carbonaceous material that formed at low temperatures and inclusions of the most refractory minerals—perovskite ($CaTiO_3$), hibonite ($CaAl_{12}O_{19}$), and melilite (solid solutions of $Ca_2Al_2SiO_7$ and $Ca_2MgSi_2O_7$).

CI carbonaceous chondrites

Perhaps the most interesting type of meteorite is the CI carbonaceous chondrite. Strictly speaking, one could legitimately question why such meteorites are called chondrites at all inasmuch as they do not contain chondrules. When compared with solar abundances (Figure 73), however, it turns out that they are the least differentiated meteorites of all, and in making a classification scheme it certainly makes sense to group them with the other undifferentiated meteorites. In accordance with the correlation already observed between chemical undifferentiation and

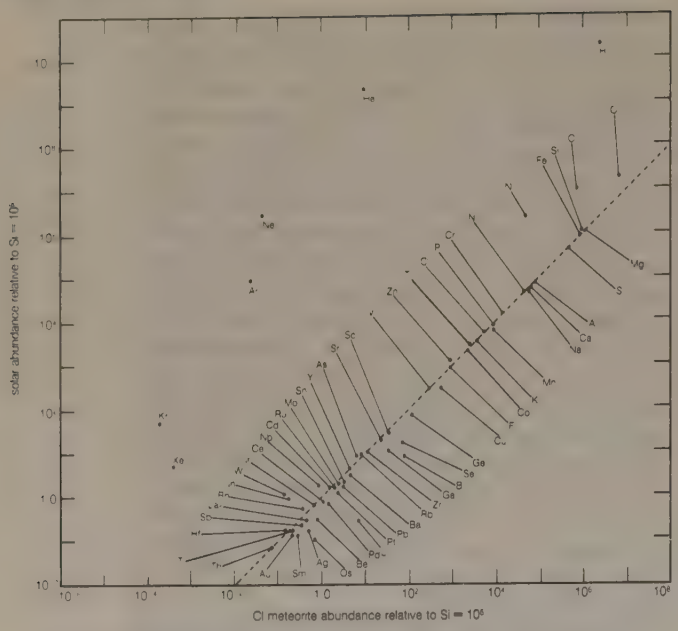

Figure 73: *Comparison of solar and meteoritic carbonaceous chondrite (CI) abundances of elements (relative to silicon = 10^6).*
For most elements, the solar and meteoritic abundances are very similar and therefore fall near a line with a slope of 45°. For the most volatile elements (hydrogen, noble gases, carbon, nitrogen, oxygen), the meteorites are highly depleted relative to the solar composition.

Based on data from *Meteorites: Their Record of Early Solar-System History* by John T. Wasson, W.H. Freeman and Company, 1985, and B. Mason, *Handbook of Elemental Abundances in Meteorites* (1971), Gordon and Breach, Science Publishers, Inc.

chemical disequilibrium, the constituents of CI carbonaceous chondrites are far from equilibrium. The iron in these meteorites, for example, is highly oxidized, most of it occurring in the ferric iron-bearing mineral magnetite (Fe_3O_4). At the same time, carbon is present as highly reduced complex hydrocarbons. In equilibrium, the carbon would be oxidized to carbon monoxide and carbon dioxide, and the iron would be reduced to metallic iron.

Because CI chondrites are the most undifferentiated meteorites known, it has been speculated that, unlike most meteorites, they are of cometary rather than of asteroidal origin, since comets are believed to represent the most unaltered material in the solar system. There are difficulties in accepting this speculation as being correct. For example, detailed study of these meteorites shows that, in spite of their chemically undifferentiated and unequilibrated nature, they have had a complex chemical and physical history and are not simply a collection of interstellar dust. On the other hand, scientific knowledge about the nature and origin of comets is still limited, so that it would be unwise to dismiss this intriguing hypothesis prematurely.

Differentiated meteorites. Differentiated meteorites exhibit the type of chemical fractionation one would expect to occur on a planetary body that underwent core formation and magmatic differentiation similar to that observed in terrestrial and lunar volcanic rocks. Indeed, at one time it was thought likely that the most abundant type of differentiated stony meteorite, the basaltic achondrites, were actually lunar mare basalts. Their similarities to the lunar basalts subsequently returned by the Apollo missions showed that this was by no means a farfetched idea, but detailed considerations such as oxygen isotope ratios showed that it was not correct.

Iron meteorites and achondrites

In classifying differentiated meteorites, the major division is made between the iron meteorites and the stony differentiated meteorites, the achondrites ("not chondrites"). In addition, there are a number of stony-iron meteorites that contain mixtures of large masses of nickel-iron metal and differentiated silicate rock. The usual classification scheme for differentiated meteorites is given in Tables 29 and 30.

There are compelling reasons for believing that, like the chondrites, all differentiated meteorites, with the exception of those few from the Moon and possibly Mars, are asteroidal fragments. Because asteroids are too small to have experienced the accretional and long-lived radioactive heating that powers igneous processes on the inner planets, this may seem surprising. A partial solution to this enigma comes from radiometric dating, which shows that this differentiation took place very early in the history of the solar system, about 4.6 billion years ago. At that time other heating mechanisms may have been available—*e.g.*, heating by short-lived radioactive isotopes such as aluminum-26 (which has a half-life of about 700,000 years) or inductive heating by intense solar activity. It is even possible that asteroids from which differentiated meteorites seem to be derived are fragments of much larger differentiated planetesimals originally present in the inner planet region during the development of the Earth and Venus and which were stored in quasi-stable orbits in the innermost asteroid belt (2.2 AU) of the early solar system.

Specific asteroidal source regions for recovered meteorites. There is compelling, even if circumstantial, evidence that nearly all meteorites are derived from the asteroid belt. For scientific understanding of this matter to be complete, it is necessary to know which asteroids are the sources of particular types of meteorites and the mechanisms by which meteorites are transported from the asteroid belt to the Earth. It is possible that the ultimate answer will not be found until asteroids are explored by spacecraft. Nevertheless, considerable information relevant to this question is already available.

For the most abundant meteorite type, the ordinary

Table 29: Classification of Iron Meteorites*

class	subclass	symbol	nickel (%)	Widmanstätten structure kamacite (α-iron) bandwidth (mm)	percentage of total irons

*Differentiated meteorites of this type consist principally of nickel-iron metal and iron sulfide; they make up 4 percent of all meteorite falls. The classification given here is structural. Another classification is based on the trace element concentrations of iron meteorites, particularly gallium, germanium, and iridium. This classification tends to group the same meteorites that are grouped in the structural classification, but the grouping is not exactly the same. For either classification, a significant number (10–15 percent) of meteorites do not fit well and must be classified "anomalous."

Orbits of Earth-impacting ordinary chondrites

chondrites, there is a fairly large body of evidence that indicates that most of these meteorites strike the Earth while traveling in a rather special type of orbit. Such an orbit has its perihelion just inside the Earth's orbit, as well as low inclination (less than about 10°) and fairly high eccentricity (about 0.6). This has been determined on the basis of the time of day during which meteorites are observed to fall. It has been noted that about twice as many ordinary chondrites fall during the daylight afternoon hours as during daylight hours before noon. This fact requires that the meteorite must be moving faster than the Earth at the time of impact and, therefore, must be near its perihelion according to Keplerian dynamics. Quantitative consideration of the implications of time of fall data is entirely consistent with evidence obtained by visual observations of meteorite radiants and with about 30 fireballs identified by the Prairie Network as being, at least physically, equivalent to stony meteorites (see above).

This distribution of orbits places strong constraints on the source region in the asteroid belt from which ordinary chondrites can be derived. If meteorites in the kilogram mass range are to be derived directly from the asteroid belt, the mechanism by which they are extracted from the belt and transferred to an Earth-crossing orbit must operate quite rapidly on a time scale of a few million years. Only then can a meteoroid escape destruction by collision while near its aphelion in the asteroid belt. This collisional lifetime is not simply a theoretical result but is measured directly by the cosmic-ray exposure ages of meteorites, as discussed below.

High-energy galactic cosmic rays—primarily protons—have a range of penetration on the order of a few metres in meteoritic material. Any meteoroid of smaller dimensions will be radiated throughout by this proton bombardment. The high-energy protons cause spallation reactions (nuclear interactions that result in the release of many nucleons) on the abundant elements in the meteoroidal target. As a consequence, a large number of otherwise rare isotopic species, both stable and radioactive, are produced. These include the stable noble gas isotopes helium-3, neon-21, and argon-36, as well as the rare isotope potassium-40 and various short- and moderately long-lived radioactive isotopes, including hydrogen-3 (with a half-life of 12.26 years), beryllium-7 (53.29 days), beryllium-10 (1.6×10^6 years), aluminum-26 (7.2×10^5 years), manganese-53 (3.7×10^6 years), and cobalt-60 (5.272 years). The concentration of the shorter-lived radioactive isotopes can be used to monitor the cosmic-ray bombardment rate, and the accumulation of the stable species (*e.g.*, neon-21) measures the time in the past that this bombardment began—*i.e.*, the time that the meteoroidal fragment was separated from a larger object that was large enough to have shielded it from cosmic-ray bombardment. For chondritic meteorites, the distribution of cosmic-ray exposure age falls off quite quickly with age. This is to some extent a consequence of the dynamic evolution of the meteoroid orbits but for the most part should be attributed to a "collision half-life" of 5 to 10 million years.

Cosmic-ray exposure age

There are only two processes known that can accelerate meteoroidal fragments into Earth-crossing orbits on this short time scale given by cosmic-ray exposure ages. These processes are direct collisional ejection at velocities of about five kilometres per second and gravitational acceleration by dynamic resonances in the asteroid belt, of which the 3:1 resonance at 2.5 AU is of dominant importance. In a hypervelocity collision, some material is ejected at the required high velocity, but the quantity of this material is small and most of it is pulverized by the associated shock pressures. High-velocity ejection is likely to be responsible for the occurrence of meteorites from Mars or the Moon, but it completely fails to provide the observed quantity of meteoroids from the asteroid belt. The resonant mechanisms are therefore of much greater importance. Bodies orbiting the Sun with a semimajor axis near 2.5 AU will complete three revolutions about the Sun in the time that Jupiter, a strong source of gravitational perturbations, executes one revolution. The resulting resonant acceleration will cause the orbit of the body to become "chaotic," and its perihelion will become Earth-crossing in about one million years.

The calculated quantity of asteroidal material in the meteorite size range delivered to the Earth from the 3:1 resonance agrees well with the 10^8 gram per year terrestrial impact rate of ordinary chondritic meteoroids. Moreover, this resonant acceleration presents a natural mechanism for concentrating meteoroid perihelia near the Earth's orbit, thereby explaining the special distribution of orbits observed for ordinary chondrites. In fact, as it turns out, meteoroids derived by this resonance acceleration mechanism should be overly concentrated near 1 AU; the ratio of afternoon to morning falls should be about 3:1 instead of the observed 2:1. This discrepancy is removed when one takes into account the fact that larger asteroidal fragments (those reaching the size of Apollo objects) will also be accelerated into an Earth-crossing orbit by the same resonant mechanism. Meteorite-size fragments will be produced as collision debris from these larger bodies, but they will not have the special distribution of orbits exhibited by the smaller asteroidal fragments introduced more directly into Earth-crossing orbits. When the contribution from resonant asteroidal ejecta over the entire size range is averaged, the predicted and observed orbital distribution match rather well.

Orbital statistics are not very well known for other meteorite types. It does appear that the differentiated basaltic achondrites fail to share the special orbital distribution observed for the ordinary chondrites. Basaltic achondrites are most likely the collision debris of Apollo objects that were extracted by another resonance mechanism known to operate in the innermost belt; this mechanism can be shown to be effective only in providing larger Earth-crossing bodies. Although more work remains to be done on

this problem, it seems likely that known resonant mechanisms are adequate to explain the dynamical processes by which all classes of meteorites are delivered from their asteroidal source regions into Earth-crossing orbits.

Derivation of meteoritic material from these designated regions of the inner asteroid belt implies that asteroids in such regions have the chemical and mineralogical composition observed in the meteorites. The surface mineralogical composition of asteroids can be determined directly by Earth-based reflectance spectrometry. These measurements have been made for most of the larger asteroids. Although no two reflectance spectra are exactly alike in detail, most asteroids fall into one of two general groups, the S class and the C class. The S-class asteroids have moderate albedos (though comparatively high overall) and contain mixtures of olivine (magnesium, iron silicates), pyroxene (silicates containing magnesium, iron, calcium, and aluminum), and metallic iron. These are the same minerals found in ordinary chondrites and in basaltic achondrites. The C-class asteroids have low reflectance, and their more featureless spectra indicate the presence of light-absorbing opaque minerals. It is plausible to consider these asteroids as candidate sources for carbonaceous meteorites.

Chemical and mineralogical similarities between the major classes of asteroids and meteorites

When considered in more detail, there are certain difficulties in identifying the required number of S-class asteroids as ordinary chondrite sources. Although qualitatively the mineralogy of these asteroids agrees with that of ordinary chondrites, the proportions of the constituent minerals to one another does not match as well. In particular, the S-class asteroids appear to have, at least on their surfaces, about twice as much metallic iron as the ordinary chondrites. The solution to this discrepancy is not known at present. It may be that the surfaces of the asteroids are not truly representative of their interiors, having been altered by collisional bombardment or exposure to solar radiation and particles. Another possibility is that a systematic change in mineralogical composition occurs during the process of collisional grinding of asteroids into ever-smaller bodies, ultimately to those of meteorite size. There is some indication that the discrepancy is less serious for small asteroidal fragments observed as Apollo objects, which is consistent with this hypothesis.

Meteorites, asteroids, and the early solar system. A prime long-range objective of exploring the Moon and planets by spacecraft is to collect samples of these bodies for detailed laboratory study. With the few exceptions noted earlier, meteorites are samples of asteroids delivered to Earth by fairly well-understood natural mechanisms. It also is believed that samples collected from asteroids will prove especially valuable, because such small bodies are most likely to be "primitive" and thus retain the record of events that occurred during their own formation and that of the solar system in general. The study of meteorites is already providing scientists with much valuable information directly related to this matter.

Isotopic records. Meteorites indicate to investigators that the asteroid belt must always have been a relatively tranquil region of the solar system. Some unequilibrated chondrites have inherited and preserved without complete mixing the remnants of presolar interstellar grains. This is demonstrated by variations of the ratios of the oxygen isotopes oxygen-16, oxygen-17, and oxygen-18 within a single meteorite and between different meteorites. It is well known that the oxygen isotopes are fractionated by natural chemical processes. Variations in the ratio of oxygen-18 to oxygen-16, for example, form the basis for paleotemperature studies of ancient terrestrial sedimentary rocks by making use of the temperature dependence of the isotopic chemical equilibrium between seawater and the calcium carbonate that forms the shells of marine organisms. It is characteristic of this natural fractionation dependent on isotopic mass that the degree of fractionation is proportional to the difference of the masses of the isotopes. Thus, in these marine sediments, the variation in the ratio oxygen-18:oxygen-16 is twice that of oxygen-17 to oxygen-16. In some unequilibrated chondrites, however, the variations in the oxygen-18 to oxygen-16 ratios are equal to those in oxygen-17:oxygen-16. It is possible to devise special chemical processes that could produce fractionation of this kind, but it is much more likely that the variations found in the meteorites are caused by nuclear processes that predated the formation of the Sun and solar system. The interstellar grains that were the carriers of these isotope anomalies were probably formed in stellar atmospheres and preserved the signatures of the isotope-formation processes of stars of particular types. These isotopic variations of nuclear origin are found not only in oxygen but also in other less abundant elements, including neon, xenon, titanium, and chromium.

Remnants of presolar interstellar grains

Probable early evolution of the solar system based on meteoritic evidence. The need to provide an environment sufficiently tranquil to preserve this isotopic record, as well as other fragile relics of early solar system events observed in meteorites, places important constraints on the formation of the solar system. If one examines the distribution of matter in the present solar system, it is seen that the density is high both in the region of the inner planets and in the region of the giant planets in the outer solar system but very low in the wide space between Mars and Jupiter. This fact itself is surprising: Why should the solar nebula from which the solar system formed have had a great hole in it? The answer is that it probably did not. In order for asteroids to have formed and developed at all on the time scale of a few million years indicated by the radiometric dating of meteorites, densities more like those in the regions occupied by the giant planets would have been required, as shown by theoretical calculations. It is difficult to escape the conclusion that the quantity of matter in what is now the asteroid belt must have been much greater, perhaps by as much as 10,000 times the quantity observed there today. Therefore some natural process has to have removed almost all the material in this region of the solar system after the formation of asteroidal bodies, but in a sufficiently gentle way to have preserved the relics of presolar and early solar events found in meteorites.

Although the details are not yet understood, it seems most likely that the formation of the giant planets, particularly Jupiter, quickly resulted in the evacuation of most of the matter from this region of the solar system. This means that Jupiter formed rapidly, before bodies in the asteroid belt had grown to become full-fledged planets. The mineralogical and chemical record of the undifferentiated meteorites is not compatible with their once having been part of a planet even as large as the Moon. Also, the very energetic collisional events that would be associated with the dispersal of large planets in the asteroid belt would preclude preservation of the observed relics.

These constraints, for the most part based on meteoritic evidence, define a conceivable chain of events for the early evolution of the solar system beyond the region of the inner planets. Even though the density of matter was at least as great in the asteroid belt as in the region of Jupiter, planetary growth must have been more rapid in Jupiter's vicinity than in the asteroid belt. (Some suggestions have been made as to how this may be possible, but it remains to be seen if they are satisfactory.) Within about one million years, proto-Jupiter(s) began to capture the massive quantities of hydrogen and helium from the solar nebula that constitute most of the giant planet today. At the same time, thousands of large asteroids greater than 100 kilometres in diameter, including some as big as the largest present-day asteroids but not much bigger, had formed. Shortly thereafter, as Jupiter approached its present mass, most of the residual nebular gas was removed by the intense solar ultraviolet radiation characteristic of young stars.

Planetary growth and changes in mass distribution in the outer solar system

Up until the time Jupiter approached its present mass, the asteroids moved in nearly circular orbits in accordance with the weak mutual gravitational perturbations expected for small bodies. During the final formation of Jupiter and Saturn and the removal of the nebular gas, the changing mass distribution in the outer solar system caused waves of resonant perturbations to sweep through the asteroid belt, increasing the eccentricities and inclinations of the asteroids to the moderate values observed today. Because the asteroids had not grown larger than the asteroids of today, collisions at the relative velocities of about five kilometres per second, associated with their present-day

eccentricities and inclinations, would begin to grind down the smaller bodies. This would occur without the shock effects associated with disruption of larger planetary bodies at higher impact velocities.

The foregoing scenario of planetary growth is certain to be wrong in detail and may well be wrong altogether. Nevertheless, without the samples of asteroids provided by recovered meteorites, there would be little observational basis at all for formulating models of this kind. All the qualitative statements made above should be considered not as established facts but rather as statements of theoretical problems that need to be thoroughly worked out. Their results must be compared with old and new observational data and reformulated and reworked until a satisfactory understanding of planetary formation is achieved.

Thermal evolution of the solar nebula and planetesimals. The available meteoritic evidence is relevant to many other unsolved central questions concerning the early solar system, including some that bear on the way the Sun was formed and its early history. One of these is the question of the thermal evolution of the solar nebula and the planetesimals that formed and grew within it.

As discussed above, the environment of the early asteroid belt must have been a rather "tranquil" one. By tranquil, one actually means thermally, rather than physically, uneventful. The collisions that led to the removal of most of the material from the asteroid belt were highly disruptive, and there is ample evidence of extensive physical disruption in the textures of even the most primitive meteorites. Yet, the preservation of primordial relics, such as the isotope anomalies, argues against widespread heating of the asteroidal region to temperatures as high as 1,000 K.

Low-temperature origin of the asteroidal region

A relatively cool solar nebula at distances this far from the Sun is in agreement with most current theoretical calculations of the formation of the Sun. In addition to the evidence for an overall low-temperature origin for this region of the solar system, however, the meteoritic record clearly shows the imprint of high-temperature events of major importance, which are not well understood at present. The most apparent of these is the very abundant presence of chondrules in all undifferentiated meteorites except the CI chondrites. Chondrules appear to have once been melted droplets primarily of silicate composition and would have required temperatures of about 1,500 K to have formed.

Formation of chondrules

If chondrules were a relatively rare meteoritic curiosity, one could legitimately consider them an interesting detail to be explained someday but not a matter of central importance. Yet, the fact that chondrules (or their broken fragments) make up most of the mass of the most abundant class of meteorites, the ordinary chondrites, and a major portion of other chondrites, indicates that their formation must have been of major importance in the early solar system. Even if ordinary chondrites formed only within a restricted region of the asteroid belt adjacent to the 3:1 Kirkwood gap (*i.e.,* between 2.44 and 2.56 AU), this is still about 10 percent of the entire asteroid belt. It also is likely that other chondrule-bearing meteorites formed outside this region, even though their asteroidal sources may be in that region today.

It seems impossible that chondrules are the product of igneous differentiation because they are of nearly undifferentiated solar composition except for the most volatile elements. Nor does it seem likely that they are impact droplets, such as those found in the lunar soil. The expected low impact velocities of asteroidal planetesimals argue against a ubiquitous high-velocity impact environment. Thus, there seems to be no way by which the chondrules could have formed in or on planetesimals. In all likelihood, they were formed in the solar nebula. At the same time, the evidence for rapid cooling of chondrules argues against their formation by large-scale condensation from a very hot solar nebula. Local, transient heating events appear to have been important on a wide scale in the solar nebula, but the nature and cause of these events remain unknown.

A problem of similar difficulty is that of the origin of the large (up to more than one centimetre in diameter), highly refractory inclusions found in the CV meteorites (see Table 27), especially prominent in the Allende carbonaceous chondrites. Though not as ubiquitous as chondrules, these inclusions are by no means of negligible abundance. Unlike chondrules, they are highly fractionated chemically, apparently as a result of more prolonged heating to about 1,500 K. Because many of the isotopic anomalies are associated with these refractory inclusions, interpretation of this important evidence is limited by a poor understanding of their origin.

Evidence of internal heating in differentiated meteorites

The foregoing thermal events most likely occurred in the solar nebula rather than on growing asteroidal bodies. In addition, thermal effects are observed in meteorites associated with internal heating. The most apparent of these are the differentiated meteorites, which probably represent about 10 percent of the asteroidal region sampled. The asteroids from which these meteorites were fragmented, though probably formed from a relatively cool solar nebula, experienced internal heating, core formation, and igneous differentiation within a few million years of the formation of the solar nebula itself. Clear and detailed evidence for this is based on (1) radiometric dating of the minerals formed by this igneous differentiation, (2) the mineral assemblages of the resulting igneous rocks, and (3) the slow cooling that produced large crystals of differentiated minerals (*e.g.,* the so-called Widmanstätten structure observed in many nickel-iron meteorites). The actual process responsible for this heating is yet unknown, but several good possibilities are being evaluated. These include heating by the short-lived radioactive isotope aluminum-26, heating by electric currents induced by early solar activity, and accretional heating of planetesimals in the terrestrial planetary region, followed by fragmentation and transfer to the innermost asteroid belt.

The ordinary chondrites also experienced heating after the formation of chondritic planetesimals, but not enough to produce melting. As a result, chondritic material, presumably once resembling the unequilibrated ordinary chondrites, was metamorphosed to produce the more abundant equilibrated ordinary chondrites. The time scale for this metamorphism is, within uncertainties, the same as that which produced the parent asteroids of the differentiated meteorites. It is plausible that some of the same heat sources (*e.g.,* aluminum-26) may have been responsible.

(G.W.We.)

BIBLIOGRAPHY

General works. Good overviews of the solar system include J. KELLY BEATTY, CAROLYN COLLINS PETERSON, and ANDREW CHAIKIN (eds.), *The New Solar System,* 4th ed. (1999); and DAVID MORRISON and TOBIAS OWEN, *The Planetary System,* 2nd ed. (1996). Individual solar system objects are treated in the excellent series of books published by the University of Arizona Press: FAITH VILAS, CLARK R. CHAPMAN, and MILDRED SHAPLEY MATTHEWS (eds.), *Mercury* (1988); RICHARD P. BINZEL, TOM GEHRELS, and MILDRED SHAPLEY MATTHEWS (eds.), *Asteroids II* (1989); JAY T. BERGSTRALH, ELLIS D. MINER, and MILDRED SHAPLEY MATTHEWS (eds.), *Uranus* (1991); HUGH H. KEIFFER *et al.* (eds.), *Mars* (1992); DALE P. CRUIKSHANK (ed.), *Neptune and Triton* (1995); S.W. BOUGHER, D.M. HUNTEN, and R.J. PHILLIPS (eds.), *Venus II: Geology, Geophysics, Atmosphere, and Solar Wind Environment* (1997); and S. ALAN STERN and DAVID J. THOLEN (eds.), *Pluto and Charon* (1997). Annually revised orbital and physical data about planets, moons, and selected comets and asteroids appear in *The Astronomical Almanac,* published by the U.S. Naval Observatory *et al.*; *The Observer's Handbook,* published annually by the Royal Astronomical Society of Canada, provides excellent information for observing solar system objects with the naked eye or small telescopes. International reports of research on solar system objects appear regularly in *The Astrophysical Journal,* published by the American Astronomical Society and University of Chicago; *The Astronomical Journal,* published by the American Institute of Physics and American Astronomical Society; *Astronomy and Astrophysics,* published by the European Southern Observatory; *Icarus,* a journal of solar system studies published by the American Astronomical Society; *Journal of Geophysical Research,* published by the American Geophysical Union; and *Annual Review of Earth and Planetary Sciences.* A superior monthly periodical for the nonprofessional, with regular coverage of the solar system and its constituents, is *Sky and Telescope.*

(T.C.O.)

Origin of the solar system. An excellent collection of papers on the general subject of solar system origin appears in VINCENT MANNINGS, ALAN P. BOSS, and SARA S. RUSSELL (eds.), *Protostars & Planets IV* (2000); the volume includes papers about newly discovered planets around other stars. Volumes of original technical

articles by different authors on facets of the topic are RICHARD GREENBERG, ANDRÉ BRAHIC, and MILDRED SHAPLEY MATTHEWS (eds.), *Planetary Rings* (1984); JOHN F. KERRIDGE and MILDRED SHAPLEY MATTHEWS (eds.), *Meteorites and the Early Solar System* (1988); and S.K. ATREYA, J.B. POLLACK, and MILDRED SHAPLEY MATTHEWS (eds.), *Origin and Evolution of Planetary and Satellite Atmospheres* (1989). The formation of the inner planets has been extensively studied by GEORGE W. WETHERILL, "Formation of the Earth," *Annual Review of Earth and Planetary Sciences*, 18:205–256 (1990), a review of his and others' work in the field. (T.C.O.)

The Sun. Popular works on the Sun include HERBERT FRIEDMAN, *Sun and Earth* (1986); RONALD G. GIOVANELLI, *Secrets of the Sun* (1984); and ROBERT W. NOYES, *The Sun, Our Star* (1982). KARL HUFBAUER, *Exploring the Sun: Solar Science Since Galileo* (1991), chronicles the history of developments in this field. Works of a more technical nature include PETER FOUKAL, *Solar Astrophysics* (1990); R.O. PEPIN, J.A. EDDY, and R.B. MERRILL, *The Ancient Sun: Fossil Record in the Earth, Moon, and Meteorites* (1980); MICHAEL STIX, *The Sun: An Introduction* (1989), showing the many techniques and ideas utilized to study the Sun; WASABURO UNNO *et al.*, *Nonradial Oscillations of Stars* (1979); HAROLD ZIRIN, *Astrophysics of the Sun* (1988); A.N. COX, W.C. LIVINGSTON, and M.S. MATTHEWS (eds.), *Solar Interior and Atmosphere* (1991); and papers from three Skylab Solar Workshops: JACK B. ZIRKER (ed.), *Coronal Holes and High Speed Wind Streams* (1977); PETER A. STURROCK, *Solar Flares* (1980); and FRANK Q. ORRALL, *Solar Active Regions* (1981). (H.Zi.)

The planets and their moons. *Mercury:* ROBERT G. STROM and ANN L. SPRAGUE, *Exploring Mercury: The Iron Planet* (2003), by two expert researchers in the field, was written during the development of the Messenger spacecraft mission. J. KELLY BEATTY, CAROLYN COLLINS PETERSEN, and ANDREW CHAIKIN (eds.), *The New Solar System*, 4th ed. (1999), contains several chapters of information related to Mercury, especially in the context of the terrestrial planets. FAITH VILAS, CLARK R. CHAPMAN, and MILDRED SHAPLEY MATTHEWS (eds.), *Mercury* (1988), is a comprehensive collection of technical chapters and overviews covering knowledge of the planet to the time of publication, with an extensive bibliography. Nontechnical treatments of the Mariner 10 mission are found in BRUCE MURRAY and ERIC BURGESS, *Flight to Mercury* (1977); and JAMES A. DUNNE and ERIC BURGESS, *The Voyage of Mariner 10: Mission to Venus and Mercury*, NASA Special Publication 424 (1978); the latter is a well-illustrated account of the drama surrounding the mission, with pictures of people, instruments, and trajectories plus a large collection of images and maps of Mercury. An excellent collection of Mariner 10 photographs is available in MERTON E. DAVIES *et al.* (eds.), *Atlas of Mercury* (1976). (C.R.C.)

Venus: LADISLAV E. ROTH and STEPHEN D. WALL (eds.), *The Face of Venus: The Magellan Radar-Mapping Mission* (1995), is a good post-Magellan popular-level book on the Venusian surface, with many excellent illustrations. Still informative pre-Magellan popular-level treatments include GARRY E. HUNT and PATRICK MOORE, *The Planet Venus* (1982); and ERIC BURGESS, *Venus, an Errant Twin* (1985). The scientific understanding of Venus is definitively and comprehensively summarized in S.W. BOUGHER, D.M. HUNTEN, and R.J. PHILLIPS (eds.), *Venus II* (1997), a collection of papers written after the Magellan and Galileo missions. MIKHAIL YA. MAROV and DAVID H. GRINSPOON, *The Planet Venus* (1998), provides an excellent post-Magellan treatment of Venusian geology and most other aspects of the planet. A pre-Magellan overview of Venus' surface is given by ALEXANDER T. BASILEVSKY and JAMES W. HEAD III, "The Geology of Venus," *Annual Review of Earth and Planetary Sciences*, 16:295–317 (1988). An interesting collection of papers by Soviet scientists in English on Venus is V.L. BARSUKOV *et al.* (eds.), *Venus Geology, Geochemistry, and Geophysics* (1992). The results of major spacecraft missions to Venus are reported in several journals: on Pioneer Venus, *Journal of Geophysical Research*, 85:7573–8337 (1980); V.L. BARSUKOV *et al.*, "The Geology and Geomorphology of the Venus Surface as Revealed by the Radar Images Obtained by Veneras 15 and 16," *Journal of Geophysical Research*, part B, *Solid Earth and Planets*, 91(B4):D378–D398 (March 30, 1986); *Science*, 253:1457–1612 (Sept. 27, 1991), an issue devoted to the Galileo flyby of Venus; and two issues of *Journal of Geophysical Research*, part E, *Planets*, vol. 97, devoted to detailed Magellan mission results, no. 8 (Aug. 25, 1992) and no. 10 (Oct. 25, 1992). (S.W.S.)

Earth: PETER D. WARD and DON BROWNLEE, *Rare Earth: Why Complex Life Is Uncommon in the Universe*, 2nd rev. ed. (2003), lays out for general readers a case for the uncommon nature of planet Earth. JONATHAN I. LUNINE, *Earth: Evolution of a Habitable World* (1999); and JOHN J.W. ROGERS, *A History of the Earth* (1993), provide comprehensive introductions to Earth from, respectively, planetological and geologic perspectives. WILLIAM K. HARTMANN, *The History of Earth: An Illustrated Chronicle of an Evolving Planet* (1991), is a lavishly illustrated introduction. A graduate-level text comprising excellent chapters on its subject matter is ROBIN M. CANUP and KEVIN RIGHTER (eds.), *Origin of the Earth and Moon* (2000). A popular and balanced account of the physical causes of mass extinctions is given in CHARLES FRANKEL, *The End of the Dinosaurs: Chicxulub Crater and Mass Extinctions* (1999; originally published in French, 1996). The periodical *Scientific American* (monthly) is an excellent and accessible source for the latest thinking on Earth and planetary processes; see, for example, a good description of plate tectonics in IAN W.D. DALZIEL, "Earth Before Pangea," 272(1):58–63 (January 1995). The *State of the World* report (annual), published by the Worldwatch Institute, provides authoritative updates on Earth's vital signs for the general reader. (J.I.L.)

The Moon: Revival of interest in the Moon and in lunar exploration after the long post-Apollo hiatus is reflected in PAUL D. SPUDIS, *The Once and Future Moon* (1996), a readable and well-illustrated summary of recent scientific knowledge as well as arguments advocating continued exploration and eventual human return to the Moon. The rich and expanding scientific literature about the Moon is well represented in *Proceedings of Lunar and Planetary Science*, published collections of papers from the annual Lunar and Planetary Science Conference. The finest book about lunar exploration remains DAVIS THOMAS (ed.), *Moon: Man's Greatest Adventure*, rev. ed. (1973), splendidly illustrated, with text by scholars describing the history and culture, engineering and projects, and early scientific results of the great human drive that began in ancient times and culminated in the Apollo missions. A more modest but still comprehensive and well-illustrated book is PATRICK MOORE, *The Moon* (1981, reprinted 1984). DON E. WILHELMS, *The Geologic History of the Moon* (1987), is illustrated with many beautiful explanatory pictures and drawings. Examples of relevant literature on theories of lunar origin include W.K. HARTMANN, R.J. PHILLIPS, and G.J. TAYLOR (eds.), *Origin of the Moon* (1986); and A.V. VITIAZEV, G.V. PECHERNIKOVA, and V.S. SAFRONOV, *Planety zemnoy gruppy: proiskhozhdeniye i rannyaya evolyutsiya* ("Terrestrial Planets: Their Origin and Early Evolution"; 1990). STUART ROSS TAYLOR, *Planetary Science: A Lunar Perspective* (1982); and W.W. MENDELL (ed.), *Lunar Bases and Space Activities of the 21st Century* (1985), are collections of specialized papers, although most of the material is accessible to the general reader. The realization that the Moon is an enormous storehouse of resources that may be useful to humankind in the future has prompted several publications, including GERARD K. O'NEILL, *The High Frontier*, 3rd ed. (2000); a series of conference papers, *Space Manufacturing* (biennial); and a book commissioned by NASA to serve as a primary reference, GRANT HEIKEN, DAVID VANIMAN, and BEVAN M. FRENCH (eds.), *Lunar Sourcebook: A User's Guide to the Moon* (1991), which with its compendious bibliography is an excellent summary of what is known about the Moon. PETER ECKART (ed.), *The Lunar Base Handbook: An Introduction to Lunar Base Design, Development, and Operations* (1999), gives up-to-date information on lunar resources and their uses, plus engineering and scientific aspects of the creation of human habitats on the Moon. (J.D.Bu.)

Mars: DONALD GOLDSMITH, *The Hunt for Life on Mars* (1997), describes the events that led to the controversial claims for evidence of life in the Martian meteorite ALH84001. JOHN NOBLE WILFORD, *Mars Beckons: The Mysteries, the Challenges, the Expectations of Our Next Great Adventure in Space* (1990), provides a general introduction to the planet. All aspects of Mars science are addressed in HUGH H. KIEFFER *et al.* (eds.), *Mars* (1992), a huge, comprehensive technical summary of existing knowledge. VICTOR R. BAKER, *The Channels of Mars* (1982), is a well-illustrated discussion of how these features came about and their implications for the history of Mars. MICHAEL H. CARR, *The Surface of Mars* (1981), is a profusely illustrated survey of scientists' perception of Mars after the Viking missions, and *Water on Mars* (1996) discusses the role that water has played in the evolution of the Martian surface. Volumes of papers detailing the results of Mars missions appear in the *Journal of Geophysical Research:* for Viking, 82, no. 28 (1977); for Mars Pathfinder, 104, no. E4 (1999), and for Mars Global Surveyor, 106, no. E4 (2001). These results are summarized in several excellent papers in *Nature* 412:207–253 (July 12, 2001). (M.C.Ma./M.H.Ca.)

Jupiter: A comprehensive, popular-level review of knowledge of the Jovian system, including early results from the Galileo space probe, is RETA BEEBE, *Jupiter: The Giant Planet*, 2nd ed. (1997). Detailed descriptions of the Galileo mission and its findings are provided in DAVID M. HARLAND, *Jupiter Odyssey: The Story of NASA's Galileo Mission* (2000); and DANIEL FISCHER, *Mission Jupiter: The Spectacular Journey of the Galileo Spacecraft* (2001). The original reference for visual observations of Jupiter with telescopes of moderate size is BERTRAND M. PEEK, *The Planet Jupiter*, rev. by PATRICK MOORE (1981). A more recent account that includes results from the Voyager space probes is

JOHN H. ROGERS, *The Giant Planet Jupiter* (1995). Details regarding the Voyager missions may be found in DAVID MORRISON and JANE SAMZ, *Voyage to Jupiter* (1980). (T.C.O.)

Saturn: DAVID MORRISON, *Voyages to Saturn* (1982), is a nontechnical presentation. More advanced treatments are contained in TOM GEHRELS and MILDRED SHAPLEY MATTHEWS (eds.), *Saturn* (1984), a collection of essays. Journal articles include G.F. LINDAL, D.N. SWEETNAM, and V.R. ESHLEMAN, "The Atmosphere of Saturn: An Analysis of the Voyager Radio Occultation Measurements," *The Astronomical Journal,* 90(6):1136–1146 (June 1984), specific experimental results on the structure of Saturn's atmosphere; and two issues of *Journal of Geophysical Research,* part A, *Space Physics:* vol. 85, no. A11 (Nov. 1, 1980), devoted to Pioneer 11 results, and vol. 88, no. A11 (Nov. 1, 1983), devoted to Voyager 1 and 2 results. (W.B.H.)

Uranus: A.P. INGERSOLL, "Uranus," *Scientific American,* 256(1):30–37 (January 1987), provides an introductory review article with illustrations and diagrams. GARRY HUNT and PATRICK MOORE, *Atlas of Uranus* (1989), offers an in-depth introduction. The first reports of the Voyager 2 encounter written by the Voyager scientists are included in a set of 12 articles in *Science,* 233(4759):39–109 (July 4, 1986), which contains most of the best images of the planet, its satellites, and its rings. JAY T. BERGSTRALH, ELLIS D. MINER, and MILDRED SHAPLEY MATTHEWS (eds.), *Uranus* (1991), with chapters written by specialists in the field, is the definitive reference work on the subject. ELLIS D. MINER, *Uranus: The Planet, Rings, and Satellites* (1990), reviews current knowledge of the planet, with much background information on the Voyager mission. GARRY HUNT (ed.), *Uranus and the Outer Planets* (1982), is a pre-Voyager summary dealing almost exclusively with Uranus, with some interesting historical chapters. ERIC BURGESS, *Uranus and Neptune: The Distant Giants* (1988), also focuses primarily on Uranus. MARK LITTMANN, *Planets Beyond: Discovering the Outer Solar System,* updated and rev. ed. (1990), chronicles the history of the discovery of Uranus, Neptune, and Pluto. (A.P.I.)

Neptune: PATRICK MOORE, *The Planet Neptune* (1988), provides a good summary of pre-Voyager knowledge of the planet. A set of articles in *Science,* 246(4936):1417–1501 (Dec. 15, 1989), comprises the initial report of the Voyager findings at Neptune; more detailed reports of the findings are in a set of articles in *Journal of Geophysical Research, Supplement,* 96:18,-903–19,268 (Oct. 30, 1991); and ERIC BURGESS, *Far Encounter: The Neptune System* (1991), a popular work which also contains some discussion of Pluto. See also the work by Littmann cited above for Uranus. (E.D.M.)

Pluto: S.A. STERN and J. MITTON, *Pluto and Charon: Ice Worlds on the Ragged Edge of the Solar System* (1998, reissued 2000), is a popular-level discussion of the Pluto-Charon system. An authoritative collection of papers by experts in the field is presented in S.A. STERN and DAVID J. THOLEN (eds.), *Pluto and Charon* (1997). CLYDE W. TOMBAUGH and PATRICK MOORE, *Out of the Darkness, the Planet Pluto* (1980), is the story of the planet's discovery cowritten by its discoverer (Tombaugh). The detection of Charon is reported in articles by its discoverers in J.W. CHRISTY and R.S. HARRINGTON, "The Satellite of Pluto," *The Astronomical Journal,* 83(8):1005–08 (August 1978), and "The Discovery and Orbit of Charon," *Icarus,* 44(1):38–40 (October 1980). See also the work by Littmann cited above for Uranus. (T.C.O.)

Other constituents of the solar system. A.H. DELSEMME (ed.), *Comets, Asteroids, Meteorites: Interrelations, Evolution, and Origins* (1977), an extensive collection of colloquium papers, provides a scholarly overview of the minor solar system bodies addressed below. (A.H.De.)

Asteroids: Summary articles can be found in RICHARD P. BINZEL, M. ANTONIETTA BARUCCI, and MARCELLO FULCHIGNONI, "The Origins of the Asteroids," *Scientific American,* 265(4):88–94 (October 1991). Review and research papers are collected in RICHARD P. BINZEL, TOM GEHRELS, and MILDRED SHAPLEY MATTHEWS (eds.), *Asteroids II* (1989); and C.-I. LAGERKVIST *et al.* (eds.), *Asteroids, Comets, Meteors III* (1990). (E.F.T.)

Comets: General introductory works are ARMAND H. DELSEMME, "Whence Come Comets?" *Sky and Telescope,* 77(3):260–264 (March 1989), an elementary discussion on their origin; FRED L. WHIPPLE and DANIEL W.E. GREEN, *The Mystery of Comets* (1985); and ROBERT D. CHAPMAN and JOHN C. BRANDT, *The Comet Book: A Guide for the Return of Halley's Comet* (1984), a historical treatment. More advanced are R.L. NEWBURN, JR., M. NEUGEBAUER, and J. RAHE (eds.), *Comets in the Post-Halley Era,* 2 vol. (1991), containing reviews, summaries, and scientific papers by about 100 authors; K.S. KRISHNA SWAMY, *Physics of Comets* (1986), including a section on spectroscopy; and JOHN C. BRANDT and ROBERT D. CHAPMAN, *Introduction to Comets* (1981). DONALD K. YEOMANS, *Comets: A Chronological History of Observation, Science, Myth, and Folklore* (1991), is a comprehensive reference book on all cometary apparitions, full of anecdotes. LAUREL L. WILKENING and MILDRED SHAPLEY MATTHEWS (eds.), *Comets* (1982), is a definitive collection of essays covering all aspects at a technical level. See also D.A. MENDIS, H.L.F. HOUPIS, and M.L. MARCONI, "The Physics of Comets," *Fundamentals of Cosmic Physics,* 10 (1–4):1–380 (1985). BRIAN G. MARSDEN, *Catalogue of Cometary Orbits,* 7th ed. (1992), covers 1,353 cometary orbits, with detailed references and notes; a complementary volume is GARY W. KRONK, *Comets: A Descriptive Catalog* (1984). (A.H.De.)

Meteoroids, meteors, and meteorites: Introductory information can be found in HARRY Y. MCSWEEN, JR., *Meteorites and Their Parent Planets* (1987); ROBERT T. DODD, *Thunderstones and Shooting Stars: The Meaning of Meteorites* (1986); JOHN G. BURKE, *Cosmic Debris: Meteorites in History* (1986); ROBERT HUTCHISON, *The Search for Our Beginning: An Enquiry, Based on Meteorite Research, into the Origin of Our Planet and of Life* (1983); and JOHN A. WOOD, *Meteorites and the Origin of Planets* (1968). More advanced treatments are JOHN T. WASSON, *Meteorites: Their Record of Early Solar-System History* (1985), and *Meteorites: Classification and Properties* (1974); V.A. BRONSHTEN, *Physics of Meteoric Phenomena* (1983; originally published in Russian, 1981); and ROBERT T. DODD, *Meteorites: A Petrologic-Chemical Synthesis* (1981). A descriptive and historical treatment of iron meteorites, including beautiful photographs, is VAGN F. BUCHWALD, *Handbook of Iron Meteorites, Their Distribution, Composition, and Structure,* 3 vol. (1975). H.H. NININGER, *Out of the Sky: An Introduction to Meteorites* (1952, reprinted 1959), provides firsthand experiences of fall phenomena on a nontechnical level. See also D.E. BROWNLEE, "Cosmic Dust: Collection and Research," *Annual Reviews of Earth and Planetary Sciences,* 13:147–173 (1985). A catalog of known meteorites, including data regarding their fall, is A.L. GRAHAM, A.W.R. BEVAN, and R. HUTCHISON (eds.), *Catalogue of Meteorites,* 4th ed. rev. and enlarged (1985). There are two journals devoted to papers on meteorites and related bodies: *Meteoritika* (annual), published in Russia; and *Meteoritics and Planetary Science* (monthly). Many papers on meteorites are published in *Geochimica et Cosmochimica Acta* (semimonthly). (G.W.We.)

Sound

One question that has long been argued over, by philosophers as well as children, is whether a tree falling in a forest where nobody can hear it fall will actually make a sound. This article defines sound as mechanical vibrations traveling through the air or some other medium at a frequency to which the human ear is sensitive. Therefore, it would answer the above question in the affirmative, arguing that the mechanical vibrations composing a sound wave do exist whether or not anyone is present to hear them.

The science of sound is called acoustics, a word derived from the Greek *akoustos,* meaning "hearing." Beginning with its origins in the study of mechanical vibrations and the radiation of these vibrations through mechanical waves, acoustics has had important applications in almost every area of life. It has been fundamental to many developments in the arts—some of which, especially in the area of musical scales and instruments, took place after long experimentation by artists and were only much later explained as theory by scientists. For example, much of what is now known about architectural acoustics was actually learned by trial and error over centuries of experience and was only recently formalized into a science. Other applications of acoustic technology are in the study of geologic, atmospheric, and underwater phenomena. Psychoacoustics, the study of the physical effects of sound on biological systems, has been of interest since Pythagorus first heard the sounds of vibrating strings and of hammers hitting anvils in the 6th century BC, but the application of modern ultrasonic technology has only recently provided some of the most exciting developments in medicine. Even today, research continues into many aspects of the fundamental physical processes involved in waves and sound and into possible applications of these processes in modern life.

This article begins with an explanation of the physical properties of waves and sound and then discusses applications of acoustics to the areas of science, technology, the arts, and medicine. Also discussed are the related sciences of ultrasonics and infrasonics, which technically are not sound because they are not perceived by the ear but which have very important applications in modern technology.

Sound waves follow physical principles that can be applied to the study of all waves; these principles are discussed thoroughly in the *Macropædia* article MECHANICS. The article SENSORY RECEPTION explains in detail the physiological process of hearing—that is, receiving certain wave vibrations and interpreting them as sound.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 128 and 735, and the *Index.*

The article is divided into the following sections:

History of acoustics 556
  Early experimentation 556
  Measuring the speed of sound 557
  Modern advances 557
  Amplifying, recording, and reproducing 558
The propagation and perception of sound 558

History of acoustics

EARLY EXPERIMENTATION

The origin of the science of acoustics is generally attributed to the Greek philosopher Pythagorus (6th century BC), whose experiments on the properties of vibrating strings that produce pleasing musical intervals were of such merit that they led to a tuning system that bears his name. Aristotle (4th century BC) correctly suggested that a sound wave propagates in air through motion of the air—a hypothesis based more on philosophy than on experimental physics; however, he also incorrectly suggested that high frequencies propagate faster than low frequencies—an error that persisted for many centuries. Vitruvius, a Roman architectural engineer of the 1st century BC, determined the correct mechanism for the transmission of sound waves, and he contributed substantially to the acoustic design of theatres. In the 6th century AD, the Roman philosopher Boethius documented several ideas relating science to music, including a suggestion that the human perception of pitch is related to the physical property of frequency.

The modern study of waves and acoustics is said to have originated with Galileo Galilei (1564–1642), who elevated to the level of science the study of vibrations and the correlation between pitch and frequency of the sound source. His interest in sound was inspired in part by his father, who was a mathematician, musician, and composer of some repute. Following Galileo's foundation work, progress in acoustics came relatively rapidly. The French mathematician Marin Mersenne studied the vibration of stretched

strings; the results of these studies were summarized in the three Mersenne's laws. Mersenne's *Harmonicorum Libri* (1636) provided the basis for modern musical acoustics. Later in the century Robert Hooke, an English physicist, first produced a sound wave of known frequency, using a rotating cog wheel as a measuring device. Further developed in the 19th century by the French physicist Félix Savart, and now commonly called Savart's disk, this device is often used today for demonstrations during physics lectures. In the late 17th and early 18th centuries, detailed studies of the relationship between frequency and pitch and of waves in stretched strings were carried out by the French physicist Joseph Sauveur, who provided a legacy of acoustic terms used to this day and first suggested the name acoustics for the study of sound.

The "bell-in-vacuum" experiment

One of the most interesting controversies in the history of acoustics involves the famous and often misinterpreted "bell-in-vacuum" experiment, which has become a staple of contemporary physics lecture demonstrations. In this experiment the air is pumped out of a jar in which a ringing bell is located; as air is pumped out, the sound of the bell diminishes until it becomes inaudible. As late as the 17th century many philosophers and scientists believed that sound propagated via invisible particles originating at the source of the sound and moving through space to affect the ear of the observer. The concept of sound as a wave directly challenged this view, but it was not established experimentally until the first bell-in-vacuum experiment was performed by Athanasius Kircher, a German scholar, who described it in his book *Musurgia Universalis* (1650). Even after pumping the air out of the jar, Kircher could still hear the bell, so he concluded incorrectly that air was not required to transmit sound. In fact, Kircher's jar was not entirely free of air, probably because of inadequacy in his vacuum pump. By 1660 the Anglo-Irish scientist Robert Boyle had improved vacuum technology to the point where he could observe sound intensity decreasing virtually to zero as air was pumped out. Boyle then came to the correct conclusion that a medium such as air is required for transmission of sound waves. Although this conclusion is correct, as an explanation for the results of the bell-in-vacuum experiment it is misleading. Even with the mechanical pumps of today, the amount of air remaining in a vacuum jar is more than sufficient to transmit a sound wave. The real reason for a decrease in sound level upon pumping air out of the jar is that the bell is unable to transmit the sound vibrations efficiently to the less dense air remaining, and that air is likewise unable to transmit the sound efficiently to the glass jar. Thus, the real problem is one of an impedance mismatch between the air and the denser solid materials—and not the lack of a medium such as air, as is generally presented in textbooks. Nevertheless, despite the confusion regarding this experiment, it did aid in establishing sound as a wave rather than as particles. (For further discussion of the concept of acoustic impedance, see below *The propagation and perception of sound.*)

MEASURING THE SPEED OF SOUND

Once it was recognized that sound is in fact a wave, measurement of the speed of sound became a serious goal. In the 17th century, the French scientist and philosopher Pierre Gassendi made the earliest known attempt at measuring the speed of sound in air. Assuming correctly that the speed of light is effectively infinite compared with the speed of sound, Gassendi measured the time difference between spotting the flash of a gun and hearing its report over a long distance on a still day. Although the value he obtained was too high—about 478.4 metres per second (1,569.6 feet per second)—he correctly concluded that the speed of sound is independent of frequency. In the 1650s, Italian physicists Giovanni Alfonso Borelli and Vincenzo Viviani obtained the much better value of 350 metres per second using the same technique. Their compatriot G.L. Bianconi demonstrated in 1740 that the speed of sound in air increases with temperature. The earliest precise experimental value for the speed of sound, obtained at the Academy of Sciences in Paris in 1738, was 332 metres per second—incredibly close to the presently accepted value, considering the rudimentary nature of the measuring tools of the day. A more recent value for the speed of sound, 331.45 metres per second (1,087.4 feet per second), was obtained in 1942; it was amended in 1986 to 331.29 metres per second at 0° C (1,086.9 feet per second at 32° F).

The speed of sound in air

The speed of sound in water was first measured by Daniel Colladon, a Swiss physicist, in 1826. Strangely enough, his primary interest was not in measuring the speed of sound in water but in calculating water's compressibility—a theoretical relationship between the speed of sound in a material and the material's compressibility having been established previously. Colladon came up with a speed of 1,435 metres per second at 8° C; the presently accepted value interpolated at that temperature is about 1,439 metres per second.

Two approaches were employed to determine the velocity of sound in solids. In 1808 Jean-Baptiste Biot, a French physicist, conducted direct measurements of the speed of sound in 1,000 metres of iron pipe by comparing it with the speed of sound in air. A better measurement had earlier been carried out by a German, Ernst Florenz Friedrich Chladni, using analysis of the nodal pattern in standing-wave vibrations in long rods.

MODERN ADVANCES

Simultaneous with these early studies in acoustics, theoreticians were developing the mathematical theory of waves required for the development of modern physics, including acoustics. In the early 18th century, the English mathematician Brook Taylor developed a mathematical theory of vibrating strings that agreed with previous experimental observations, but he was not able to deal with vibrating systems in general without the proper mathematical base. This was provided by Isaac Newton of England and Gottfried Wilhelm Leibniz of Germany, who, in pursuing other interests, independently developed the theory of calculus, which in turn allowed the derivation of the general wave equation by the French mathematician and scientist Jean Le Rond d'Alembert in the 1740s. The Swiss mathematicians Daniel Bernoulli and Leonhard Euler, as well as the Italian-French mathematician Joseph-Louis Lagrange, further applied the new equations of calculus to waves in strings and in the air. In the 19th century, Siméon-Denis Poisson of France extended these developments to stretched membranes, and the German mathematician Rudolf Friedrich Alfred Clebsch completed Poisson's earlier studies. A German experimental physicist, August Kundt, developed a number of important techniques for investigating properties of sound waves. These included the Kundt's tube, discussed below (see *The propagation and perception of sound: Standing waves*).

One of the most important developments in the 19th century involved the theory of vibrating plates. In addition to his work on the speed of sound in metals, Chladni had earlier introduced a technique of observing standing-wave patterns on vibrating plates by sprinkling sand onto the plates—a demonstration commonly used today. Perhaps the most significant step in the theoretical explanation of these vibrations was provided in 1816 by the French mathematician Sophie Germain, whose explanation was of such elegance and sophistication that errors in her treatment of the problem were not recognized until some 35 years later, by the German physicist Gustav Robert Kirchhoff.

Early spectral analysis

The analysis of a complex periodic wave into its spectral components was theoretically established early in the 19th century by Jean-Baptiste-Joseph Fourier of France and is now commonly referred to as the Fourier theorem. The German physicist Georg Simon Ohm first suggested that the ear is sensitive to these spectral components; his idea that the ear is sensitive to the amplitudes but not the phases of the harmonics of a complex tone is known as Ohm's law of hearing (distinguishing it from the more famous Ohm's law of electrical resistance).

Hermann von Helmholtz made substantial contributions to understanding the mechanisms of hearing and to the psychophysics of sound and music. His book *On the Sensations of Tone As a Physiological Basis for the Theory of Music* (1863) is one of the classics of acoustics. In addition, he constructed a set of resonators, covering much of

the audio spectrum, which were used in the spectral analysis of musical tones. The Prussian physicist Karl Rudolph Koenig, an extremely clever and creative experimenter, designed many of the instruments used for research in hearing and music, including a frequency standard and the manometric flame. The flame-tube device, used to render standing sound waves "visible," is still one of the most fascinating of physics classroom demonstrations. The English physical scientist John William Strutt, 3rd Baron Rayleigh, carried out an enormous variety of acoustic research; much of it was included in his two-volume treatise, *The Theory of Sound*, publication of which in 1877–78 is now thought to mark the beginning of modern acoustics. Much of Rayleigh's work is still directly quoted in contemporary physics textbooks.

The study of ultrasonics was initiated by the American scientist John LeConte, who in the 1850s developed a technique for observing the existence of ultrasonic waves with a gas flame. This technique was later used by the British physicist John Tyndall for the detailed study of the properties of sound waves. The piezoelectric effect, a primary means of producing and sensing ultrasonic waves, was discovered by the French physical chemist Pierre Curie and his brother Jacques in 1880. Applications of ultrasonics, however, were not possible until the development in the early 20th century of the electronic oscillator and amplifier, which were used to drive the piezoelectric element.

Among 20th-century innovators were the American physicist Wallace Sabine, considered to be the originator of modern architectural acoustics, and the Hungarian-born American physicist Georg von Békésy, who carried out experimentation on the ear and hearing and validated the commonly accepted place theory of hearing first suggested by Helmholtz. Békésy's book *Experiments in Hearing*, published in 1960, is the magnum opus of the modern theory of the ear.

AMPLIFYING, RECORDING, AND REPRODUCING

The earliest known attempt to amplify a sound wave was made by Athanasius Kircher, of "bell-in-vacuum" fame; Kircher designed a parabolic horn that could be used either as a hearing aid or as a voice amplifier. The amplification of body sounds became an important goal, and the first stethoscope was invented by a French physician, René Laënnec, in the early 19th century.

Attempts to record and reproduce sound waves originated with the invention in 1857 of a mechanical sound-recording device called the phonautograph by Édouard-Léon Scott de Martinville. The first device that could actually record and play back sounds was developed by the American inventor Thomas Alva Edison in 1877. Edison's phonograph employed grooves of varying depth in a cylindrical sheet of foil, but a spiral groove on a flat rotating disk was introduced a decade later by the German-born American inventor Emil Berliner in an invention he called the gramophone. Much significant progress in recording and reproduction techniques was made during the first half of the 20th century, with the development of high-quality electromechanical transducers and linear electronic circuits. The most important improvement on the standard phonograph record in the second half of the century was the compact disc, which employed digital techniques developed in mid-century that substantially reduced noise and increased the fidelity and durability of the recording.

The phonograph

The propagation and perception of sound

As stated above, sound is essentially a wave, so that a discussion of sound should begin with the properties of sound waves. There are two basic types of wave, transverse and longitudinal, differentiated by the way in which the wave is propagated. In a transverse wave, such as the wave generated in a stretched rope when one end is wiggled back and forth, the motion that constitutes the wave is perpendicular, or transverse, to the direction (along the rope) in which the wave is moving. An important family of transverse waves is generated by electromagnetic sources such as light or radio, in which the electric and magnetic fields constituting the wave oscillate perpendicular to the direction of propagation.

Sound propagates through air or other mediums as a longitudinal wave, in which the mechanical vibration constituting the wave occurs along the direction of propagation of the wave. A longitudinal wave can be created in a coiled spring by squeezing several of the turns together to form a compression and then releasing them, allowing the compression to travel the length of the spring. Air can be viewed as being composed of layers analogous to such coils, with a sound wave propagating as layers of air "push" and "pull" at one another much like the compression moving down the spring.

Sound as a longitudinal wave

A sound wave thus consists of alternating compressions and rarefactions, or regions of high pressure and low pressure, moving at a certain speed. Put another way, it consists of a periodic (that is, oscillating or vibrating) variation of pressure occurring around the equilibrium pressure prevailing at a particular time and place. Equilibrium pressure and the sinusoidal variations caused by passage of a pure sound wave (that is, a wave of a single frequency) are represented in Figure 1A and 1B, respectively.

PLANE WAVES

A discussion of sound waves and their propagation can begin with an examination of a plane wave of a single frequency passing through the air. A plane wave is a wave that propagates through space as a plane, rather than as a sphere of increasing radius. As such, it is not perfectly representative of sound (see below *Circular and spherical waves*). A wave of single frequency would be heard as a pure sound such as that generated by a tuning fork that has been lightly struck. As a theoretical model, it helps to elucidate many of the properties of a sound wave.

Wavelength, period, and frequency. Figure 1C is another representation of the sound wave illustrated in Figure 1B. As represented by the sinusoidal curve, the pressure variation in a sound wave repeats itself in space over a specific distance. This distance is known as the wavelength of the sound, usually measured in metres and represented by λ. As the wave propagates through the air, one full wavelength takes a certain time period to pass a specific point in space; this period, represented by T, is usually measured in fractions of a second. In addition, during each one-second time interval, a certain number of wavelengths pass a point in space. Known as the frequency of the sound wave, the number of wavelengths passing per second is traditionally measured in hertz or kilohertz and is represented by f.

There is an inverse relation between a wave's frequency and its period, such that

$$fT = 1 \text{ or } f = \frac{1}{T}. \qquad (1)$$

This means that sound waves with high frequencies have short periods, while those with low frequencies have long periods. For example, a sound wave with a frequency of 20 hertz would have a period of 0.05 second (*i.e.*, 20 wavelengths/second $\times$ 0.05 second/wavelength = 1), while a sound wave of 20 kilohertz would have a period of 0.00005 second (20,000 wavelengths/second $\times$ 0.00005 second/wavelength = 1). Between 20 hertz and 20 kilohertz lies the frequency range of hearing for humans. The physical property of frequency is perceived physiologically as pitch, so that the higher the frequency, the higher the perceived pitch. There is also a relation between the wavelength of a sound wave, its frequency or period, and the speed of the wave (S), such that

The frequency range of human hearing

$$S = f\lambda = \frac{\lambda}{T}. \qquad (2)$$

Amplitude and intensity. *Mathematical values.* The equilibrium value of pressure, represented by the evenly spaced lines in Figure 1A and by the axis of the graph in Figure 1C, is equal to the atmospheric pressure that would prevail in the absence of the sound wave. With passage of the compressions and rarefactions that constitute the sound wave, there would occur a fluctuation above and below atmospheric pressure. The magnitude of this fluctu-

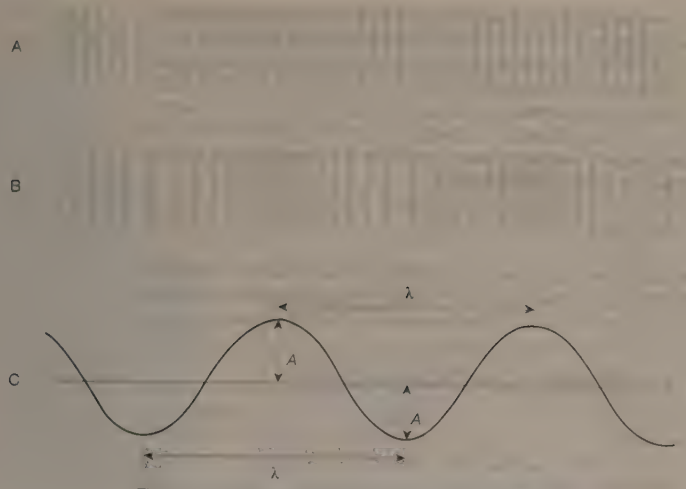

Figure 1: *Graphic representations of a sound wave.*
(A) Air at equilibrium, in the absence of a sound wave; (B) compressions and rarefactions that constitute a sound wave; (C) transverse representation of the wave, showing amplitude (A) and wavelength (λ).

ation from equilibrium is known as the amplitude of the sound wave; measured in pascals, or newtons per square metre, it is represented by the letter A. The displacement or disturbance of a plane sound wave can be described mathematically by the general equation for wave motion, which is written in simplified form as:

$$y(x,t) = A \sin 2\pi(ft - x/\lambda). \quad (3)$$

This means that the size of the disturbance (y), for any value of time (t) or distance (x) away from the source of the sound, is equal to the amplitude (A) times the sine of 2π, times a quantity equal to the frequency (f) times elapsed time (t) minus the distance from origin (x) divided by the wavelength (λ).

The amplitude of a sound wave determines its intensity, which in turn is perceived by the ear as loudness. Acoustic intensity is defined as the average rate of energy transmission per unit area perpendicular to the direction of propagation of the wave. Its relation with amplitude can be written as

$$I = \frac{A^2}{2\rho S}, \quad (4)$$

where ρ is the equilibrium density of the air (measured in kilograms per cubic metre) and S is the speed of sound (in metres per second). Intensity (I) is measured in watts per square metre, the watt being the standard unit of power in electrical or mechanical usage.

The value of atmospheric pressure under "standard atmospheric conditions" is generally given as about 10^5 pascals, or 10^5 newtons per square metre. The minimum amplitude of pressure variation that can be sensed by the human ear is about 10^{-5} pascal, and the pressure amplitude at the threshold of pain is about 10 pascals, so the pressure variation in sound waves is very small compared with the pressure of the atmosphere. Under these conditions a sound wave propagates in a linear manner—that is, it continues to propagate through the air with very little loss, dispersion, or change of shape. However, when the amplitude of the wave reaches about 100 pascals (approximately one one-thousandth the pressure of the atmosphere), significant nonlinearities develop in the propagation of the wave.

Nonlinearity of high-amplitude waves

Nonlinearity arises from the peculiar effects on air pressure caused by a sinusoidal displacement of air molecules. When the vibratory motion constituting a wave is small, the increase and decrease in pressure are also small and are very nearly equal. But when the motion of the wave is large, each compression generates an excess pressure of greater amplitude than the decrease in pressure caused by each rarefaction. This can be predicted by the ideal gas law, which states that increasing the volume of a gas by one-half decreases its pressure by only one-third, while decreasing its volume by one-half increases the pressure by a factor of two. The result is a net excess in pressure—a phenomenon that is significant only for waves with amplitudes above about 100 pascals.

The decibel scale. The ear mechanism is able to respond to both very small and very large pressure waves by virtue of being nonlinear; that is, it responds much more efficiently to sounds of very small amplitude than to sounds of very large amplitude. Because of the enormous nonlinearity of the ear in sensing pressure waves, a nonlinear scale is convenient in describing the intensity of sound waves. Such a scale is provided by the sound intensity level, or decibel level, of a sound wave, which is defined by the equation

$$L = 10 \log \left(\frac{I}{I_0}\right). \quad (5)$$

Here L represents decibels, which correspond to an arbitrary sound wave of intensity I, measured in watts per square metre. The reference intensity I_0, corresponding to a level of 0 decibels, is approximately the intensity of a wave of 1,000 hertz frequency at the threshold of hearing—about 10^{-12} watt per square metre. Because the decibel scale mirrors the function of the ear more accurately than a linear scale, it has several advantages in practical use; these are discussed in *Hearing*, below.

A fundamental feature of this type of logarithmic scale is that each unit of increase in the decibel scale corresponds to an increase in absolute intensity by a constant multiplicative factor. Thus, an increase in absolute intensity from 10^{-12} to 10^{-11} watt per square metre corresponds to an increase of 10 decibels, as does an increase from 10^{-1} to 1 watt per square metre. The correlation between the absolute intensity of a sound wave and its decibel level is shown in Table 1, along with examples of sounds at each level. When the defining level of 0 decibel (10^{-12} watt per square metre) is taken to be at the threshold of hearing for a sound wave with a frequency of 1,000 hertz, then 130 decibels (10 watts per square metre) corresponds to the threshold of feeling, or the threshold of pain. (Sometimes the threshold of pain is given as 120 decibels, or 1 watt per square metre.)

Table 1: Sound Levels for Nonlinear (Decibel) and Linear (Intensity) Scales

decibels	intensity*	type of sound
130	10	artillery fire at close proximity (threshold of pain)
120	1	amplified rock music; near jet engine
110	10^{-1}	loud orchestral music, in audience
100	10^{-2}	electric saw
90	10^{-3}	bus or truck interior
80	10^{-4}	automobile interior
70	10^{-5}	average street noise; loud telephone bell
60	10^{-6}	normal conversation; business office
50	10^{-7}	restaurant; private office
40	10^{-8}	quiet room in home
30	10^{-9}	quiet lecture hall; bedroom
20	10^{-10}	radio, television, or recording studio
10	10^{-11}	soundproof room
0	10^{-12}	absolute silence (threshold of hearing)

*In watts per square metre.

Although the decibel scale is nonlinear, it is directly measurable, and sound-level meters are available for that purpose. Sound levels for audio systems, architectural acoustics, and other industrial applications are most often quoted in decibels.

The speed of sound. *In gases.* For longitudinal waves such as sound, wave velocity is in general given as the square root of the ratio of the elastic modulus of the medium (that is, the ability of the medium to be compressed by an external force) to its density:

$$S = \sqrt{\frac{B}{\rho}}. \quad (6)$$

Here ρ is the density and B the bulk modulus (the ratio of the applied pressure to the change in volume per unit volume of the medium). In gas mediums this equation is modified to

$$S = \sqrt{\frac{1}{\rho K}}. \quad (7)$$

where K is the compressibility of the gas. Compressibility (K) is the reciprocal of the bulk modulus (B), as in

$$K = \frac{1}{B}. \quad (8)$$

Using the appropriate gas laws, wave velocity can be calculated in two ways, in relation to pressure or in relation to temperature:

$$S = \sqrt{\frac{\gamma p}{\rho}}; \quad (9)$$

or

$$S = \sqrt{\frac{\gamma R\theta}{M}}. \quad (10)$$

Here p is the equilibrium pressure of the gas in pascals, ρ is its equilibrium density in kilograms per cubic metre at pressure p, θ is absolute temperature in kelvins, R is the gas constant per mole, M is the molecular weight of the gas, and γ is the ratio of the specific heat at a constant pressure to the specific heat at a constant volume,

$$\gamma = \sqrt{\frac{C_p}{C_v}}. \quad (11)$$

Values for γ for various gases are given in many physics textbooks and reference works. The speed of sound in several different gases, including air, is given in Table 2.

Table 2: Speed of Sound in Selected Gases

gas	speed	
	(metres/second)	(feet/second)
Helium, at 0° C (32° F)	965	3,165
Nitrogen, at 0° C	334	1,096
Oxygen, at 0° C	316	1,036
Carbon dioxide, at 0° C	259	850
Air, dry, at 0° C	345.45	1,133
Steam, at 134° C (273° F)	494	1,620

Velocity independent of pressure and frequency

Equation (10) states that the speed of sound depends only on absolute temperature and not on pressure, since, if the gas behaves as an ideal gas, then its pressure and density, as shown in equation (9), will be proportional. This means that the speed of sound does not change between locations at sea level and high in the mountains and that the pitch of wind instruments at the same temperature is the same anywhere. In addition, both equations (9) and (10) are independent of frequency, indicating that the speed of sound is in fact the same at all frequencies—that is, there is no dispersion of a sound wave as it propagates through air. One assumption here is that the gas behaves as an ideal gas. However, gases at very high pressures no longer behave like an ideal gas, and this results in some absorption and dispersion. In such cases equations (9) and (10) must be modified, as they are in advanced books on the subject.

In liquids. For a liquid medium, the appropriate modulus is the bulk modulus, so that the speed of sound is equal to the square root of the ratio of the bulk modulus (B) to the equilibrium density (ρ), as shown in equation (6) above. The speed of sound in liquids under various conditions is given in Table 3. The speed of sound in liquids varies slightly with temperature—a variation that is accounted for by empirical corrections to equation (6), as is indicated in the values given for water in Table 3.

Table 3: Speed of Sound in Selected Liquids
(at one atmosphere pressure)

liquid	speed	
	(metres/second)	(feet/second)
Pure water, at 0° C (32° F)	1,402.3	4,600
Pure water, at 30° C (86° F)	1,509.0	4,950
Pure water, at 50° C (122° F)	1,542.5	5,060
Pure water, at 70° C (158° F)	1,554.7	5,100
Pure water, at 100° C (212° F)	1,543.0	5,061
Salt water, at 0° C	1,449.4	4,754
Salt water, at 30° C	1,546.2	5,072
Methyl alcohol, at 20° C (68° F)	1,121.2	3,678
Mercury, at 20° C	1,451.0	4,760

In solids. For a long, thin solid the appropriate modulus is the Young's, or stretching, modulus (the ratio of the applied stretching force per unit area of the solid to the resulting change in length per unit length; named for the English physicist and physician Thomas Young). The speed of sound, therefore, is

$$S = \sqrt{\frac{Y}{\rho}}, \quad (12)$$

where Y is the Young's modulus and ρ is the density. Table 4 gives the speed of sound in representative solids.

In the case of a three-dimensional solid, in which the wave is traveling outward in spherical waves, the above expression becomes more complicated. Both the shear modulus, represented by η, and the bulk modulus B play a role in the elasticity of the medium:

$$S = \sqrt{\frac{(B + 4\eta/3)}{\rho}}. \quad (13)$$

Table 4: Speed of Sound in Selected Solids

solid	speed	
	(metres/second)	(feet/second)
Aluminum, rolled	5,000	16,500
Copper, rolled	3,750	12,375
Iron, cast	4,480	14,784
Lead	1,210	3,993
Pyrex (trademark)	5,170	17,061
Lucite (trademark)	1,840	6,072

CIRCULAR AND SPHERICAL WAVES

The above discussion of the propagation of sound waves begins with a simplifying assumption that the wave exists as a plane wave. In most real cases, however, a wave originating at some source does not move in a straight line but expands in a series of spherical wavefronts. The fundamental mechanism for this propagation is known as

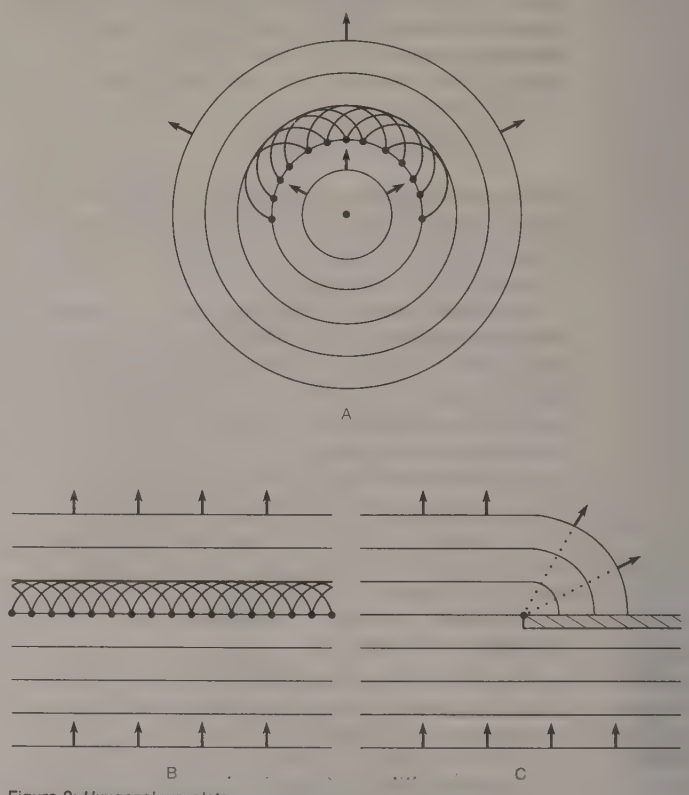

Figure 2: *Huygens' wavelets.*
Originating along the fronts of (A) circular waves and (B) plane waves, wavelets recombine to produce the propagating wave front. (C) The diffraction of sound around a corner arising from Huygens' wavelets.

Huygens' wavelets

Huygens' principle, according to which every point on a wave is a source of spherical waves in its own right. The result is a Huygens' wavelet construction, illustrated in Figure 2A and 2B for a two-dimensional plane wave and circular wave. The insightful point suggested by the Dutch physicist Christiaan Huygens is that all the wavelets of Figure 2A and 2B, including those not shown but originating between those that are shown, form a new coherent wave that moves along at the speed of sound to form the next wave in the sequence. In addition, just as the wavelets add up in the forward direction to create a new wavefront, they also cancel one another, or interfere destructively, in the backward direction, so that the waves continue to propagate only in the forward direction.

The principle behind the adding up of Huygens' wavelets, involving a fundamental difference between matter and waves, is known as the principle of superposition. The old saying that no two things can occupy the same space at the same time is correct when applied to matter, but it does not apply to waves. Indeed, an infinite number of waves can occupy the same space at the same time; furthermore, they do this without affecting one another, so that each wave retains its own character independent of how many other waves are present at the same point and time. A radio or television antenna can receive the signal of any single frequency to which it is tuned, unaffected by the existence of any others. Likewise, the sound waves of two people talking may cross each other, but the sound of each voice is unaffected by the waves' having been simultaneously at the same point.

Superposition plays a key role in many of the wave properties of sound discussed in this section. It is also fundamental to the addition of Fourier components of a wave in order to obtain a complex wave shape (see below *Steady-state waves*).

Attenuation. *The inverse square law.* A plane wave of a single frequency in theory will propagate forever with no change or loss. This is not the case with a circular or spherical wave, however. One of the most important properties of this type of wave is a decrease in intensity as the wave propagates. The mathematical explanation of this principle, which derives as much from geometry as from physics, is known as the inverse square law.

Decreasing intensity of an expanding wave

As a circular wave front (such as that created by dropping a stone onto a water surface) expands, its energy is distributed over an increasingly larger circumference. The intensity, or energy per unit of length along the circumference of the circle, will therefore decrease in an inverse relationship with the growing radius of the circle, or distance from the source of the wave. In the same way, as a spherical wave front expands, its energy is distributed over a larger and larger surface area. Because the surface area of a sphere is proportional to the square of its radius, the intensity of the wave is inversely proportional to the square of the radius. This geometric relation between the growing radius of a wave and its decreasing intensity is what gives rise to the inverse square law.

The decrease in intensity of a spherical wave as it propagates outward can also be expressed in decibels. Each factor of two in distance from the source leads to a decrease in intensity by a factor of four. For example, a factor of four decrease in a wave's intensity is equivalent to a decrease of six decibels, so that a spherical wave attenuates at a rate of six decibels for each factor of two increase in distance from the source. If a wave is propagating as a hemispherical wave above an absorbing surface, the intensity will be further reduced by a factor of two near the surface because of the lack of contributions of Huygens' wavelets from the missing hemisphere. Thus, the intensity of a wave propagating along a level, perfectly absorbent floor falls off at the rate of 12 decibels for each factor of two in distance from the source. This additional attenuation leads to the necessity of sloping the seats of an auditorium in order to retain a good sound level in the rear.

Sound absorption. In addition to the geometric decrease in intensity caused by the inverse square law, a small part of a sound wave is lost to the air or other medium through various physical processes. One important process is the direct conduction of the vibration into the medium as heat, caused by the conversion of the coherent molecular motion of the sound wave into incoherent molecular motion in the air or other absorptive material. Another cause is the viscosity of a fluid medium (*i.e.*, a gas or liquid). These two physical causes combine to produce the classical attenuation of a sound wave. This type of attenuation is proportional to the square of the sound wave's frequency, as expressed in the formula α/f^2, where α is the attenuation coefficient of the medium and f is the wave frequency. The amplitude of an attenuated wave is then given by

$$A(x) = A_o\, e^{-\alpha x}, \tag{14}$$

where A_o is the original amplitude of the wave and $A(x)$ is the amplitude after it has propagated a distance x through the medium.

Table 5 gives sound-absorption coefficients for several gases. The magnitudes of the coefficients indicate that, although attenuation is rather small for audible frequencies, it can become extremely large for high-frequency ultrasonic waves. Attenuation of sound in air also varies with temperature and humidity.

Table 5: Attenuation of Sound in Selected Fluids

fluid	attenuation coefficient $10^{13}\alpha/f^2$ (s^2/cm)
Helium	52.5
Hydrogen	16.9
Nitrogen	133.0
Oxygen	165.0
Air	137.0
Carbon dioxide	140.0
Water, at 0° C (32° F)	0.569
Water, at 20° C (68° F)	0.253
Water, at 80° C (176° F)	0.079
Mercury, at 25° C (77° F)	0.057
Methyl alcohol, at 30° C (86° F)	0.302

Greater propagation of sound in solids and liquids

Because less sound is absorbed in solids and liquids than in gases, sounds can propagate over much greater distances in these mediums. For instance, the great range over which certain sea mammals can communicate is made possible partially by the low attenuation of sound in water. In addition, because absorption increases with frequency, it becomes very difficult for ultrasonic waves to penetrate a dense medium. This is a persistent limitation on the development of high-frequency ultrasonic applications.

Most sound-absorbing materials are nonlinear, in that they do not absorb the same fraction of acoustical waves of all frequencies. In architectural acoustics, an enormous effort is expended to use construction materials that absorb undesirable frequencies but reflect desired frequencies. Absorption of undesirable sound, such as that from machines in factories, is critical to the health of workers, and noise control in architectural and industrial acoustics has expanded to become an important field of environmental engineering.

Diffraction. A direct result of Huygens' wavelets is the property of diffraction, the capacity of sound waves to bend around corners and to spread out after passing through a small hole or slit. If a barrier is placed in the path of half of a plane wave, as shown in Figure 2C, the part of the wave passing just by the barrier will propagate in a series of Huygens' wavelets, causing the wave to spread into the shadow region behind the barrier. In light waves, wavelengths are very small compared with the size of everyday objects, so that very little diffraction occurs and a relatively clear shadow can be formed. The wavelengths of sound waves, on the other hand, are more nearly equal to the size of everyday objects, so that they readily diffract.

Diffraction of sound is helpful in the case of audio systems, in which sound emanating from loudspeakers spreads out and reflects off of walls to fill a room. It is also the reason why "sound beams" cannot generally be produced like light beams. On the other hand, the ability of a sound wave to diffract decreases as frequency rises and wavelength shrinks. This means that the lower frequencies of a voice bend around a corner more readily than the higher frequencies, giving the diffracted voice a "muffled"

sound. Also, because the wavelengths of ultrasonic waves become extremely small at high frequencies, it is possible to create a beam of ultrasound. Ultrasonic beams have become very useful in modern medicine (see below *Applications of sound*).

Scattering of sound

The scattering of a sound wave is a reflection of some part of the wave off of an obstacle around which the rest of the wave propagates and diffracts. The way in which the scattering occurs depends upon the relative size of the obstacle and the wavelength of the scattering wave. If the wavelength is large in relation to the obstacle, then the wave will pass by the obstacle virtually unaffected. In this case, the only part of the wave to be scattered will be the tiny part that strikes the obstacle; the rest of the wave, owing to its large wavelength, will diffract around the obstacle in a series of Huygens' wavelets and remain unaffected. If the wavelength is small in relation to the obstacle, the wave will not diffract strongly, and a shadow will be formed similar to the optical shadow produced by a small light source. In extreme cases, arising primarily with high-frequency ultrasound, the formalism of ray optics often used in lenses and mirrors can be conveniently employed.

If the size of the obstacle is the same order of magnitude as the wavelength, diffraction may occur, and this may result in interference among the diffracted waves. This would create regions of greater and lesser sound intensity, called acoustic shadows, after the wave has propagated past the obstacle. Control of such acoustic shadows becomes important in the acoustics of auditoriums.

Refraction. Diffraction involves the bending or spreading out of a sound wave in a single medium, in which the speed of sound is constant. Another important case in which sound waves bend or spread out is called refraction. This phenomenon involves the bending of a sound wave owing to changes in the wave's speed. Refraction is the reason why ocean waves approach a shore parallel to the beach and why glass lenses can be used to focus light waves. An important refraction of sound is caused by the natural temperature gradient of the atmosphere. Under normal conditions the Sun heats the Earth and the Earth heats the adjacent air. The heated air then cools as it rises, creating a gradient in which atmospheric temperature decreases with elevation by an amount known as the adiabatic lapse rate. Because sound waves propagate faster in warm air, they travel faster closer to the Earth. This greater speed of sound in warmed air near the ground creates Huygens' wavelets that also spread faster near the ground. Because a sound wave propagates in a direction perpendicular to the wave front formed by all the Huygens' wavelets, sound under these conditions tends to refract upward and become "lost." The sound of thunder created by lightning may be refracted upward so strongly that a shadow region is created in which the lightning can be seen but the thunder cannot be heard. This typically occurs at a horizontal distance of about 22.5 kilometres (14 miles) from a lightning bolt about 4 kilometres high.

Greater propagation of sound at night

At night or during periods of dense cloud cover, a temperature inversion occurs; the temperature of the air increases with elevation, and sound waves are refracted back down to the ground. Temperature inversion is the reason why sounds can be heard much more clearly over longer distances at night than during the day—an effect often incorrectly attributed to the psychological result of nighttime quiet. The effect is enhanced if the sound is propagated over water, allowing sound to be heard remarkably clearly over great distances.

Refraction is also observable on windy days. Wind, moving faster at greater heights, causes a change in the effective speed of sound with distance above ground. When one speaks with the wind, the sound wave is refracted back down to the ground, and one's voice is able to "carry" farther than on a still day. When one speaks into the wind, however, the sound wave is refracted upward, away from the ground, and the voice is "lost."

Another example of sound refraction occurs in the ocean. Under normal circumstances the temperature of the ocean decreases with depth, resulting in the downward refraction of a sound wave originating under water—just the opposite of the shadow effect in air described above. Many marine biologists believe that this refraction enhances the propagation of the sounds of marine mammals such as dolphins and whales, allowing them to communicate with one another over enormous distances. For ships such as submarines located near the surface of the water, this refraction creates shadow regions, limiting their ability to locate distant vessels.

Reflection. A property of waves and sound quite familiar in the phenomenon of echoes is reflection. This plays a critical role in room and auditorium acoustics, in large part determining the adequacy of a concert hall for musical performance or other functions. In the case of light waves passing from air through a glass plate, close inspection shows that some of the light is reflected at each of the air-glass interfaces while the rest passes through the glass. This same phenomenon occurs whenever a sound wave passes from one medium into another—that is, whenever the speed of sound changes or the way in which the sound propagates is substantially modified.

The direction of propagation of a wave is perpendicular to the front formed by all the Huygens' wavelets. As a plane wave reflects off some reflector, the reflector directs the wave fronts formed by the Huygens' wavelets just as a light reflector directs light "rays." The same law of reflection is followed for both sound and light, so that focusing a sound wave is equivalent to focusing a light ray.

Focusing of sound

Reflectors of appropriate shape are used for a variety of purposes or effects. For example, a parabolic reflector will focus a parallel wave of sound onto a specific point, allowing a very weak sound to be more easily heard. Such reflectors are used in parabolic microphones to collect sound from a distant source or to choose a location from which sound is to be observed and then focus it onto a microphone. An elliptical shape, on the other hand, can be used to focus sound from one point onto another—an arrangement called a whispering chamber. Domes in cathedrals and capitols closely approximate the shape of an ellipse, so that such buildings often possess focal points and function as a type of whispering chamber. Concert halls must avoid the smooth, curved shape of ellipses and parabolas, because strong echoes or focusing of sound from one point to another are undesirable in an auditorium.

Impedance. One of the important physical characteristics relating to the propagation of sound is the acoustic impedance of the medium in which the sound wave travels. Acoustic impedance (Z) is given by the ratio of the wave's acoustic pressure (p) to its volume velocity (U):

$$Z = \frac{p}{U} \qquad (15)$$

Like its analogue, electrical impedance (or electrical resistance), acoustic impedance is a measure of the ease with which a sound wave propagates through a particular medium. Also like electrical impedance, acoustic impedance involves several different effects applying to different situations. For example, specific acoustic impedance (z), the ratio of acoustic pressure to particle speed, is an inherent property of the medium and of the nature of the wave. Acoustic impedance, the ratio of pressure to volume velocity, is equal to the specific acoustic impedance per unit area. Specific acoustic impedance is useful in discussing waves in confined mediums, such as tubes and horns. For the simplest case of a plane wave, specific acoustic impedance is the product of the equilibrium density (ρ) of the medium and the wave speed (S):

$$z = \rho S. \qquad (16)$$

The unit of specific acoustic impedance is the pascal second per metre, often called the rayl, after Lord Rayleigh. The unit of acoustic impedance is the pascal second per cubic metre, called an acoustic ohm, by analogy to electrical impedance.

Impedance mismatch. Mediums in which the speed of sound is different generally have differing acoustic impedances, so that, when a sound wave strikes an interface between the two, it encounters an impedance mismatch. As a result, some of the wave reflects while some is transmitted into the second medium. This situation is similar to that of a light wave entering glass, where a close

inspection will show that in general some light is reflected while most of the light is transmitted into the glass. In the case of the bell-in-vacuum experiment described above (see *History of acoustics*), the impedance mismatches between the bell and the air and between the air and the jar result in very little transmission of sound when the air is at low pressure.

Reducing the impedance mismatch

The efficiency with which a sound source radiates sound is enhanced by reducing the impedance mismatch between the source and the outside air. For example, if a tuning fork is struck and held in the air, it will be nearly inaudible because of the inability of the vibrations of the tuning fork to radiate efficiently to the air. Touching the tuning fork to a wooden plate such as a tabletop will enhance the sound by providing better coupling between the vibrating tuning fork and the air. This principle is used in the violin and the piano, in which the vibrations of the strings are transferred first to the back and belly of the violin or to the piano's sounding board, and then to the air.

Acoustic filtration. Filtration of sound plays an important part in the design of air-handling systems. In order to attenuate the level of sound from blower motors and other sources of vibration, regions of larger or smaller cross-sectional area are inserted into air ducts, as illustrated in Figure 3. The impedance mismatch introduced into a duct by a change in the area of the duct or by the addition of a side branch reflects undesirable frequencies, as determined by the size and shape of the variation. A region of either larger or smaller area will function as a low-pass filter, reflecting high frequencies; an opening or series of openings will function as a high-pass filter, removing low frequencies. Some automobile mufflers make use of this type of filter.

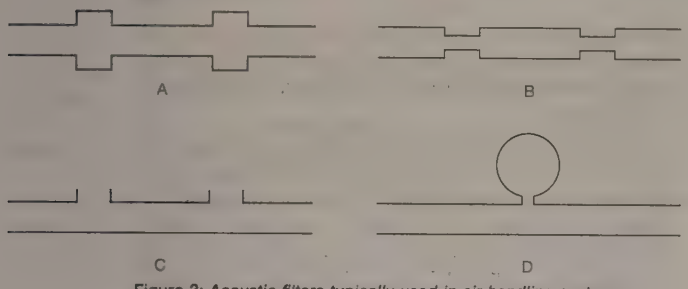

Figure 3: *Acoustic filters typically used in air-handling systems.* (A) and (B) Low-pass filters; (C) a high-pass filter; (D) a band-pass filter, which actually filters out vibrations within a narrow frequency range (see text).

A connected spherical cavity, forming what is called a band-pass filter, actually functions as a type of band absorber or notch filter, removing a band of frequencies around the resonant frequency of the cavity (see below, *Standing waves: The Helmholtz resonator*).

Interference. *Constructive and destructive.* The particular manner in which sound waves can combine is known as interference. Two identical waves in the same place at the same time can interfere constructively if they are in phase or destructively if they are out of phase. "Phase" is a term that refers to the time relationship between two periodic signals. "In phase" means that they are vibrating together, while "out of phase" means that their vibrations are opposite. Opposite vibrations added together cancel each other.

Phase

Constructive interference leads to an increase in the amplitude of the sum wave, while destructive interference can lead to the total cancellation of the contributing waves. An interesting example of both interference and diffraction of sound, called the "speaker and baffle" experiment, involves a small loudspeaker and a large, square wooden sheet with a circular hole in it the size of the speaker. When music is played on the loudspeaker, sound waves from the front and back of the speaker, which are out of phase, diffract into the entire region around the speaker. The two waves interfere destructively and cancel each other, particularly at very low frequencies, where the wavelength is longest and the diffraction is thus greatest. When the speaker is held up behind the baffle, though, the sounds can no longer diffract and mix while they are out of phase, and as a consequence the intensity increases enormously. This experiment illustrates why loudspeakers are often mounted in boxes, so that the sound from the back cannot interfere with the sound from the front. In a home stereo system, when two speakers are wired properly, their sound waves are in phase along an antinodal line between the two speakers and in the area of best listening. If the two speakers are wired incorrectly—the wires being reversed on one of the speakers—their waves will be out of phase in the area of best listening and will interfere destructively—especially at low frequencies, so that the bass frequencies will be strongly attenuated.

One possible application of destructive interference is in industrial noise control. This would involve sensing the ambient sound in a workplace, electronically reproducing a sound with the opposite phase, and then introducing that sound into the environment so that it would interfere destructively with the ambient sound and reduce the overall sound level.

Beats. An important occurrence of the interference of waves is in the phenomenon of beats. In the simplest case, beats result when two sinusoidal sound waves of equal amplitude and very nearly equal frequencies mix. The frequency of the resulting sound (F) would be the average of the two original frequencies (f_1 and f_2):

$$F = \frac{f_1 + f_2}{2}. \tag{17}$$

The amplitude or intensity of the combined signal would rise and fall at a rate (f_b) equal to the difference between the two original frequencies,

$$f_b = f_1 - f_2, \tag{18}$$

where f_1 is greater than f_2.

Beats are useful in tuning musical instruments to each other: the farther the instruments are out of tune, the faster the beats. Other types of beats are also of interest. Second-order beats occur between the two notes of a mistuned octave, and binaural beats involve beating between tones presented separately to the two ears, so that they do not mix physically.

Moving sources and observers. *The Doppler effect.* The Doppler effect is a change in the frequency of a tone that occurs by virtue of relative motion between the source of sound and the observer. When the source and the observer are moving closer together, the perceived frequency is higher than the normal frequency, or the frequency heard when the observer is at rest with respect to the source. When the source and the observer are moving farther apart, the perceived frequency is lower than the normal frequency. For the case of a moving source, one example is the falling frequency of a train whistle as the train passes a crossing. In the case of a moving observer, a passenger on the train would hear the warning bells at the crossing drop in frequency as the train sped by.

Perceived frequency

For the case of motion along a line, where the source moves with speed v_s and the observer moves with speed v_o through still air in which the speed of sound is S, the general equation describing the change in frequency heard by the observer is

$$f_o = f_s \frac{S + v_o}{S - v_s}. \tag{19}$$

In this equation the speeds of the source and the observer will be negative if the relative motion between the source and observer is moving them apart, and they will be positive if the source and observer are moving together.

From this equation, it can be deduced that a Doppler effect will always be heard as long as the relative speed between the source and observer is less than the speed of sound. The speed of sound is constant with respect to the air in which it is propagating, so that, if the observer moves away from the source at a speed greater than the speed of sound, nothing will be heard. If the source and the observer are moving with the same speed in the same direction, v_o and v_s will be equal in magnitude but with the opposite sign; the frequency of the sound will therefore remain unchanged, like the sound of a train whistle as heard by a passenger on the moving train.

Shock waves. If the speed of the source is greater than the speed of sound, another type of wave phenomenon will occur: the sonic boom. A sonic boom is a type of shock wave that occurs when waves generated by a source over a period of time add together coherently, creating an unusually strong sum wave. An analogue to a sonic boom is the V-shaped bow wave created in water by a motorboat when its speed is greater than the speed of the waves. In the case of an aircraft flying faster than the speed of sound (about 1,230 kilometres per hour, or 764 miles per hour), the shock wave takes the form of a cone in three-dimensional space called the Mach cone. The Mach number is defined as the ratio of the speed of the aircraft to the speed of sound. The higher the Mach number—that is, the faster the aircraft—the smaller the angle of the Mach cone.

STANDING WAVES

This section focuses on waves in bounded mediums—in particular, standing waves in such systems as stretched strings, air columns, and stretched membranes. The principles discussed here are directly applicable to the operation of string and wind instruments.

Combining of component waves

When two identical waves move in opposite directions along a line, they form a standing wave—that is, a wave form that does not travel through space or along a string even though (or because) it is made up of two oppositely traveling waves. The resulting standing wave is sinusoidal, like its two component waves, and it oscillates at the same frequency. An easily visualized standing wave can be created by stretching a rubber band between two fixed points, displacing its centre slightly, and releasing it so that it vibrates back and forth between two extremes. In musical instruments, a standing wave can be generated by driving the oscillating medium (such as the reeds of a woodwind) at one end; the standing waves are then created not by two separate component waves but by the original wave and its reflections off the ends of the vibrating system.

In stretched strings. *Fundamentals and harmonics.* For a stretched string of a given mass per unit length (μ) and under a given tension (F), the speed (v) of a wave in the string is given by the following equation:

$$v = \sqrt{\frac{F}{\mu}}. \tag{20}$$

When a string of a given length (L) is plucked gently in the middle, a vibration is produced with a wavelength (λ) that is twice the length of the string:

$$\lambda = 2L. \tag{21}$$

The frequency (f_1) of this vibration can then be obtained by the following adaptation of equation (2):

$$f_1 = \frac{v}{\lambda} = \left(\frac{1}{2L}\right)\sqrt{\frac{F}{\mu}}. \tag{22}$$

As the vibration that has the lowest frequency for that particular type and length of string under a specific tension, this frequency is known as the fundamental, or first harmonic.

Additional standing waves can be created in a stretched string; the three simplest are represented graphically in Figure 4. At the top is a representation of the fundamental, which is labeled $n = 1$. Because a string must be stretched by holding it in place at its ends, each end is fixed, and there can be no motion of the string at these points. The ends are called nodal points, or nodes, and labeled N. The shape of the string at the extreme positions in its oscillation is illustrated by curved solid and dashed lines, the two positions occurring at time intervals of one-half period. In the centre of the string is the point at which the string vibrates with its greatest amplitude; this is called an antinodal point, or antinode, and labeled A.

Nodes and antinodes

The next two vibrational modes of the string are also represented in Figure 4. For these vibrations the string is divided into equal segments called loops. Each loop is one-half wavelength long, and the wavelength is related to the length of the string by the following equation:

$$\lambda_n = \frac{2L}{n}. \tag{23}$$

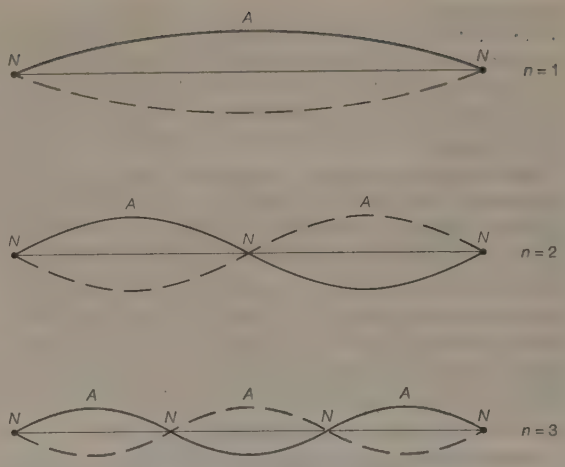

Figure 4: *The first three harmonic standing waves in a stretched string.*
Nodes (N) and antinodes (A) are marked. The harmonic number (n) for each standing wave is given on the right (see text).

Here the integer n equals the number of loops in the standing wave. From equation (22) above, the frequencies of these vibrations (f_n) can be deduced as:

$$f_n = \frac{v}{\lambda_n} = \left(\frac{n}{2L}\right)\sqrt{\frac{F}{\mu}}; \tag{24}$$

or, in terms of the fundamental frequency f_1,

$$f_n = nf_1. \tag{25}$$

Here n is called the harmonic number, because the sequence of frequencies existing as standing waves in the string are integral multiples, or harmonics, of the fundamental frequency.

In the middle representation of Figure 4, labeled $n = 2$ and called the second harmonic, the string vibrates in two sections, so that the string is one full wavelength long. Because the wavelength of the second harmonic is one-half that of the fundamental, its frequency is twice that of the fundamental. Similarly, the frequency of the third harmonic (labeled $n = 3$) is three times that of the fundamental.

Overtones. Another term sometimes applied to these standing waves is overtones. The second harmonic is the first overtone, the third harmonic is the second overtone, and so forth. "Overtone" is a term generally applied to any higher-frequency standing wave, whereas the term harmonic is reserved for those cases in which the frequencies of the overtones are integral multiples of the frequency of the fundamental. Overtones or harmonics are also called resonances. In the phenomenon of resonance, a system that vibrates at some natural frequency is subjected to external vibrations of the same frequency; as a result, the system resonates, or vibrates at a large amplitude.

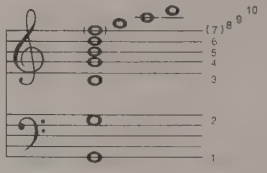

Figure 5: *The first 10 notes in the overtone series of G_2*
The harmonic number of each note is to the right (see text).

The overtone series

The sequence of frequencies defined by equation (25), known as the overtone series, plays an important part in the analysis of musical instruments and musical tone quality. If the fundamental frequency is the note G_2 at the bottom of the bass clef, the first 10 frequencies in the series will correspond closely to the notes shown in Figure 5. Here the frequencies of the octaves (harmonics 1, 2, 4, and 8) are exactly those of the notes shown, but the other frequencies of the overtone series differ by a small

amount from the frequencies of the notes on the equal-tempered scale. The seventh harmonic is quite out of tune when compared with the actual note, so it is enclosed in parentheses.

During the Middle Ages in Europe, keyboard instruments were sometimes tuned to a scale in which the primary chords were true frequencies of the overtone series. This tuning method, called just intonation, provided beatless chords, because the notes in the chord were members of a single overtone series.

Mersenne's laws. From equation (22) can be derived three "laws" detailing how the fundamental frequency of a stretched string depends on the length, tension, and mass per unit length of the string. Known as Mersenne's laws, these can be written as follows:

1. The fundamental frequency of a stretched string is inversely proportional to the length of the string, keeping the tension and the mass per unit length of the string constant:

$$f_1 \propto \frac{1}{L}. \tag{26}$$

2. The fundamental frequency of a stretched string is directly proportional to the square root of the tension in the string, keeping the length and the mass per unit length of the string constant:

$$f_1 \propto \sqrt{F}. \tag{27}$$

3. The fundamental frequency of a stretched string is inversely proportional to the mass per unit length of the string, keeping the length and the tension in the string constant:

$$f_1 \propto \frac{1}{\sqrt{\mu}}. \tag{28}$$

Operation of string instruments

Mersenne's laws help explain the construction and operation of string instruments. The lower strings of a guitar or violin are made with a greater mass per unit length, and the higher strings made thinner and lighter. This means that the tension in all the strings can be made more nearly the same, resulting in a more uniform sound. In a grand piano, the tension in each string is over 100 pounds, creating a total force on the frame of between 40,000 and 60,000 pounds. A large variation in tension between the lower and the higher strings could lead to warping of the piano frame, so that, in order to apply even tension throughout, the higher strings are shorter and smaller in diameter while the bass strings are constructed of heavy wire wound with additional thin wire. This construction makes the wires stiff, causing the overtones to be higher in frequency than the ideal harmonics and leading to the slight inharmonicity that plays an important part in the characteristic piano tone.

In air columns. In a manner analogous to the treatment of standing waves in a stretched string, it is possible to carry out an analysis of the structure of standing waves in air columns. If two identical sinusoidal waves move in opposite directions in a column of air, a standing wave of the same frequency will be formed, just as it is in a string. The standing wave will consist of equally spaced nodes and antinodes with a loop length equal to one-half wavelength in air. Because the motion of the air forming this standing wave is rather complicated, the graphic representation is more abstract, but it can be drawn in a similar manner to that of the string. The simplest standing waves in both open and closed air columns are shown in Figure 6. Each standing wave is identified by its harmonic number (n), and location of the nodes (N) and antinodes (A) are indicated.

Tubes are classified by whether both ends of the tube are open (an open tube) or whether one end is open and one end closed (a closed tube). The basic acoustic difference is that the open end of a tube allows motion of the air; this results in the occurrence there of a velocity or displacement antinode similar to the centre of the fundamental mode of a stretched string, as illustrated at the top of Figure 4. On the other hand, the air at the closed end of a tube cannot move, so that a closed end results in a velocity node similar to the ends of a stretched string.

Open tubes. In an open tube, the standing wave of the lowest possible frequency for that particular length of tube (in other words, the fundamental) has antinodes at each end and a node in the centre. This means that an open tube is one-half wavelength long. The fundamental frequency (f_1) is thus

$$f_1 = \frac{S}{\lambda} = \frac{S}{2L_o}, \tag{29}$$

where L_o is the length of the open tube. The standing wave of each successive harmonic has one additional loop, as shown by $n = 2$ and $n = 3$ in Figure 6. The wavelength (λ_n) of each successive standing wave is calculated as

$$\lambda_n = \frac{2L_o}{n}, \tag{30}$$

and the frequency (f_n) as

$$f_n = \frac{nS}{2L_o} = nf_1, \tag{31}$$

just as in the case of the stretched string.

Closed tubes. The end conditions of a closed tube create a node at the closed end and an antinode at the open end, so that the length of a closed tube (L_c) is one-quarter of a wavelength. For this reason, the length of the closed tubes represented in Figure 6 is one-half that of the open tubes, so that both open and closed tubes produce the same fundamental frequency. In addition, the boundary conditions of a closed tube allow only an odd number of quarter-wavelengths to occupy any given length, so that

$$\lambda = \frac{4L_c}{n}, \tag{32}$$

where only odd n are allowed. Thus, the frequencies of standing waves in a closed tube include only the odd harmonics,

$$f_n = \frac{nS}{4L_c} = nf_1, \tag{33}$$

where values for n are odd integers only.

The Kundt's tube

Measuring techniques. A dramatic device used to "observe" the motion of air in a standing wave is the Kundt's tube. Cork dust is placed on the bottom of this tube, and a standing wave is created. A standing wave in a Kundt's tube consists of a complex series of small cell oscillations, an example of which is illustrated in Figure 7. The air is set in motion, and the vortex motion of the air cells blows the cork dust into small piles, forming a striation pattern. This pattern is very clear and strong at the velocity antinodes of the standing wave, but it disappears at the locations of nodal points. Alternating locations of nodes and antinodes are thus readily observed using this technique.

Under actual conditions, a node is located exactly at the closed end of a tube, but the antinode, owing to the way a wave reflects when it hits the open end, is actually out past the end of the tube by a small distance known as the end correction. The end correction depends primarily

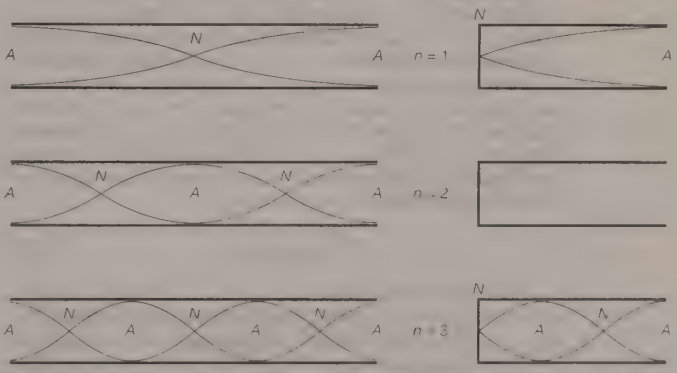

Figure 6: *The first three harmonic standing waves in* (left) *open and* (right) *closed tubes.*
Velocity nodes (N) and antinodes (A) are marked. The harmonic number (n) for each standing wave is given in the centre. The second harmonic does not exist in a closed tube (see text).

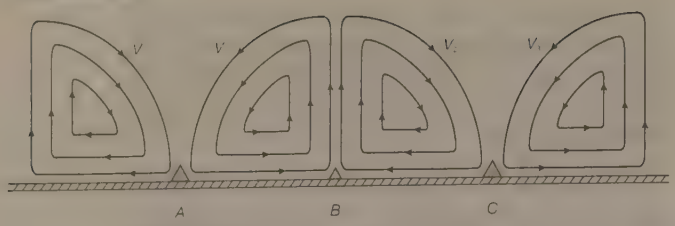

Figure 7: *Motion of air in a standing wave in a Kundt's tube.* In this side view along the tube, cork dust is swept up by vortices V_0–V_4 and deposited at points *A*–*C*, which define the striation patterns of the standing wave (see text).
From R.A. Carman, "Kundt Tube Dust Striations," *American Journal of Physics*, vol. 23 (1955)

on the radius of the tube: it is approximately equal to 0.6 times the radius of an unflanged tube and 0.82 times the radius of a flanged tube. The effective length of the tube, which must be assumed for the value of L in the equations above, incorporates the end correction.

An important feature of this discussion of standing waves in air columns is that the terms node and antinode refer to the places in the vibrating medium where there is zero and maximum displacement or velocity. Many textbooks and reference works use illustrations in which the wave drawn in a tube represents pressure rather than velocity or displacement. In this case, all the nodes and the antinodes are the reverse of those shown in Figure 6—that is, a pressure node (corresponding to a displacement or velocity antinode) occurs at the open end of a tube, while a pressure antinode (corresponding to a displacement or velocity node) occurs at the closed end. Because most microphones respond to changes in pressure, this type of representation may be more useful when discussing experimental observations involving the use of microphones.

In solid rods. A thin metal rod can sustain longitudinal vibrations in much the same way as an air column. The ends of a rod, when free, act as antinodes, while any point at which the rod is held becomes a node, so that the representation of their standing waves is identical to that of an open tube. Such standing waves can be activated by sharply striking the end of the rod with a hard object or by scraping the rod with a cloth or with fingers coated with resin. The harmonic frequencies are then given by

$$f_n = \left(\frac{n}{2L}\right)\sqrt{\frac{Y}{\rho}}, \tag{34}$$

where n is the harmonic number, Y is the Young's modulus (as described above in *Plane waves: The speed of sound*), and ρ is the density of the material. This type of standing wave was used by Ernst Chladni in determining the speed of sound in metals.

In nonharmonic systems. The resonant systems described above have a series of standing-wave resonances that vibrate at the frequencies of the overtone series, but there are several systems whose resonances are not so simply related.

The Helmholtz resonator. An important type of resonator with very different acoustic characteristics is the Helmholtz resonator, named after the German physicist Hermann von Helmholtz. Essentially a hollow sphere with a short, small-diameter neck, a Helmholtz resonator has a single isolated resonant frequency and no other resonances below about 10 times that frequency. The resonant frequency (f) of a classical Helmholtz resonator, shown in Figure 8, is determined by its volume (V) and by the length (L) and area (A) of its neck:

$$f = \left(\frac{S}{2\pi}\right)\sqrt{\frac{A}{LV}}, \tag{35}$$

where S is the speed of sound in air. As with the tubes discussed above, the value of the length of the neck should be given as the effective length, which depends on its radius.

Studying components of musical tones

The isolated resonance of a Helmholtz resonator made it useful for the study of musical tones in the mid-19th century, before electronic analyzers had been invented. When a resonator is held near the source of a sound, the air in it will begin to resonate if the tone being analyzed has a spectral component at the frequency of the resonator. By listening carefully to the tone of a musical instrument with such a resonator, it is possible to identify the spectral components of a complex sound wave such as those generated by musical instruments.

The air cavity of a string instrument, such as the violin or guitar, functions acoustically as a Helmholtz-type resonator, reinforcing frequencies near the bottom of the instrument's range and thereby giving the tone of the instrument more strength in its low range. The acoustic band-pass filter shown in Figure 3D uses a Helmholtz resonator to absorb a band of frequencies from the sound wave passing down an air duct and then reemitting them with the opposite phase, so that they will interfere destructively with the incoming wave and cause it to attenuate. The large jugs used in a jug band also function as Helmholtz resonators, resonating at a single low frequency when air is blown across their openings. Tuning forks are often mounted on boxes, because the air cavity in a box oscillates like a Helmholtz resonator and provides coupling between the tuning fork and the outside air.

Rectangular boxes. An air cavity in the shape of a rectangular box has a sequence of nonharmonic resonances. In such a case the walls are nodal points, and there are standing waves between two parallel walls and mixed standing waves involving several walls. The frequencies of such standing waves are given by the relation

$$f = \left(\frac{S}{2}\right)\sqrt{\left(\frac{N_x}{x}\right)^2 + \left(\frac{N_y}{y}\right)^2 + \left(\frac{N_z}{z}\right)^2}, \tag{36}$$

where x, y, and z are the dimensions of the box and N_x, N_y, and N_z are any integers. In the case where $N_y = N_z = 0$ and $N_x = 1$, the frequency is

$$f = \frac{S}{2x}, \tag{37}$$

corresponding to a half-wavelength the length of the box. This type of resonance is found inside a loudspeaker box, and it must be avoided when tuning a bass reflex speaker port. Such resonances are also readily observed in shower stalls and small rooms such as music practice rooms with parallel walls. Because of these resonances, practice rooms are often made with oblique walls.

Stretched membranes. In a two-dimensional system—for instance, a vibrating plate or a stretched membrane such as a drumhead—the resonant frequencies are not related by integral multiples; that is, their resonances or overtones are inharmonic. Most tuned percussion instruments fall into this category, which is one reason why a tune played on bells or timpani is sometimes more difficult to follow than a tune played on a violin or trumpet. Part of the design goal for tuned bar instruments is to make the shape such that two or more of the resonant frequencies line up like those of wind or string instruments, rendering the pitch clearer. Some, such as the marimba and xylophone, use tubular resonators tuned to the desired frequency of the bar in order to reinforce any overtones that are harmonics of the tube. The South Asian tabla

achieves its relatively clear pitch by using a nonuniform, or weighted, drumhead.

STEADY-STATE WAVES

Spectral analysis. *The Fourier theorem.* Fundamental to the analysis of any musical tone is the spectral analysis, or Fourier analysis, of a steady-state wave. According to the Fourier theorem, a steady-state wave is composed of a series of sinusoidal components whose frequencies are those of the fundamental and its harmonics, each component having the proper amplitude and phase. The sequence of components that form this complex wave is called its spectrum.

The sawtooth wave

The synthesis of a complex wave from its spectral components is illustrated by the sawtooth wave in Figure 9. The wave to be synthesized is shown by the graph at the upper middle, with its fundamental to the left and right. Adding the second through fifth harmonics, as shown on the left below the fundamental, results in the sawtooth shapes shown on the right. Figure 10A shows the spectrum of the sawtooth wave taken to the 10th harmonic. In Figure 10B and 10C are the wave form and spectrum of a clarinet playing the note B♭ = 233.08 hertz.

The sound spectrograph. A sound that changes in time, such as a spoken word or a bird call, can be more completely described by examining how the Fourier spectrum changes with time. In a graph called the sound spectrograph, frequency of the complex sound is plotted versus time, with the more intense frequency components shown in the third dimension or more simply as a darker point on a two-dimensional graph. The so-called voiceprint is an example of a sound spectrograph. At one time it was believed that people have voiceprints that are as unique as their fingerprints, so that individuals could be identified by their voiceprints, but the technology of the voiceprint has never been developed. In certain bird atlases, sound spectrographs of bird calls are included with other information, allowing identification of each bird by its call.

Generation by musical instruments. The steady-state tone of any musical instrument can also be analyzed and its Fourier spectrum constructed. The amplitudes of the various spectral components partially determine the tone quality, or timbre, of the instrument.

Bore configuration and harmonicity. The bore shapes of musical instruments, which have developed over the centuries, have rather interesting effects. Cylindrical and conical bores can produce resonances that are harmonics of the fundamental frequencies, but bores that flare faster than a cone create nonharmonic overtones and thus produce raucous tones rather than good musical sounds. A fact discovered by early musical instrument builders, this is the reason why the musical instruments that have developed over the past millennium of Western history are limited to those with either cylindrical or conical bores. In general, a rapidly flaring bell is added to the end of the instrument to reduce the impedance mismatch as the sound emerges from the instrument, thus increasing the ability of the instrument to radiate sound.

Characteristic spectra of musical instruments

The presence of any given harmonic in the spectrum of a particular musical instrument depends on the nature of the vibrating system. For example, if the system functions acoustically as an open tube or a vibrating string, all harmonics will likely be present in the wave. Examples of this are the flute, the recorder, and the violin. On the other hand, the clarinet functions acoustically as a closed tube, because it is cylindrical in shape and has a reed end.

From R.E. Berg and D.G. Stork, *The Physics of Sound* (1982). Prentice-Hall, Inc., Englewood Cliffs, New Jersey

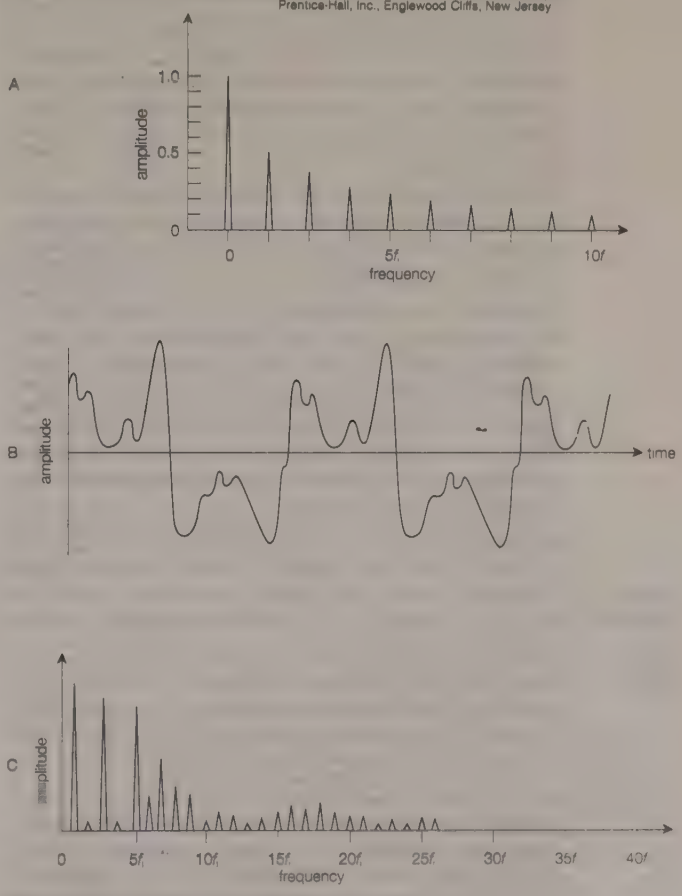

Figure 10: (A) The first 10 components of the Fourier spectrum of a sawtooth wave of frequency f_1. (B) The wave shape and (C) the spectrum of a clarinet playing the note B♭ = 233.08 hertz.

Therefore, as explained above in *Standing waves: In air columns,* the odd harmonics are emphasized in the clarinet spectrum—particularly at low frequencies, as seen in Figure 10C. Other wind instruments function acoustically as open tubes for a variety of reasons. The addition of a mouthpiece and a bell to a tube, either cylindrical or conical, results in all harmonics being possible, as in both the trumpet (cylindrical) and cornet (conical) family of brasses. Even after fixing a reed to one end of a conical tube—as in the oboe, bassoon, and saxophone families—the instruments still function acoustically as open tubes, producing all harmonics. The sawtooth wave, having all harmonics, therefore sounds more like a trumpet or a saxophone than like a clarinet.

Other effects on tone. Because many musical instrument families have similar spectra, there must be other factors that affect their tone quality and by which their tones can be distinguished. Attack transients, such as the way in which a string is bowed, a trumpet tongued, or a piano key struck, and decay transients, such as the way the sound of a plucked string dies away, are very important in many instruments, particularly those that are struck or plucked. Vibrato (a periodic slow change in pitch) and tremolo (a periodic slow change in amplitude) also aid the analysis of steady-state sounds.

Inharmonicities, or deviations of the frequencies of the harmonics from the exact multiples of the fundamental, are very important in tuned percussion instruments. For example, because of the inherent stiffness of piano strings, the overtones of the piano have slight inharmonicities. Indeed, the frequency of the 16th harmonic as played on the piano is about one-half step higher than the exact frequency of the harmonic.

Variations in air pressure. Basic to flutes and recorders, an edge tone is a stream of air that strikes a sharp edge, where it creates pressure changes in the air column that propagate down the tube. Reflections of these pressure variations then force the air stream back and forth across the edge, reinforcing the vibration at the resonant frequency of the tube. The time required to set up this steady-state oscillation is called the transient time of the instrument. The human ear is extremely sensitive to transients in musical tones, and such transients are crucial to the identification of various musical instruments whose spectra are similar.

In musical instruments the pressure variations generated by edge tones, a reed, or the lips set up standing waves in the air column that in turn drive the air stream, reed, or lips. Thus, contrary to common belief, the vibrations of the air column drive the reed or the lips open and closed; the reed or lips do not drive the air column. In the clarinet, for example, air is forced through the reed, creating a pulse of air that travels down the tube. Simultaneously, the reed is pulled closed by pressure of the lips and by rapid air flow out of the reed. After one reflection off the end of the tube, the pulse reflects as a rarefaction, holding the reed shut, but after the second reflection the pulse returns as a compression, forcing the reed open so that the process is repeated.

Acoustic function of the vocal column

The human voice. Groups of emphasized harmonics, known as formants, play a crucial role in the vowel sounds produced by the human voice. Vocal formants arise from resonances in the vocal column. The vocal column is about 17.5 centimetres (7 inches) long, on the average, with its lower end at the vocal folds and its upper end at the lips. Like a reed or like lips at the mouthpiece of a wind instrument, the vocal folds function acoustically as a closed end, so that the vocal column is a closed-tube resonator with resonant frequencies of about 500, 1,500, 2,500, and 3,500 hertz, and so on. The vibration frequency of the vocal folds, determined by the folds' tension, determines the frequency of the vocal sound. When a sound is produced, all harmonics are present in the spectrum, but those near the resonant frequencies of the vocal column are increased in amplitude. These emphasized frequency regions are the vocal formants. By changing the shape of the throat, mouth, and lips, the frequencies of the formants are varied, creating the different vowel sounds.

Noise. The idea of noise is fundamental to the sound of many vibrating systems, and it is useful in describing the spectra of vocal sibilants as well. Just as white light is the combination of all the colours of the rainbow, so white noise can be defined as a combination of equally intense sound waves at all frequencies of the audio spectrum. A characteristic of noise is that it has no periodicity, and so it creates no recognizable musical pitch or tone quality, sounding rather like the static that is heard between stations of an FM radio.

Another type of noise, called pink noise, is a spectrum of frequencies that decrease in intensity at a rate of three decibels per octave. Pink noise is useful for applications of sound and audio systems because many musical and natural sounds have spectra that decrease in intensity at high frequencies by about three decibels per octave. Other forms of coloured noise occur when there is a wide noise spectrum but with an emphasis on some narrow band of frequencies—as in the case of wind whistling through trees or over wires. In another example, as water is poured into a tall cylinder, certain frequencies of the noise created by the gurgling water are resonated by the length of the tube, so that pitch rises as the tube is effectively shortened by the rising water.

HEARING

Dynamic range of the ear. The ear has an enormous range of response, both in frequency and in intensity. The frequency range of human hearing extends over three orders of magnitude, from about 20 hertz to about 20,000 hertz, or 20 kilohertz. The minimum audible pressure amplitude, at the threshold of hearing, is about 10^{-5} pascal, or about 10^{-10} standard atmosphere, corresponding to a minimum intensity of about 10^{-12} watt per square metre. The pressure fluctuation associated with the threshold of pain, meanwhile, is over 10 pascals—one million times the pressure or one trillion times the intensity of the threshold of hearing. In both cases, the enormous dynamic range of the ear dictates that its response to changes in frequency and intensity must be nonlinear.

Equal-loudness curves

Shown in Figure 11 is a set of equal-loudness curves, sometimes called Fletcher-Munson curves after the investigators, the Americans Harvey Fletcher and W.A. Munson, who first measured them. The curves show the varying absolute intensities of a pure tone that has the same loudness to the ear at various frequencies. The determination of each curve, labeled by its loudness level in phons, involves the subjective judgment of a large number of people and is therefore an average statistical result. However, the curves are given a partially objective basis by defining the number of phons for each curve to be the same as the sound intensity level in decibels at 1,000 hertz—a physically measurable quantity. Fletcher and Munson placed the threshold of hearing at 0 phons, or 0 decibels at 1,000

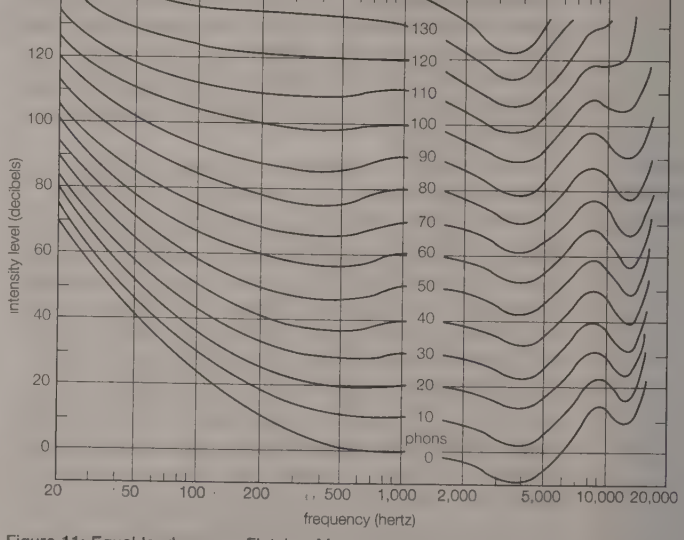

Figure 11: Equal-loudness, or Fletcher-Munson, curves.

hertz, but more accurate measurements now indicate that the threshold of hearing is slightly greater than that. For this reason, the curve labeled 0 phons in Figure 11 is slightly lower than the intensity level of the threshold of hearing over the entire frequency range. The curve labeled 120 phons is sometimes called the threshold of pain, or the threshold of feeling.

Several interesting observations can be made regarding Figure 11. The minimum intensity in the threshold of hearing occurs at about 4,000 hertz. This corresponds to the fundamental frequency at which the ear canal, acting as a closed tube about two centimetres long, has a specific resonance. The pressure variation corresponding to the threshold of hearing, roughly equivalent to placing the wing of a fly on the eardrum, causes a vibration of the eardrum of less than the radius of an atom. If the threshold of hearing did not rise for low frequencies, body sounds, such as heartbeat and blood pulsing, would be continually audible. Music is normally played at intensity levels between about 30 and 100 decibels. When it is played more softly, decreasing the sound level of all frequencies by the same amount, bass frequencies fall below the threshold of hearing. This is why the loudness control on an audio system raises the intensity of low frequencies—so that the music will have the same proportion of treble and bass to the ear as when it is played at a higher level.

As stated above, the ear has an enormous dynamic range, the threshold of pain corresponding to an intensity 12 orders of magnitude (10^{12} times) greater than the threshold of hearing. This leads to the necessity of a nonlinear intensity response. In order to be sensitive to intense waves and yet remain sensitive to very low intensities, the ear must respond proportionally less to higher intensity than to lower intensity. This response is logarithmic, because the ear responds to ratios rather than absolute pressure or intensity changes. At almost any region of the Fletcher-Munson diagram, the smallest change in intensity of a sinusoidal sound wave that can be observed, called the intensity just noticeable difference, is about one decibel (further reinforcing the value of the decibel intensity scale). One decibel corresponds to an absolute energy variation of a factor of about 1.25. Thus, the minimum observable change in the intensity of a sound wave is greater by a factor of nearly 10^{12} at high intensities than it is at low intensities.

Frequency response of the ear

The frequency response of the ear is likewise nonlinear. Relating frequency to pitch as perceived by the musician, two notes will "sound" similar if they are spaced apart in frequency by a factor of two, or octave. This means that the frequency interval between 100 and 200 hertz sounds the same as that between 1,000 and 2,000 hertz or between 5,000 and 10,000 hertz. In other words, the tuning of musical scales and musical intervals is associated with frequency ratios rather than absolute frequency differences in hertz. As a result of this empirical observation that all octaves sound the same to the ear, each frequency interval equivalent to an octave on the horizontal axis of the Fletcher-Munson scale is equal in length.

The audio frequency range encompasses nearly nine octaves. Over most of this range, the minimum change in the frequency of a sinusoidal tone that can be detected by the ear, called the frequency just noticeable difference, is about 0.5 percent of the frequency of the tone, or about one-tenth of a musical half-step. The ear is less sensitive near the upper and lower ends of the audible spectrum, so that the just noticeable difference becomes somewhat larger.

The ear as spectrum analyzer. The ear actually functions as a type of Fourier analysis device, with the mechanism of the inner ear converting mechanical waves into electrical impulses that describe the intensity of the sound as a function of frequency. Ohm's law of hearing is a statement of the fact that the perception of the tone of a sound is a function of the amplitudes of the harmonics and not of the phase relationships between them. This is consistent with the place theory of hearing, which correlates the observed pitch with the position along the basilar membrane of the inner ear that is stimulated by the corresponding frequency.

The intensity level at which a sound can be heard is affected by the existence of other stimuli. This effect, called masking, plays an important role in the psychophysical response to sound. Low frequencies mask higher frequencies much more strongly than high frequencies mask lower ones; this is one reason why a complex wave is perceived as having a different tone quality or timbre from a pure wave of the same frequency, even though they have the same pitch. Noise of low frequencies can be used to mask unwanted distracting sounds, such as nearby conversation in an office, and to create greater privacy.

Masking

The ear is responsive to the periodicity of a wave, so that it will hear the frequency of a complex wave as that of the fundamental whether or not the fundamental is actually present as a component in the wave, although the wave will have a different timbre than it would were the fundamental actually present. This effect, known as the missing fundamental, subjective fundamental, or periodicity pitch, is used by the ear to create the fundamental in sound radiating from a small loudspeaker that is not capable of providing low frequencies.

If the intensity of a sound is sufficiently great, the wave shape will be distorted by the ear mechanism, owing to its nonlinearity. The spectral analysis of the sound will then include frequencies that are not present in the sound wave, causing a distorted perception of the sound. If two or more sounds of great intensity are presented to the ear, this effect will introduce what are called combination tones. Two pure tones of frequency f_1 and f_2 will create a series of new pure tones: the sum tones,

$$f_+ = nf_1 + mf_2; \tag{38}$$

and the difference tones,

$$f_- = |nf_1 - mf_2|. \tag{39}$$

(Here n and m are any two integers.) Sum tones are difficult to hear because they are masked by the higher-intensity tones creating them, but difference tones are often observed in musical performance. For example, if the two tones are adjacent members of the harmonic series, the fundamental of that series will be produced as a difference tone, enhancing the ability of the ear to identify the fundamental pitch.

Binaural perception. The paths from the ears to the brain are separate; that is, each ear converts the sound reaching it into electrical impulses, so that sounds from the two ears mix in the brain not as physical vibrations but as electrical signals. This separation of pathways has the direct result that, if two pure tones are presented to each ear separately (*i.e.*, binaurally) at low levels, it will be very difficult for the ears to compare the frequencies because with no direct mixing of the mechanical waves there will be no regular beats. This difference in pitch perception between the two ears, called diplacusis, is generally not a problem. A type of beating known as binaural beats can sometimes be observed when the two tones are presented binaurally.

Also, two tones very close to an octave apart produce another type of monaural beating as they change in phase. This effect, known as second-order beats or quality beats, is observed as a slight periodic change in the quality of the combined tone. It serves as a counterexample to Ohm's law of hearing, which suggests that the quality of a sound depends only on the amplitudes of the harmonics and not on their phases.

Although the two ears are not connected by mechanical means, the brain is sensitive to phase and is able to determine the phase relationship between stimuli presented to the two ears. Locating a sound source laterally in space makes use of fundamental properties of sound waves as well as the ability of the brain to identify the phase difference between signals from the two ears. At low frequencies, where the wavelength is large and the waves diffract strongly, the brain is able to perceive the phase difference between the same sound reaching both ears, and it can thus locate the direction from which the sound is coming. On the other hand, at high frequencies the wavelength may be so short that there may be more than one period of time delay between the signals arriving at the two ears,

Locating sound by phase difference

creating an ambiguity in the phase difference. Fortunately, at these high frequencies there is so much less diffraction of sound waves that the head actually shields one ear more than the other. In such cases the difference in intensity of the sound waves reaching the two ears, rather than their phase difference, is used by the ears in spatial localization. Spatial localization in the vertical direction is poor for most people.

Applications of sound

ELECTROMECHANICAL TRANSDUCERS

Basic to the operation of the microphone and the loudspeaker is the electroacoustical transducer. A transducer is any type of electromechanical device that either converts an electrical signal into sound waves (as in a loudspeaker) or converts a sound wave into an electrical signal (as in the microphone). Many of the transducers used in everyday life operate in both directions, such as the speakerphone on certain intercoms.

Microphones. In order to evaluate the adequacy of various types of microphones for specific uses, one must consider the linearity of their frequency response, their directional characteristics, their durability, and their cost.

Linearity and directivity. Frequency linearity is the ability of a microphone to yield an electrical output that is proportional to the amplitude of the sound input over the entire frequency range. For music, this must extend to much lower and much higher frequencies than for voice use only. For high-quality musical reproduction, the flatter, or more nearly linear, microphone is generally the best choice.

Microphones also have directional characteristics. Those that uniformly pick up signals coming from all directions are referred to as omnidirectional. A common directional microphone is the cardioid microphone, so called because, when the intensity response as a function of angle is plotted on a polar graph, the curve is heart-shaped. A cardioid microphone is useful for recording live performances, where it is desirable to eliminate audience noise. A shotgun microphone has a very strong forward directional response. A parabolic reflector, similar to that of a reflecting telescope, is used to pick up and amplify relatively weak sounds coming from a certain direction. This is useful for such diverse applications as listening to bird calls and listening to the quarterback's signals at a football game.

Types of transducers. Most microphones use either an electromagnetic or an electrostatic technique to convert sound waves into electrical signals. The dynamic microphone is constructed with a small magnet that oscillates inside a coil attached to the diaphragm. When a sound wave causes the diaphragm of the microphone to vibrate, the relative motion of the magnet and coil creates an electrical signal by magnetic induction. Either a moving-coil or a moving-magnet system may be employed, depending on which element is connected to the moving diaphragm; the moving coil is used more often. The dynamic microphone is rugged and has reasonably good linearity, so that high-quality models are useful in recording. Because a moving-coil microphone and a moving-coil loudspeaker are very similar, intercoms are often made with the same element serving both functions.

The dynamic microphone

The electrostatic or condenser microphone is constructed with the diaphragm as one plate of a parallel-plate capacitor. The most popular form of this type of microphone is the electret condenser microphone, in which the plates are given a permanent electrical charge. When a sound wave causes the charged diaphragm plate to vibrate, the voltage across the plates changes, creating a signal that can be amplified and transmitted to the recording device. An amplifier is often mounted in the microphone, so this type of microphone requires the use of a battery to power the amplifier. Because the diaphragm of a condenser microphone can be very light, compared with the more massive dynamic microphone, it is able to respond faster and at higher frequencies. Consequently, condenser microphones generally have better linearity and a greater frequency range than dynamic microphones.

The crystal microphone uses a piezoelectric crystal as its transducer. Piezoelectric crystals are durable and cheap, and they have relatively large electrical output; for this reason, they are often used in telephones and portable sound systems. They do not have very good linearity and so are inadequate for quality sound recording.

The ribbon microphone is unique in that it responds to the air velocity of the sound wave, not to the pressure variation. Because ribbon microphones are very sensitive, they cannot be used where they will suffer mechanical shocks. Ribbon microphones are bidirectional and can be used to pick up sounds coming from both sides of the microphone equally well.

Loudspeakers. *Electromagnetic speakers.* Most loudspeakers are of the electromagnetic, or dynamic, variety, in which a voice coil moves in the gap of a permanent magnet when a time-varying current flows through the coil. The magnet is generally in the shape of a "W" or a ring. The diaphragm, or cone, of such a loudspeaker moves with the coil, converting the electric current in the coil into a pressure wave. A lit candle placed in front of a loudspeaker cone that is oscillating at about 10 hertz can render the sound wave "visible," as the flame vibrates back and forth longitudinally with the air.

As is the case with microphones, loudspeakers are evaluated largely on their frequency linearity. In order to achieve good frequency response at low frequencies, it is necessary to use a rather large cone; however, owing to the relatively large mass of the loudspeaker coil and cone, it is difficult to achieve good response at high frequencies with the same loudspeaker. Response can be improved by using rather large magnets, but these make a good loudspeaker rather heavy. In addition, the suspension of the coil in the magnet gap is critical, because it must provide for both rapid response and quick damping to its equilibrium position when the signal ceases. Each loudspeaker has a frequency at which it resonates most readily. For large loudspeakers this resonant frequency is useful in enhancing the bass response of the system.

Loudspeaker enclosures

Loudspeakers are mounted in a box, horn, or other enclosure in order to separate the waves from the front and the rear of the loudspeaker and thereby prevent them from canceling each other. (This type of destructive interference is discussed above in *Circular and spherical waves: Interference.*) The most common type of enclosure is the acoustic suspension system, in which the loudspeaker is mounted in an airtight box. To prevent resonances in the box of the type described by equation (36), the inside is generally coated with some sound-absorbent material. Because of the airtight seal, the cone must compress and expand the air inside the box as it moves, so that this type of system is not very efficient in converting electrical energy into sound, especially at bass frequencies.

The tuned port or bass reflex enclosure achieves greater efficiency and extends the bass frequency range by carefully adjusting the shape and position of a hole or tube connecting the inside of the speaker box with the outside. The volume of the box thus acts as a type of Helmholtz resonator, with a resonant frequency that is determined by the geometry of the hole or tube and is deliberately chosen so that it extends the frequency range of the speaker system smoothly to a significantly lower value. In addition, the existence of the port greatly reduces the air pressure variation inside the box, allowing the loudspeaker cone to move much more freely. For these reasons, the typical bass reflex enclosure is much more efficient than the typical acoustic suspension system.

A horn enclosure uses a flared tube to obtain the best acoustic coupling between the loudspeaker cone and the outside, thereby radiating the best possible coherent wave from the speaker cone. Such a system is extremely efficient and is therefore used in public-address systems, open-air theatres, or other places in which great acoustic power is desired. Because a good quality bass horn enclosure is very large, such devices often use bent or folded tubes. The Klipschorn, named for its inventor, the American engineer Paul W. Klipsch, uses the walls in the corner of a room as part of the flared horn.

Because high efficiency and linearity of a single speaker

cannot be extended over the entire audible frequency range, loudspeaker systems are generally formed from two or more individual loudspeakers. A larger speaker, or woofer, produces the lower frequencies, while a smaller speaker, or tweeter, produces the higher frequencies. In such a two-way system, a passive electronic circuit called a crossover network is employed to direct the higher and lower frequencies to the appropriate loudspeaker. A larger or more efficient three-way system may add a midrange speaker, helping to create a more nearly linear response between woofer and tweeter.

Loudspeakers in large areas

The loudspeaker arrays regularly seen in large auditoriums often make use of a single woofer and a single midrange speaker but two or even three high-frequency tweeters. The necessity for using a greater number of tweeters arises from the relatively smaller diffraction of high-frequency (or low-wavelength) sound waves. Because these spread out less and are therefore more directional, it may be necessary to provide several tweeters and aim them so as to cover the entire auditorium. This is unnecessary for the woofer because of the large diffraction of long wavelengths.

Electrostatic speakers. Electrostatic loudspeakers make use of a large, thin metal plate between two parallel screens. An amplified audio signal is impressed onto the screens, polarizing the metal sheet, and the resulting electrostatic force creates a motion of the sheet, producing a sound wave. Electrostatic speakers function well at high frequencies, but they are unable to move enough air to perform well at low frequencies and often require somewhat greater power than electromagnetic speakers. Because of these limitations and other technical problems, they have seen only limited use and are not popular in consumer audio systems.

SOUND RECORDING

The three most popular recording formats used in home audio systems are the long-playing phonograph disc, the audiocassette, and the compact disc.

The phonograph disc. A monaural phonograph record makes use of a spiral 90° V-shaped groove impressed into a plastic disc. As the record revolves at 33⅓ rotations per minute, a tiny "needle," or stylus, simultaneously moves along the groove and vibrates back and forth parallel to the surface of the disc and perpendicular to the groove, tracing out the sound wave. The upper end of the stylus is connected to a tiny magnet, which moves back and forth through a small coil, inducing an electrical voltage that recreates the recorded sound wave. The rate of oscillation of the stylus determines the frequency of the sound, while the amplitude of the oscillation determines its loudness.

Just as the use of two eyes creates a perception of depth, so can the effect of musical "presence" be achieved by stereophonics, recording music with two appropriately positioned microphones and playing it back on two separated loudspeakers. A stereophonic recording provides the two separate signal channels as oscillations perpendicular to either one or the other of the faces of the record groove. The single coil of the monaural pickup is replaced by two coils, which sense the motion of the stylus perpendicular to each groove wall; the inside wall is used as the left channel and the outside wall as the right channel. These two signals are then fed into an audio amplifier and to the loudspeakers.

Limiting variation in frequency

The criterion for frequency control of a recording is that the variation in frequency should not be observable to the ear—*i.e.*, less than about 0.1 percent, which is less than the just noticeable difference in frequency over most of the audible frequency range. In order to eliminate both slow variations in pitch of the recording, called wow, and rapid variations, called flutter, the rotation speed of the record is carefully controlled by use of a heavy turntable and a precision motor. Mechanical vibration of the turntable is isolated from the stylus to avoid "rumble." The stylus itself is elliptical in shape, with the long axis of the ellipse oriented across the groove. In order to achieve good compliance—that is, the ability of the stylus to track the groove and produce a linear signal—the tip of the stylus must be less than 25 micrometres (0.025 millimetre, or $^1/_{1000}$ inch) in size, so that it is generally made of industrial diamond.

Faraday's law of magnetic induction introduces some important features into the science of phonograph records. According to this law, the electric potential induced in the coil of the magnetic pickup is directly proportional to the magnetic field of the moving magnet in the pickup and inversely proportional to the period of the oscillation. This means that, in order to produce a sound wave of constant amplitude at all frequencies, it is necessary to reduce the amplitude of the motion of the stylus at high frequencies and greatly increase that motion at low frequencies. Unfortunately, limitations in the compliance of such a recording system make it impossible for the stylus to accurately track a sufficiently large-amplitude oscillation at low frequencies. Furthermore, the inherent graininess of the plastic from which phonographic recordings are pressed creates high-frequency vibrations of the stylus, which are heard as high-frequency noise, or hiss. Because of these problems, the electrical signal must be amplified at very high frequencies, attenuated at very low frequencies, and approximately linearized for midrange frequencies before the signal is converted into a groove shape and impressed onto the plastic disc—a process called pre-emphasis. Upon playback this sequence is reversed in a process called equalization, providing the listener with a linear and realistic sound.

The audiotape. Audiocassette tape recording also makes use of electromagnetic phenomena to record and reproduce sound waves. The tape consists of a plastic backing coated with a thin layer of tiny particles of magnetic powder, usually ferric oxide (Fe_2O_3) and to a lesser extent chromium dioxide (CrO_2). The recording head of the tape deck consists of a tiny C-shaped magnet with its gap adjacent to the moving tape. The incoming sound wave, having been converted by a microphone into an electrical signal, produces a time-varying magnetic field in the gap of the magnet. As the tape moves past the recording head the powder is magnetized in such a way that the tape carries a record of the shape of the wave being recorded. The frequency of the impressed signal determines the distance along the tape over which the impressed magnetic field must be reversed, and the amplitude of the signal determines the extent of the magnetization of the tape.

Problems in magnetic recording

There are inherent problems with the magnetic recording system. As magnetic domains are flipped in magnetizing the material, they exhibit a certain magnetic inertia, or unwillingness to respond, so that it requires a greater magnetic field than expected to magnetize the oxide on the tape. This effect, known as hysteresis, leads to distortion of the wave shape on the tape. In order to overcome this problem, a sinusoidal signal of about 100 kilohertz is added to the wave immediately before the wave is impressed onto the tape. Known as equalization bias, this signal has the effect of linearizing an inherently nonlinear magnetic medium, largely eliminating distortion.

Another problem arises from the inability of the recording system to organize completely the magnetic domains in these tiny magnetic crystals. The resulting random orientation of the domains results in random noise, which is heard by the listener as tape hiss. Because lower frequencies are more effective in magnetizing the tape, and because the random variation in magnetization is a microscopic effect, tape hiss is primarily a high-frequency phenomenon. Several systems have been designed to deal with this problem, the most prevalent of which is Dolby noise reduction. In the Dolby system the higher-frequency components of a sound wave are amplified before the signal is impressed on the tape so that their amplitudes are well above the amplitude of the tape hiss. On playback, the high frequencies are attenuated after they are read off the tape, reducing their amplitudes to the correct level.

The compact disc. The compact disc, or digital disc, uses digital technology to avoid or mitigate some of the technical problems and requirements inherent in phonograph and audiotape recording. Whereas both phonograph recordings and audiotape have limited dynamic range and frequency response, the compact disc has both a greater dynamic range—ideally, over 90 decibels—and a linear

frequency response from less than 20 hertz to over 20,000 hertz—greater than that of the human ear.

Digital recording uses sampling of the sound wave at a series of points at equal time intervals along the wave to approximate the full wave. In order to maintain frequency response up to 20 kilohertz, the limit of human hearing, it is necessary to sample at slightly above twice that frequency, so that compact discs actually have a sample rate of 44.1 kilohertz. The signal level is divided into 2^{15} (about 32,000) equal intervals. With such a large number of intervals being employed, both large and small wave intensities can be reproduced accurately. Indeed, intensity variations of less than one decibel (the approximate value of the intensity just noticeable difference of the ear) can be achieved over the entire dynamic range of the compact disc.

Accurate reproduction of wave intensity

Each sampled point on the wave is encoded in binary form, and a series of points are impressed on the compact disc. Playback is essentially the reverse of recording. Each point on the wave is read in and stored in a computer memory called a first-in first-out buffer. Using an internal 44.1-kilohertz clock, each point is converted in order into analog form and then input into a standard power amplifier and loudspeaker. The time scale for the recording is exactly reproduced, eliminating the frequency instabilities inherent in other types of recording.

ARCHITECTURAL ACOUSTICS

Reverberation time. Although architectural acoustics has been an integral part of the design of structures for at least 2,000 years, the subject was only placed on a firm scientific basis at the beginning of the 20th century by Wallace Sabine. Sabine pointed out that the most important quantity in determining the acoustic suitability of a room for a particular use is its reverberation time, and he provided a scientific basis by which the reverberation time can be determined or predicted.

When a source creates a sound wave in a room or auditorium, observers hear not only the sound wave propagating directly from the source but also the myriad reflections from the walls, floor, and ceiling. These latter form the reflected wave, or reverberant sound. After the source ceases, the reverberant sound can be heard for some time as it grows softer. The time required, after the sound source ceases, for the absolute intensity to drop by a factor of 10^6—or, equivalently, the time for the intensity level to drop by 60 decibels—is defined as the reverberation time (RT, sometimes referred to as RT_{60}). Sabine recognized that the reverberation time of an auditorium is related to the volume of the auditorium and to the ability of the walls, ceiling, floor, and contents of the room to absorb sound. Using these assumptions, he set forth the empirical relationship through which the reverberation time could be determined:

$$RT = \frac{0.05V}{A}, \tag{40}$$

where RT is the reverberation time in seconds, V is the volume of the room in cubic feet, and A is the total sound absorption of the room, measured by the unit sabin. The sabin is the absorption equivalent to one square foot of perfectly absorbing surface—for example, a one-square-foot hole in a wall or five square feet of surface that absorbs 20 percent of the sound striking it.

The sabin

Both the design and the analysis of room acoustics begin with equation (40). Using this equation and the absorption coefficients of the materials from which the walls are to be constructed, an approximation can be obtained for the way in which the room will function acoustically.

Table 6: Absorption Coefficients of Common Materials at Several Frequencies

	frequency (hertz)					
material	125	250	500	1,000	2,000	4,000
Concrete	0.01	0.01	0.02	0.02	0.02	0.03
Plasterboard	0.20	0.15	0.10	0.08	0.04	0.02
Acoustic board	0.25	0.45	0.80	0.90	0.90	0.90
Curtains	0.05	0.12	0.25	0.35	0.40	0.45

Absorbers and reflectors, or some combination of the two, can then be used to modify the reverberation time and its frequency dependence, thereby achieving the most desirable characteristics for specific uses. Representative absorption coefficients—showing the fraction of the wave, as a function of frequency, that is absorbed when a sound hits various materials—are given in Table 6. The absorption from all the surfaces in the room are added together to obtain the total absorption (A).

While there is no exact value of reverberation time that can be called ideal, there is a range of values deemed to be appropriate for each application. These vary with the size of the room, but the averages can be calculated and indicated by lines on a graph, as in Figure 12. The need for clarity in understanding speech dictates that rooms used for talking must have a reasonably short reverberation time. On the other hand, the full sound desirable in the performance of music of the Romantic era, such as Wagner operas or Mahler symphonies, requires a long reverberation time. Obtaining a clarity suitable for the light, rapid passages of Bach or Mozart requires an intermediate value of reverberation time. For playing back recordings on an audio system, the reverberation time should be short, so as not to create confusion with the reverberation time of the music in the hall where it was recorded.

From R.E. Berg and D.G. Stork, *The Physics of Sound* (1982), Prentice-Hall, Inc., Englewood Cliffs, New Jersey

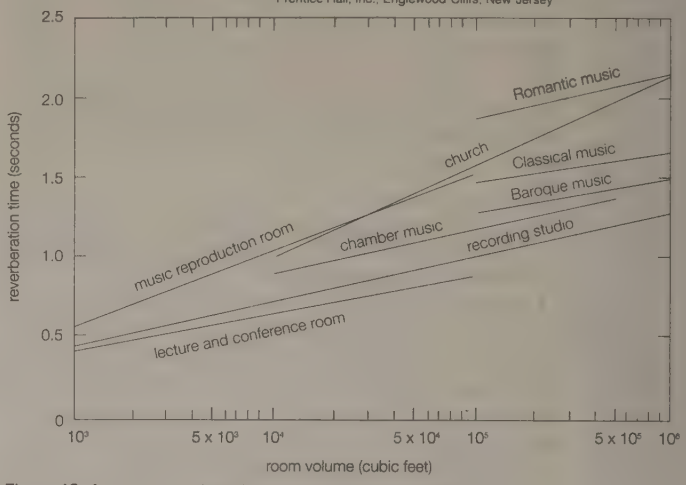

Figure 12: Average reverberation time versus room volume required to achieve optimal response for various types of room and music.

Acoustic criteria. Many of the acoustic characteristics of rooms and auditoriums can be directly attributed to specific physically measurable properties. Because the music critic or performing artist uses a different vocabulary to describe these characteristics than does the physicist, it is helpful to survey some of the more important features of acoustics and correlate the two sets of descriptions.

"Liveness" refers directly to reverberation time. A live room has a long reverberation time and a dead room a short reverberation time. "Intimacy" refers to the feeling that listeners have of being physically close to the performing group. A room is generally judged intimate when the first reverberant sound reaches the listener within about 20 milliseconds of the direct sound. This condition is met easily in a small room, but it can also be achieved in large halls by the use of orchestral shells that partially enclose the performers. Another example is a canopy placed above a speaker in a large room such as a cathedral: this leads to both a strong and a quick first reverberation and thus to a sense of intimacy with the person speaking.

The amplitude of the reverberant sound relative to the direct sound is referred to as fullness. Clarity, the opposite of fullness, is achieved by reducing the amplitude of the reverberant sound. Fullness generally implies a long reverberation time, while clarity implies a shorter reverberation time. A fuller sound is generally required of Romantic music or performances by larger groups, while more clarity would be desirable in the performance of rapid passages from Bach or Mozart or in speech.

Fullness and clarity

"Warmth" and "brilliance" refer to the reverberation time at low frequencies relative to that at higher frequencies. Above about 500 hertz, the reverberation time should be the same for all frequencies. But at low frequencies an increase in the reverberation time creates a warm sound, while, if the reverberation time increased less at low frequencies, the room would be characterized as more brilliant.

"Texture" refers to the time interval between the arrival of the direct sound and the arrival of the first few reverberations. To obtain good texture, it is necessary that the first five reflections arrive at the observer within about 60 milliseconds of the direct sound. An important corollary to this requirement is that the intensity of the reverberations should decrease monotonically; there should be no unusually large late reflections.

"Blend" refers to the mixing of sounds from all the performers and their uniform distribution to the listeners. To achieve proper blend it is often necessary to place a collection of reflectors on the stage that distribute the sound randomly to all points in the audience.

Although the above features of auditorium acoustics apply to listeners, the idea of ensemble applies primarily to performers. In order to perform coherently, members of the ensemble must be able to hear one another. Reverberant sound cannot be heard by the members of an orchestra, for example, if the stage is too wide, has too high a ceiling, or has too much sound absorption on its sides.

Acoustic problems. Certain acoustic problems often result from improper design or from construction limitations. If large echoes are to be avoided, focusing of the sound wave must be avoided. Smooth, curved reflecting surfaces such as domes and curved walls act as focusing elements, creating large echoes and leading to bad texture. Improper blend results if sound from one part of the ensemble is focused to one section of the audience. In addition, parallel walls in an auditorium reflect sound back and forth, creating a rapid, repetitive pulsing of sound known as flutter echo and even leading to destructive interference of the sound wave. Resonances at certain frequencies should also be avoided by use of oblique walls.

Acoustic shadows

Acoustic shadows, regions in which some frequency regions of sound are attenuated, can be caused by diffraction effects as the sound wave passes around large pillars and corners or underneath a low balcony. Large reflectors called clouds, suspended over the performers, can be of such a size as to reflect certain frequency regions while allowing others to pass, thus affecting the mixture of the sound.

External noise can be a serious problem for halls in urban areas or near airports or highways. One technique often used for avoiding external noise is to construct the auditorium as a smaller room within a larger room. Noise from air blowers or other mechanical vibrations can be reduced using the techniques discussed above (see *Circular and spherical waves: Impedance*) and by isolating air handlers.

Good acoustic design must take account of all these possible problems while emphasizing the desired acoustic features. One of the problems in a large auditorium involves simply delivering an adequate amount of sound to the rear of the hall. The intensity of a spherical sound wave decreases in intensity at a rate of six decibels for each factor of two increase in distance from the source, as shown above (see *Circular and spherical waves: Attenuation*). If the auditorium is flat, a hemispherical wave will result. Absorption of the diffracted wave by the floor or audience near the bottom of the hemisphere will result in even greater absorption, so that the resulting intensity level will fall off at twice the theoretical rate, at about 12 decibels for each factor of two in distance. Because of this absorption, the floors of an auditorium are generally sloped upward toward the rear.

ULTRASONICS

The term ultrasound refers to vibrations of frequencies greater than the upper limit of the audible range for humans—that is, greater than about 20 kilohertz. The term sonic is applied to ultrasound waves of very high amplitudes. Hypersound, sometimes called praetersound or microsound, is sound waves of frequencies greater than 10^{13} hertz. At such high frequencies it is very difficult for a sound wave to propagate efficiently; indeed, above a frequency of about 1.25×10^{13} hertz, it is impossible for longitudinal waves to propagate at all, even in a liquid or a solid, because the molecules of the material in which the waves are traveling cannot pass the vibration along rapidly enough.

Many animals have the ability to hear sounds in the human ultrasonic frequency range. Some ranges of hearing for mammals and insects are compared with those of humans in Table 7. A presumed sensitivity of roaches and rodents to frequencies in the 40 kilohertz region has led to the manufacture of "pest controllers" that emit loud sounds in that frequency range to drive the pests away, but they do not appear to work as advertised.

Table 7: Frequency Range of Hearing for Humans and Selected Animals

animal	frequency (hertz)	
	low	high
Humans	20	20,000
Cats	100	32,000
Dogs	40	46,000
Horses	31	40,000
Elephants	16	12,000
Cattle	16	40,000
Bats	1,000	150,000
Grasshoppers and locusts	100	50,000
Rodents	1,000	100,000
Whales and dolphins	70	150,000
Seals and sea lions	200	55,000

Transducers. An ultrasonic transducer is a device used to convert some other type of energy into an ultrasonic vibration. There are several basic types, classified by the energy source and by the medium into which the waves are being generated. Mechanical devices include gas-driven, or pneumatic, transducers such as whistles as well as liquid-driven transducers such as hydrodynamic oscillators and vibrating blades. These devices, limited to low ultrasonic frequencies, have a number of industrial applications, including drying, ultrasonic cleaning, and injection of fuel oil into burners. Electromechanical transducers are far more versatile and include piezoelectric and magnetostrictive devices. A magnetostrictive transducer makes use of a type of magnetic material in which an applied oscillating magnetic field squeezes the atoms of the material together, creating a periodic change in the length of the material and thus producing a high-frequency mechanical vibration. Magnetostrictive transducers are used primarily in the lower frequency ranges and are common in ultrasonic cleaners and ultrasonic machining applications.

Piezoelectric transducers

By far the most popular and versatile type of ultrasonic transducer is the piezoelectric crystal, which converts an oscillating electric field applied to the crystal into a mechanical vibration. Piezoelectric crystals include quartz, Rochelle salt, and certain types of ceramic. Piezoelectric transducers are readily employed over the entire frequency range and at all output levels. Particular shapes can be chosen for particular applications. For example, a disc shape provides a plane ultrasonic wave, while curving the radiating surface in a slightly concave or bowl shape creates an ultrasonic wave that will focus at a specific point.

Piezoelectric and magnetostrictive transducers also are employed as ultrasonic receivers, picking up an ultrasonic vibration and converting it into an electrical oscillation.

Applications in research. One of the important areas of scientific study in which ultrasonics has had an enormous impact is cavitation. When water is boiled, bubbles form at the bottom of the container, rise in the water, and then collapse, leading to the sound of the boiling water. The boiling process and the resulting sounds have intrigued people since they were first observed, and they were the object of considerable research and calculation by the British physicists Osborne Reynolds and Lord Rayleigh, who applied the term cavitation to the process of formation of bubbles. Because an ultrasonic wave can be used carefully to control cavitation, ultrasound has been a

useful tool in the investigation of the process. The study of cavitation has also provided important information on intermolecular forces.

Research is still being carried out on aspects of the cavitation process and its applications. A contemporary subject of research involves emission of light as the cavity produced by a high-intensity ultrasonic wave collapses. This effect, called sonoluminescence, is believed to create instantaneous temperatures hotter than the surface of the Sun.

The speed of propagation of an ultrasonic wave is strongly dependent on the viscosity of the medium. This property can be a useful tool in investigating the viscosity of materials. Because the various parts of a living cell are distinguished by differing viscosities, acoustical microscopy can make use of this property of cells to "see" into living cells, as will be discussed below in *Medical applications.*

Ranging and navigating. Sonar (sound navigation and ranging) has extensive marine applications. By sending out pulses of sound or ultrasound and measuring the time required for the pulses to reflect off a distant object and return to the source, the location of that object can be ascertained and its motion tracked. This technique is used extensively to locate and track submarines at sea and to locate explosive mines below the surface of the water. Two boats at known locations can also use triangulation to locate and track a third boat or submarine. The distance over which these techniques can be used is limited by temperature gradients in the water, which bend the beam away from the surface and create shadow regions. (See above *Circular and spherical waves: Refraction.*) One of the advantages of ultrasonic waves over sound waves in underwater applications is that, because of their higher frequencies (or shorter wavelengths), the former will travel greater distances with less diffraction.

Uses of sonic ranging

Ranging has also been used to map the bottom of the ocean, providing depth charts that are commonly used in navigation, particularly near coasts and in shallow waterways. Even small boats are now equipped with sonic ranging devices that determine and display the depth of the water so that the navigator can keep the boat from beaching on submerged sandbars or other shallow points. Modern fishing boats use ultrasonic ranging devices to locate schools of fish, substantially increasing their efficiency.

Even in the absence of visible light, bats can guide their flight and even locate flying insects (which they consume in flight) through the use of sonic ranging. Ultrasonic echolocation has also been used in traffic control applications and in counting and sorting items on an assembly line. Ultrasonic ranging provides the basis of the eye and vision systems for robots, and it has a number of important medical applications (see below).

The Doppler effect. If an ultrasonic wave is reflected off a moving obstacle, the frequency of the resulting wave will be changed, or Doppler-shifted. More specifically, if the obstacle is moving toward the source, the frequency of the reflected wave will be increased; and if the obstacle is moving away from the source, the frequency of the reflected wave will be decreased. The amount of the frequency shift can be used to determine the velocity of the moving obstacle. Just as the Doppler shift for radar, an electromagnetic wave, can be used to determine the speed of a moving car, so can the speed of a moving submarine be determined by the Doppler shift of a sonar beam. An important industrial application is the ultrasonic flow meter, in which reflecting ultrasound off a flowing liquid leads to a Doppler shift that is calibrated to provide the flow rate of the liquid. This technique also has been applied to blood flow in arteries. Many burglar alarms, both for home use and for use in commercial buildings, employ the ultrasonic Doppler shift principle. Such alarms cannot be used where pets or moving curtains might activate them.

Materials testing. Nondestructive testing involves the use of ultrasonic echolocation to gather information on the integrity of mechanical structures. Since changes in the material present an impedance mismatch from which an ultrasonic wave is reflected, ultrasonic testing can be used to identify faults, holes, cracks, or corrosion in materials, to inspect welds, to determine the quality of poured concrete, and to monitor metal fatigue. Owing to the mechanism by which sound waves propagate in metals, ultrasound can be used to probe more deeply than any other form of radiation. Ultrasonic procedures are used to perform in-service inspection of structures in nuclear reactors.

Structural flaws in materials can also be studied by subjecting the materials to stress and looking for acoustic emissions as the materials are stressed. Acoustic emission, the general name for this type of nondestructive study, has developed as a distinct field of acoustics.

High-intensity applications. High-intensity ultrasound has achieved a variety of important applications. Perhaps the most ubiquitous is ultrasonic cleaning, in which ultrasonic vibrations are set up in small liquid tanks in which objects are placed for cleaning. Cavitation of the liquid by the ultrasound, as well as the vibration, create turbulence in the liquid and result in the cleaning action. Ultrasonic cleaning is very popular for jewelry and has also been used with such items as dentures, surgical instruments, and small machinery. Degreasing is often enhanced by ultrasonic cleaning. Large-scale ultrasonic cleaners have also been developed for use in assembly lines.

Ultrasonic cleaning

Ultrasonic machining employs the high-intensity vibrations of a transducer to move a machine tool. If necessary, a slurry containing carborundum grit may be used; diamond tools can also be used. A variation of this technique is ultrasonic drilling, which makes use of pneumatic vibrations at ultrasonic frequencies in place of the standard rotary drill bit. Holes of virtually any shape can be drilled in hard or brittle materials such as glass, germanium, or ceramic.

Ultrasonic soldering has become important, especially for soldering unusual or difficult materials and for very clean applications. The ultrasonic vibrations perform the function of cleaning the surface, even removing the oxide layer on aluminum so that the material can be soldered. Because the surfaces can be made extremely clean and free from the normal thin oxide layer, soldering flux becomes unnecessary.

Chemical and electrical uses. The chemical effects of ultrasound arise from an electrical discharge that accompanies the cavitation process. This forms a basis for ultrasound's acting as a catalyst in certain chemical reactions, including oxidation, reduction, hydrolysis, polymerization and depolymerization, and molecular rearrangement. With ultrasound, some chemical processes can be carried out more rapidly, at lower temperatures, or more efficiently.

The ultrasonic delay line is a thin layer of piezoelectric material used to produce a short, precise delay in an electrical signal. The electrical signal creates a mechanical vibration in the piezoelectric crystal that passes through the crystal and is converted back to an electrical signal. A very precise time delay can be achieved by constructing a crystal with the proper thickness. These devices are employed in fast electronic timing circuits.

Medical applications. Although ultrasound competes with other forms of medical imaging, such as X-ray techniques and magnetic resonance imaging, it has certain desirable features—for example, Doppler motion study—that the other techniques cannot provide. In addition, among the various modern techniques for the imaging of internal organs, ultrasonic devices are by far the least expensive. Ultrasound is also used for treating joint pains and for treating certain types of tumours for which it is desirable to produce localized heating. A very effective use of ultrasound deriving from its nature as a mechanical vibration is the elimination of kidney and bladder stones.

Diagnosis. Much medical diagnostic imaging is carried out with X rays. Because of the high photon energies of the X ray, this type of radiation is highly ionizing—that is, X rays are readily capable of destroying molecular bonds in the body tissue through which they pass. This destruction can lead to changes in the function of the tissue involved or, in extreme cases, its annihilation.

One of the important advantages of ultrasound is that it is a mechanical vibration and is therefore a nonionizing form of energy. Thus, it is usable in many sensitive

circumstances where X rays might be damaging. Also, the resolution of X rays is limited owing to their great penetrating ability and the slight differences between soft tissues. Ultrasound, on the other hand, gives good contrast between various types of soft tissue.

Ultrasonic scanning

Ultrasonic scanning in medical diagnosis uses the same principle as sonar. Pulses of high-frequency ultrasound, generally above one megahertz, are created by a piezoelectric transducer and directed into the body. As the ultrasound traverses various internal organs, it encounters changes in acoustic impedance, which cause reflections. The amount and time delay of the various reflections can be analyzed to obtain information regarding the internal organs. In the B-scan mode, a linear array of transducers is used to scan a plane in the body, and the resultant data is displayed on a television screen as a two-dimensional plot. The A-scan technique uses a single transducer to scan along a line in the body, and the echoes are plotted as a function of time. This technique is used for measuring the distances or sizes of internal organs. The M-scan mode is used to record the motion of internal organs, as in the study of heart dysfunction. Greater resolution is obtained in ultrasonic imaging by using higher frequencies—*i.e.*, shorter wavelengths. A limitation of this property of waves is that higher frequencies tend to be much more strongly absorbed.

Because it is nonionizing, ultrasound has become one of the staples of obstetric diagnosis. During the process of drawing amniotic fluid in testing for birth defects, ultrasonic imaging is used to guide the needle and thus avoid damage to the fetus or surrounding tissue. Ultrasonic imaging of the fetus can be used to determine the date of conception, to identify multiple births, and to diagnose abnormalities in the development of the fetus.

Ultrasonic Doppler techniques have become very important in diagnosing problems in blood flow. In one technique, a three-megahertz ultrasonic beam is reflected off typical oncoming arterial blood with a Doppler shift of a few kilohertz—a frequency difference that can be heard directly by a physician. Using this technique, it is possible to monitor the heartbeat of a fetus long before a stethoscope can pick up the sound. Arterial diseases such as arteriosclerosis can also be diagnosed, and the healing of arteries can be monitored following surgery. A combination of B-scan imaging and Doppler imaging, known as duplex scanning, can identify arteries and immediately measure their blood flow; this has been extensively used to diagnose heart valve defects.

Using ultrasound with frequencies up to 2,000 megahertz, which has a wavelength of 0.75 micrometre in soft tissues (as compared with a wavelength of about 0.55 micrometre for light), ultrasonic microscopes have been developed that rival light microscopes in their resolution. The distinct advantage of ultrasonic microscopes lies in their ability to distinguish various parts of a cell by their viscosity. Also, because they require no artificial contrast mediums, which kill the cells, acoustic microscopy can study actual living cells.

Therapy and surgery. Because ultrasound is a mechanical vibration and can be well focused at high frequencies, it can be used to create internal heating of localized tissue without harmful effects on nearby tissue. This technique can be employed to relieve pains in joints, particularly in the back and shoulder. Also, research is now being carried out in the treatment of certain types of cancer by local heating, since focusing intense ultrasonic waves can heat the area of a tumour while not significantly affecting surrounding tissue.

Trackless surgery

Trackless surgery—that is, surgery that does not require an incision or track from the skin to the affected area—has been developed for several conditions. Focused ultrasound has been used for the treatment of Parkinson's disease by creating brain lesions in areas that are inaccessible to traditional surgery. A common application of this technique is the destruction of kidney stones with shock waves formed by bursts of focused ultrasound. In some cases, a device called an ultrasonic lithotripter focuses the ultrasound with the help of X-ray guidance, but a more common technique for destruction of kidney stones, known as endoscopic ultrasonic disintegration, uses a small metal rod inserted through the skin to deliver ultrasound in the 22- to 30-kilohertz frequency region.

INFRASONICS

The term infrasonics refers to waves of a frequency below the range of human hearing—*i.e.*, below about 20 hertz. Such waves occur in nature in earthquakes, waterfalls, ocean waves, volcanoes, and a variety of atmospheric phenomena such as wind, thunder, and weather patterns. Calculating the motion of these waves and predicting the weather using these calculations, among other information, is one of the great challenges for modern high-speed computers.

Aircraft, automobiles, or other rapidly moving objects, as well as air handlers and blowers in buildings, also produce substantial amounts of infrasonic radiation. Studies have shown that many people experience adverse reactions to large intensities of infrasonic frequencies, developing headaches, nausea, blurred vision, and dizziness. On the other hand, a number of animals are sensitive to infrasonic frequencies, as indicated in Table 7. It is believed by many zoologists that this sensitivity in animals such as elephants may be helpful in providing them with early warning of earthquakes and weather disturbances. It has been suggested that the sensitivity of birds to infrasound aids their navigation and even affects their migration.

S-waves, P-waves, and L-waves

One of the most important examples of infrasonic waves in nature is in earthquakes. Three principal types of earthquake wave exist: the S-wave, a transverse body wave; the P-wave, a longitudinal body wave; and the L-wave, which propagates along the boundary of stratified mediums. L-waves, which are of great importance in earthquake engineering, propagate in a similar way to water waves, at low velocities that are dependent on frequency. S-waves are transverse body waves and thus can only be propagated within solid bodies such as rocks. P-waves are longitudinal waves similar to sound waves; they propagate at the speed of sound and have large ranges.

When P-waves propagating from the epicentre of an earthquake reach the surface of the Earth, they are converted into L-waves, which may then damage surface structures. The great range of P-waves makes them useful in identifying earthquakes from observation points a great distance from the epicentre. In many cases, the most severe shock from an earthquake is preceded by smaller shocks, which provide advance warning of the greater shock to come. Underground nuclear explosions also produce P-waves, allowing them to be monitored from any point in the world if they are of sufficient intensity.

The reflection of man-made seismic shocks has helped to identify possible locations of oil and natural-gas sources. Distinctive rock formations in which these minerals are likely to be found can be identified by sonic ranging, primarily at infrasonic frequencies.

ENVIRONMENTAL NOISE

Many forms of noise in the urban environment, including traffic and airplane noise, industrial noise, and noise from electronically amplified music performed at high audio levels in confined rooms, may contribute to hearing damage. Even when the noise level in a working environment may not be dangerous, it can be distracting for those who work in that environment and therefore lead to reduced work production. In addition to the sound level, the character of the noise may be important. Identifiable noises, such as talking or music, may be more distracting for many people than noise produced by air handlers, small motors, or traffic.

Low levels of noise may be overcome using additional absorbing material, such as heavy drapery or sound-absorbent tiles in enclosed rooms. Where low levels of identifiable noise may be distracting, or where privacy of conversations in adjacent offices and reception areas may be important, the undesirable sounds may be masked. A small white-noise source such as static or rushing air, placed in the room, can mask the sounds of conversation from adjacent rooms without being offensive or dangerous to the ears of people working nearby. This type of device

is often used in offices of doctors and other professionals. Another technique for reducing personal noise level is through the use of hearing protectors, which are held over the ears in the same manner as an earmuff. By using commercially available earmuff-type hearing protectors, a decrease in sound level can be attained ranging typically from about 10 decibels at 100 hertz to over 30 decibels for frequencies above 1,000 hertz.

Environmental and industrial noise is regulated in the United States under the Occupational Safety and Health Act of 1970 and the Noise Control Act of 1972. Under these acts, the Occupational Safety and Health Administration has set up industrial noise criteria in order to provide limits on the intensity of sound exposure and on the time duration for which that intensity may be allowed. Maximum daily exposure to noise at various levels is given in Table 8. If an individual is exposed to various levels of noise for different time intervals during the day, the total exposure or dose (D) of noise is obtained from the relation

Calculating total noise exposure

$$D = \left(\frac{C_1}{T_1}\right) + \left(\frac{C_2}{T_2}\right) + \left(\frac{C_3}{T_3}\right) + \ldots, \qquad (41)$$

where C is the actual time of exposure and T is the allowable time of exposure at any level in Table 8. Using this formula, the maximum allowable daily noise dose will be 1, and any daily exposure over 1 is unacceptable.

Criteria for indoor noise are summarized in three sets of specifications that have been derived by collecting subjective judgments from a large sampling of people in a variety of specific situations. These have developed into the noise criteria (NC) and preferred noise criteria (PNC) curves, which provide limits on the level of noise introduced into the environment. The NC curves, developed in 1957, aim to provide a comfortable working or living environment by specifying the maximum allowable level of noise in octave bands over the entire audio spectrum. The complete set of 11 curves specifies noise criteria for a broad range of situations. The PNC curves, developed in 1971, add limits on low-frequency rumble and high-frequency hiss; hence, they are preferred over the older NC standard. Summarized in the curves shown in Figure 13, these criteria provide design goals for noise levels for a variety of different purposes. Part of the specification of a work or living environment is the appropriate PNC curve; in the event that the sound level exceeds PNC limits, sound-absorptive materials can be introduced into the environment as necessary to meet the appropriate standards.

Table 8: Daily Maximum Noise Exposure Permitted by the U.S. Occupational Safety and Health Act of 1970

sound level (decibels)	maximum hours per day
115	< 1/4
110	1/2
105	1

Outdoor noise limits are also important for human comfort. Standard house construction will provide some shielding from external sounds if the house meets minimum standards of construction and if the outside noise level falls within acceptable limits. These limits are generally specified for particular periods of the day—for example, during daylight hours, during evening hours, and at night during sleeping hours. Because of refraction in the atmosphere owing to the nighttime temperature inversion, relatively loud sounds can be introduced into an area from a rather distant highway, airport, or railroad. One interesting technique for control of highway noise is the erection of noise barriers alongside the highway, separating the highway from adjacent residential areas. The effectiveness of such barriers is limited by the diffraction of sound, which is greater at the lower frequencies that often predominate in road noise, especially from large vehicles. In order to be effective, they must be as close as possible to either the source or the observer of the noise (preferably to the source), thus maximizing the diffraction that would be necessary for the sound to reach the observer. Another requirement for this type of barrier is that it must also limit the amount of transmitted sound in order to bring about significant noise reduction.

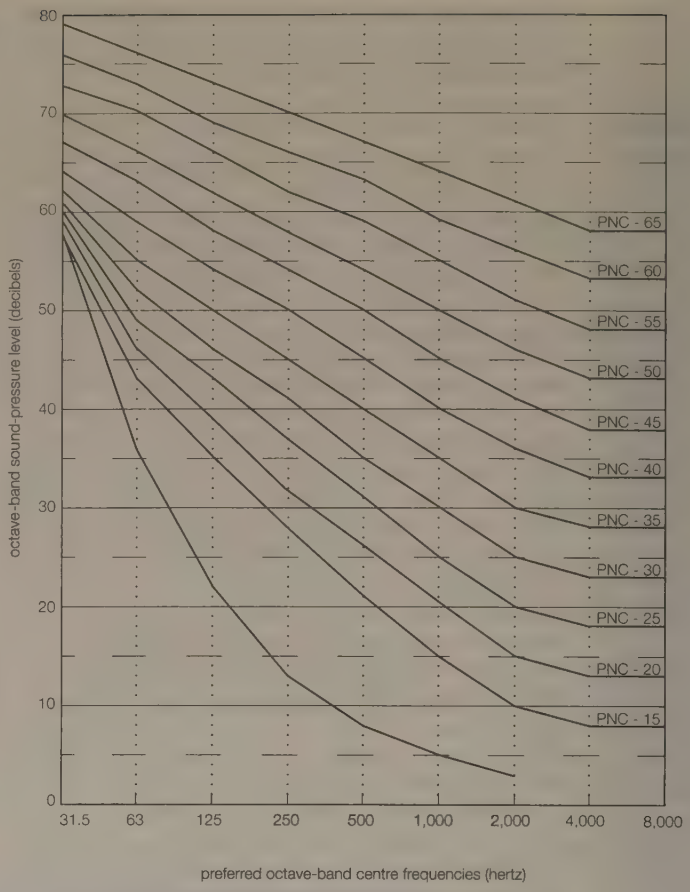

Figure 13: *Preferred noise criteria (PNC) curves.* The lowest curve indicates the approximate threshold of hearing for continuous noise.

From J.E.K. Foreman, *Sound Analysis and Noise Control* (1990), Van Nostrand Reinhold

BIBLIOGRAPHY

General works. Comprehensive discussions of the propagation and perception of sound, containing sections on the ear, on sound recording and reproduction, and on architectural acoustics, are offered in the following books, which require almost no mathematical background: JOHN BACKUS, *The Acoustical Foundations of Music,* 2nd ed. (1977); MURRAY CAMPBELL and CLIVE GREATED, *The Musician's Guide to Acoustics* (1987); JOHN R. PIERCE, *The Science of Musical Sound,* rev. ed. (1992); MICHAEL J. MORAVCSIK, *Musical Sound: An Introduction to the Physics of Music* (1987); and IAN JOHNSTON, *Measured Tones: The Interplay of Physics and Music* (1989). Books requiring an elementary understanding of mathematics include HARVEY E. WHITE and DONALD H. WHITE, *Physics and Music: The Science of Musical Sound* (1980); RICHARD E. BERG and DAVID G. STORK, *The Physics of Sound* (1982), with separate sections demanding considerable knowledge of musical notation and instruments; WILLIAM J. STRONG and GEORGE R. PLITNIK, *Music, Speech, High-Fidelity,* 2nd ed. (1983); JOHN S. RIGDEN, *Physics and the Sound of Music,* 2nd ed. (1985); and DONALD E. HALL, *Musical Acoustics,* 2nd ed. (1991). A somewhat higher level of mathematics is needed for the comprehensive ARTHUR H. BENADE, *Fundamentals of Musical Acoustics* (1976, reissued 1990), a relatively sophisticated classic in the field; and THOMAS D. ROSSING, *The Science of Sound,* 2nd ed. (1990), covering virtually every area of acoustics.

Important advanced texts include the following classics: LEO L. BERANEK, *Acoustics* (1954, reissued 1986); R. BRUCE LINDSAY, *Mechanical Radiation* (1960); and HARRY F. OLSON, *Music, Physics, and Engineering,* 2nd ed. (1967). More recent advanced comprehensive studies are ALLAN D. PIERCE, *Acoustics: An Introduction to Its Physical Principles and Applications* (1981, reissued 1989); F.B. STUMPF, *Analytical Acoustics* (1980); LAWRENCE E. KINSLER *et al., Fundamentals of Acoustics,* 3rd ed. (1982); DONALD E. HALL, *Basic Acoustics* (1987); and S.N. SEN,

Acoustics, Waves and Oscillations (1990). THOMAS D. ROSSING (ed.), *Musical Acoustics* (1988); and CARLEEN MALEY HUTCHINS (ed.), *The Physics of Music: Readings from Scientific American* (1978), are collections of articles.

An enormous amount of physical data on such topics as the velocity of sound and the elastic properties of materials, as well as surveys of important theories in the field, are found in the following reference books: HERBERT L. ANDERSON (ed.), *A Physicist's Desk Reference* (1989); DWIGHT E. GRAY (ed.), *American Institute of Physics Handbook*, 3rd ed. (1972); and RITA G. LERNER and GEORGE L. TRIGG (eds.), *Encyclopedia of Physics*, 2nd ed. (1991). For biographies of scientists who worked in the field of acoustics, see CHARLES COULSTON GILLISPIE (ed.), *Dictionary of Scientific Biography*, 16 vol. (1970–80).

Contemporary research in areas related to sound and its application is covered in periodicals: see *The Journal of the Acoustical Society of America* (monthly); *Acustica* (monthly); *Journal of Sound and Vibration* (biweekly); *Ultrasonics* (quarterly); *Soviet Physics: Acoustics* (bimonthly); and periodicals from other fields of knowledge, such as *JAMA: Journal of the American Medical Association* (weekly), for medical applications of ultrasound. *IEEE Transactions on Ultrasonics, Ferroelectrics, and Frequency Control* (bimonthly) covers topics of ongoing scientific conferences in all areas of sound and ultrasonics.

History of acoustics. JOHN WILLIAM STRUTT (BARON RAYLEIGH), *The Theory of Sound*, 2nd ed., rev. and enlarged, 2 vol. (1894–96, reissued 1945), remains a most important historical authority on nearly all aspects of theoretical acoustics. HERMAN L.F. HELMHOLTZ, *On the Sensations of Tone as a Physiological Basis for the Theory of Music*, 2nd English ed. (1885, reprinted 1954; originally published in German, 4th German ed., 1877), is the historical magnum opus in the field of psychoacoustics. Excellent collections of papers of historical interest include R. BRUCE LINDSAY (ed.), *Acoustics: Historical and Philosophical Development* (1973), and *Physical Acoustics* (1974); and STEPHEN G. BRUSH (ed.), *History of Physics: Selected Reprints* (1988).

The ear and hearing. A most important modern work on the physiology of hearing is GEORG VON BÉKÉSY, *Experiments in Hearing* (1960, reprinted 1980). JUAN G. ROEDERER, *Introduction to the Physics and Psychophysics of Music*, 2nd ed. (1975), thoroughly and clearly discusses the ear and hearing, using only basic mathematics. An excellent survey of psychoacoustics is provided in BRIAN C.J. MOORE, *An Introduction to the Psychology of Hearing*, 3rd ed. (1989). Modern experiments in hearing are described in REINIER PLOMP, *Aspects of Tone Sensation: A Psychophysical Study* (1976).

Sound in animals and birds. Data on hearing ranges in animals is collected in RICHARD R. FAY, *Hearing in Vertebrates: A Psychophysics Databook* (1988). CHANDLER S. ROBBINS, BERTEL BRUUN, and HERBERT S. ZIM, *Birds of North America*, expanded rev. ed. (1983), includes audio spectrographs of bird calls.

Electromechanical transducers, sound recording, and sound reproduction. HARRY F. OLSON, *Acoustical Engineering* (1957), and *Modern Sound Reproduction* (1972), are the advanced classics in the field, including detailed discussions of loudspeaker design. An excellent introduction to audio equipment is provided in INSTITUTE OF HIGH FIDELITY, *Official Guide to High Fidelity*, 2nd ed. (1978). A later introduction to audio reproduction is offered in KENNETH W. JOHNSON, WILLARD C. WALKER, and JOHN D. CUTNELL, *The Science of Hi-Fidelity*, 2nd ed. (1981). Advanced treatment of electromechanical transducers is found in JOSEF MERHAUT, *Theory of Electroacoustics*, trans. from Czech (1981); JOHN BORWICK, *Microphones: Technology and Technique* (1990); and MARTIN COLLOMS, *High Performance Loudspeakers*, 4th ed. (1991). JOHN EARGLE, *Sound Recording*, 2nd ed. (1980), is of interest for its treatment of older audio reproduction technology, including LP disc recordings and quadraphonic sound. Eargle's later work, *Handbook of Recording Engineering*, 2nd ed. (1992), also covers digital sound recording. Both audio and video magnetic tape technology is discussed in JOHN C. MALLINSON, *The Foundations of Magnetic Recording* (1987); and C. DENIS MEE and ERIC D. DANIEL, *Magnetic Recording*, 3 vol. (1987–88). For digital techniques, see KEN C. POHLMANN, *Principles of Digital Audio*, 2nd ed. (1989), on the compact disc; and JOHN WATKINSON, *RDAT* (1991), on the rotary head digital audiotape.

Architectural acoustics. An important survey of the subject is found in WALLACE C. SABINE, *Collected Papers on Acoustics* (1964). LEO L. BERANEK (ed.), *Noise and Vibration Control*, rev. ed. (1988), contains excellent sections applying to concert halls; and LEO L. BERANEK, *Music, Acoustics & Architecture* (1962, reprinted 1979), discusses more than 50 existing concert halls, relating physical properties of sound waves in auditoriums to their subjective effects. Eighty-seven concert halls are surveyed in the illustrated work by RICHARD H. TALASKE, EWART A. WETHERILL, and WILLIAM J. CAVANAUGH (eds.), *Halls for Music Performance: Two Decades of Experience, 1962–1982* (1982). LOTHAR CREMER and HELMUT A. MÜLLER, *Principles and Applications of Room Acoustics*, 2 vol. (1982; originally published in German, 2nd ed., 1976–78), is a detailed and advanced treatment.

Ultrasonics. Classic works in the field of ultrasonics include BASIL BROWN and JOHN E. GOODMAN, *High-Intensity Ultrasonics: Industrial Applications* (1965); ROBERT T. BEYER and STEPHEN V. LETCHER, *Physical Ultrasonics* (1969); DALE ENSMINGER, *Ultrasonics: Fundamentals, Technology, Applications*, 2nd ed., rev. and expanded (1988); and ROBERT T. BEYER, *Nonlinear Acoustics* (1974). P.N.T. WELLS, *Biomedical Ultrasonics* (1977), provides a summary of biomedical applications through the time of publication. Another survey of developments of the period is ROBERT T. BEYER, "A New Wave of Acoustics," *Physics Today*, 34(11):145–157 (November 1981). JAMES R. MATTHEWS (ed.) *Acoustic Emission* (1983), describes in great detail modern techniques for testing materials with ultrasonic emissions. A variety of applications are studied in A.P. CRACKNELL, *Ultrasonics* (1980); KENNETH S. SUSLICK (ed.), *Ultrasound: Its Chemical, Physical, and Biological Effects* (1988); and D. STANSFIELD, *Underwater Electroacoustic Transducers: A Handbook for Users and Designers* (1990). B.P. HILDEBRAND and B.B. BRENDEN, *An Introduction to Acoustical Holography* (1972), surveys holographic techniques and the basis for later development in medical imaging. HARVEY FEIGENBAUM, *Echocardiography*, 4th ed. (1986), discusses ultrasonic cardiography. RUSSEL K. HOBBIE (ed.), *Medical Physics: Selected Reprints* (1986), collects articles on advances in medical ultrasonics. Information on later research activity in the field is found in B.R. MCAVOY (ed.), *IEEE 1990 Ultrasonics Symposium: Proceedings*, 3 vol. (1989); and in the materials published in the serial *Physical Acoustics: Principles and Methods* (irregular), ed. by WARREN P. MASON and R.N. THURSTON.

Infrasonics. Infrasonic waves in nature are studied in EARL E. GOSSARD and WILLIAM H. HOOKE, *Waves in the Atmosphere: Atmospheric Infrasound and Gravity Waves: Their Generation and Propagation* (1975). Experimental infrasonic techniques are discussed in A.F. YAKUSHOVA, *Geology with the Elements of Geomorphology* (1986; originally published in Russian, 2nd rev. ed., 1983); and BRUCE A. BOLT (ed.), *Earthquakes and Volcanoes: Readings from Scientific American* (1980).

Environmental noise. U.S. law and public policy regarding environmental noise are described in UNITED STATES OFFICE OF NOISE ABATEMENT AND CONTROL, *Public Health and Welfare Criteria for Noise* (1973). A wealth of data is accumulated in CYRIL M. HARRIS (ed.), *Handbook of Noise Control*, 2nd ed. (1979). Noise control applications are examined in P.O.A.L. DAVIES, M. HECKL, and G.L. KOOPMAN, *Noise Generation and Control in Mechanical Engineering* (1982); LEWIS H. BELL *et al.*, *Industrial Noise Control: Fundamentals and Applications* (1982); and JOHN E.K. FOREMAN, *Sound Analysis and Noise Control* (1990). (R.E.B.)

South America

South America, the fourth largest of the world's continents, is the southern portion of the landmass generally referred to as the New World, the Western Hemisphere, or simply the Americas. It is compact and roughly triangular in shape, being broad in the north and tapering to a point—Cape Horn, Chile—in the south.

South America is bounded by the Caribbean Sea to the northwest and north, the Atlantic Ocean to the northeast, east, and southeast, and the Pacific Ocean to the west. In the northwest it is joined to North America by the Isthmus of Panama, which forms a land bridge narrowing to about 50 miles (80 kilometres) at one point. Drake Passage, south of Cape Horn, separates South America from Antarctica.

Relatively few islands are associated with the continent, except in the south. These include the glaciated coastal archipelagoes of Argentina and Chile. The Falkland (Malvinas) Islands are east of southern Argentina. To the north, the West Indies stretch from Trinidad to Florida, but these islands usually are associated with North America. Of the remainder, most are small oceanic islands off the coasts of South America, including the Galápagos Islands, Ecuador, in the Pacific Ocean.

South America has a total area of about 6,878,000 square miles (17,814,000 square kilometres), or roughly one-eighth of the land surface of the Earth. Its greatest north-south extent is about 4,700 miles, from Point Gallinas, Colom., to Cape Horn; while its greatest east-west extent is some 3,300 miles, from Cape Branco, Braz., to Point Pariñas, Peru. At 22,831 feet (6,959 metres) above sea level, Mount Aconcagua, in Argentina, near the border with Chile, is not only the continent's highest point but also the highest elevation in the Western Hemisphere. The Valdés Peninsula, on the southeastern coast of Argentina, includes the lowest point, at 131 feet (40 metres) below sea level. In relation to its area, the continent's coastline—some 15,800 miles in length—is exceptionally short.

The name America is derived from that of the Italian merchant and navigator Amerigo Vespucci, one of the earliest European explorers of the New World. The term America originally was applied only to South America, but the designation soon was applied to the entire landmass. Because Mexico and Central America share an Iberian heritage with nearly all of South America, this entire region frequently is grouped under the name Latin America.

South America's geologic structure consists of two dissymetric parts. In the larger, eastern portion are found a number of stable shields forming highland regions, separated by large basins (including the vast Amazon basin). The western portion is occupied almost entirely by the Andes Mountains. The Andes—formed as the South American Plate moved westward and forced the oceanic plate to the west under it—constitute a gigantic backbone along the entire Pacific coast of the continent. The basins east of the Andes and between the eastern highlands have been filled with immense quantities of sediment washed down by the continent's great rivers and their tributaries.

No other continent—except Antarctica—penetrates so far to the south. Although the northern part of South America extends north of the Equator and four-fifths of its landmass is located within the tropics, it also reaches subantarctic latitudes. Much of the high Andes lie within the tropics but include extensive zones of temperate or cold climate in the vicinity of the Equator—a circumstance that is unique. The great range in elevation produces an unrivaled diversity of climatic and ecological zones, which is probably the most prominent characteristic of South American geography.

The original inhabitants of South America are believed to have descended from the same Asiatic peoples who migrated to North America from Siberia during the most recent (Wisconsin) ice age. Few of these peoples, however, survived the arrival of Europeans after 1500, most succumbing to disease or mixing with people of European and (especially in Brazil) African origin. Some parts of the continent are now industrialized, with modern cities, but the people of most regions still follow an agricultural way of life. The wealth of mineral products and renewable resources is considerable, yet economic development in most of the continent lags behind the more industrially advanced regions of the world. Nonetheless, considerable concern has arisen about the rapidly increasing and often destructive exploitation of these resources.

(J.P.D./C.W.M.)

This article treats the physical and human geography of South America, followed by discussion of geographic features of special interest. For discussion of individual countries of the continent, see specific articles by name, *e.g.*, ARGENTINA, BRAZIL, and VENEZUELA. For discussion of major cities of the continent, see the articles BUENOS AIRES, CARACAS, LIMA, RIO DE JANEIRO, and SÃO PAULO. For discussion of the indigenous peoples of the continent, see the articles AMERICAN PEOPLES, NATIVE; and PRE-COLUMBIAN CIVILIZATIONS. Related topics are discussed in the articles AMERICAN PEOPLES, ARTS OF NATIVE; LATIN AMERICA, THE HISTORY OF; and LATIN-AMERICAN LITERATURE. For further references, see the *Index*.

PHYSICAL AND HUMAN GEOGRAPHY

Geologic history

Three stages of geologic history

The geologic history of South America can be summarized in three different developmental stages, each corresponding to a major division of geologic time. The first stage encompassed Precambrian time (3.96 billion to 570 million years ago) and was characterized by a complex series of amalgamations and dispersals of stable blocks of protocontinental crust called cratons. The second stage coincides with the Paleozoic Era (570 to 245 million years ago), during which time the cratons and material accreted to them contributed to the formation first of the supercontinent Gondwana (or Gondwanaland) and then of the even larger Pangaea. The third stage, in which the present continental structure emerged, occurred in the Mesozoic and Cenozoic eras (the last 245 million years) and includes the breakup of Pangaea and Gondwana, the opening of the South Atlantic Ocean, and the generation of the Andean cordillera.

The present tectonic framework of South America consists of three fundamental units: the ancient cratons, the relatively recent Andean ranges, and a number of basins. Five cratons—Amazonia, São Francisco, Luis Alves, Alto Paraguay, and Río de la Plata—represent the Precambrian core of South America, and (with the exception of the Alto Paraguay craton) these now appear as upwarped massifs arrayed from north to south in the immense eastern portion of the continent; a number of other Precambrian crustal blocks also were accreted along the margins of South America over geologic time. The lofty ranges and intermontane plateaus of the Andes rise along the entire western margin of the continent and represent the collision in the Cenozoic Era (the last 66.4 million years) of the Pacific and South American plates brought about by the opening of the South Atlantic. Finally, vast, downwarped, sediment-filled basins are found between the cratons and along the entire eastern margin of the Andes.

THE PRECAMBRIAN

Precambrian rocks constitute the oldest rocks of the continent and are preserved in the five core cratons. These rocks are represented by high- to low-grade metamorphosed assemblages along heavily deformed belts of plutonic (intrusive), metavolcanic (metamorphosed extrusive igneous rocks), and metasedimentary rocks. Rocks of Archean age (2.5 to 3.8 billion years old) are known in the Amazonia, Luis Alves, and São Francisco cratons, although precisely dated rock samples are scarce. Ages older than 3 billion years have been reported in the Imataca Complex of Venezuela and in the Xingu area of Brazil, both in the Amazonia craton. The oldest rocks found so far—with ages of some 3.4 billion years—are in the São Francisco craton in the Brazilian state of Bahia. In the other cratons (*e.g.*, the Río de la Plata craton in Uruguay) the dating of Archean rocks has been inconclusive. Greenstone belts, which are remnants of Archean oceanic crust emplaced in the suture zones (convergent plate boundaries), contain most of South America's known large gold deposits, such as those located near Belo Horizonte, Braz. Two major cycles of crustal deformation occurred in the Precambrian, widely separated in time from each other. The first, called the Trans-Amazonian cycle, took place approximately 2.2 to 1.8 billion years ago; and the second, the Brazilian cycle, between about 900 and 570 million years ago.

Oldest rocks on the continent

The Trans-Amazonian cycle. Trans-Amazonian rocks can be subdivided into three distinct groups: orogenic belts, such as the Maroni-Itacaiúnas belt of the Amazonia craton or the Salvador-Juazeiro belt of the São Francisco; stable cover rocks, such as the Chapada Diamantina formation in Bahia or the Carajás and Roraima platform deposits; and large extensional dike swarms (groups of tabular intrusions of igneous rock into sedimentary strata). The orogenic belts represent old mountain chains that had been formed either along the margins of the continent as geosynclines (downwarps of the Earth's crust) and then uplifted, such as the Maroni-Itacaiúnas belt, or were the result of collisions between continental blocks, such as the Tandil belt in Buenos Aires, Arg.

Such collisions are believed to have formed a supercontinent (sometimes called the first Pangaea) some 1.8 billion years ago. The sedimentary cover of this supercontinent (preserved on the Amazonia craton), consisting of post-collision rhyolites and clastic shelf deposits, was deep and widespread and obliterated earlier suture boundaries. Extensive stratified iron and manganese deposits are found in these sequences, such as near Carajás, Braz. Early phases of continental-plate dispersal produced extensive dike swarms of mafic rock, including a zone some 60 miles wide in west-central Uruguay where hundreds of gabbro dikes are now emplaced along a 150-mile stretch.

The Brazilian cycle. Rocks of the Brazilian cycle today are manifested in a series of orogenic belts—developed mainly on previously deformed continental crust—that were formed during the amalgamation of the Precambrian cratons into the first supercontinent in late Proterozoic time (900 to 570 million years ago). Most of present-day South America, encompassing the platforms of Brazil, Guyana, and southern Venezuela, was accreted at this time—together with Africa—to form the western part of the huge southern supercontinent of Gondwana; Precambrian blocks that were not part of Gondwana—notably the Santa Marta massif in Colombia, Mount Arequipa in Peru, and Patagonia in Argentina—were accreted later during Paleozoic times.

The Brasilides

The Brasilides in the southern Brazilian state of Matto Grosso represent the type locality of the Brazilian orogenic cycle. There, important sequences of green schists, platform limestones, and quartzites, as well as red bed molasse formations (associated with granitoids), permit a reconstruction of the collision between the Amazonia craton's passive (*i.e.*, without active volcanoes) margin and the Alto Paraguay craton's active margin (now partially covered by the Paraná basin). The interpreted suture zone between these two cratons corresponds to the Paraguay-Araguaia line, along which mafic and ultramafic rocks are found today.

Several other Brazilian belts are known, such as the structurally complex Borborema belt and the Dom Feliciano belt in southern Brazil and Uruguay, which resulted from the collision between the Río de la Plata craton and the Kalahari craton of present-day Africa. The Dom Feliciano belt represents a complex suture zone where rocks typical of a late Proterozoic arc system were trapped between the two cratons; these rocks were then covered by plateaus of rhyolites during the Early Cambrian Period (570 to 540 million years ago). A striking coincidence exists between this suture, which is known as the Brazilian–Pan-African suture, and the inception of the future rift system that opened the Atlantic Ocean. The Pampean Sierras in Argentina are a good example of a Brazilian belt formed by accretion of an island-arc system and several small continental plates.

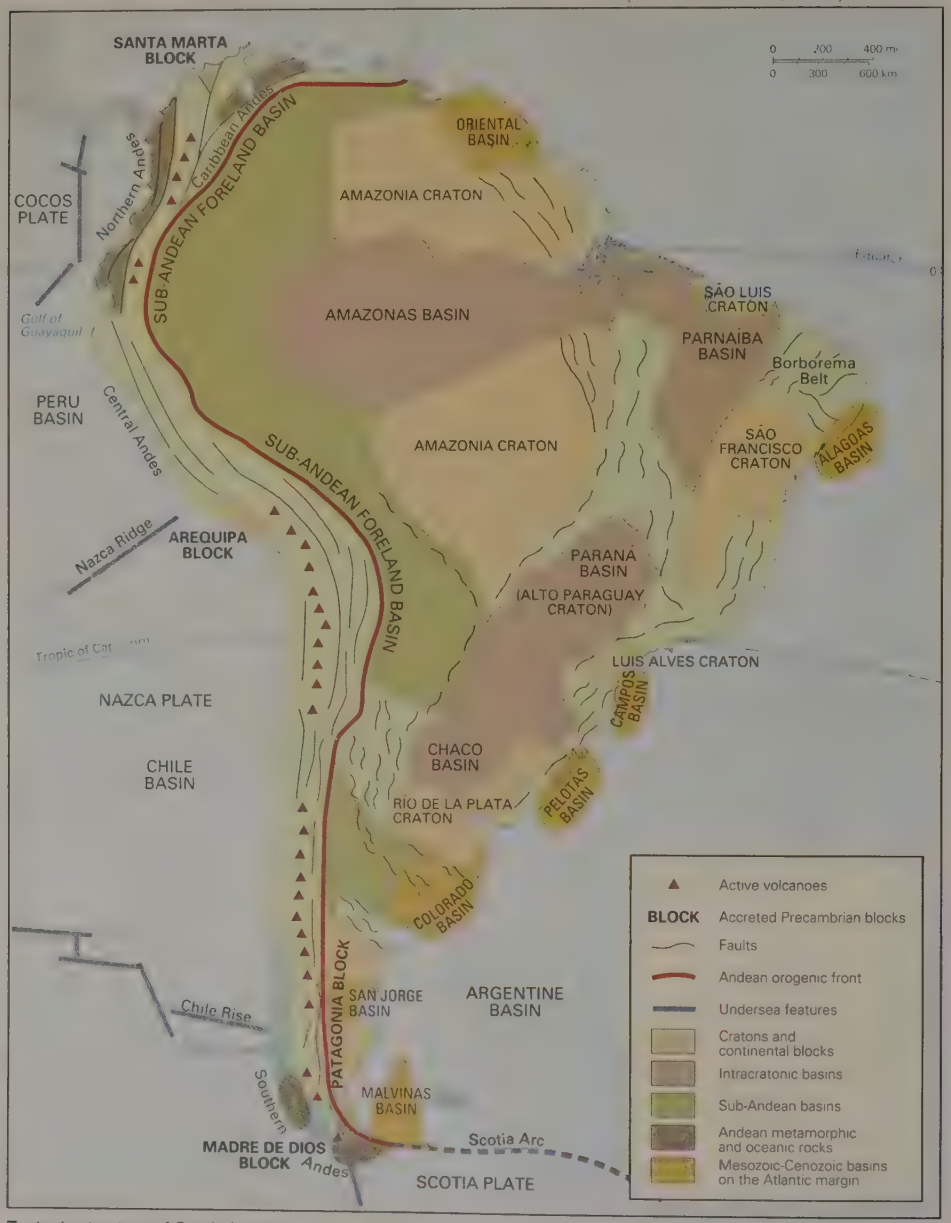
THE PALEOZOIC ERA

Early Paleozoic events. The continent's early Paleozoic rocks depict the breakup of the first supercontinent, an event probably related to the separation of eastern North America from the pre-Andean basement rocks of western South America. As a result of this separation, a series of passive continental margins developed along the western side of the continent from Venezuela and Colombia to central Argentina; essentially, the Precambrian platform amalgamated during the Brazilian cycle. These rifted margins today are represented mainly by clastic rocks from the Late Cambrian and Early Ordovician periods (*i.e.*, roughly 500 million years old) bearing numerous trilobites and graptolites, as in the Cordillera Oriental of Bolivia. The early Paleozoic rift that produced these margins also initiated the development of several large intracratonic basins within the continent (*e.g.*, the Amazonas, Parnaíba, Paraná, and Chaco basins). Thick deposits of sedimentary rocks have since accumulated in these basins.

The passive margins of the early Paleozoic were partially activated by subduction of oceanic crust (*i.e.*, the forced descent of oceanic crust beneath the leading edge of an overriding continental plate) during Late Cambrian–Ordovician times. When the oceanic crust was totally consumed, subduction ceased and a series of small continental blocks collided against the western side of the continent. Allochthonous (transported) continental blocks thus were emplaced in the Cordillera Oriental of Ecuador, Colombia, and Venezuela at the end of the Silurian Period (about 408 million years ago). Rock ages corresponding to those of the North American Grenville orogenic belt (*c.* 1.3 to 1.2 billion years old), as well as affinities to North American fauna of the Devonian Period (408 to 360 mil-

Correspondence to North American rocks

Adapted from Victor A. Ramos, University of Buenos Aires



Tectonic structure of South America.

lion years ago), suggest that these blocks were once part of North America.

Farther south, another series of blocks collided against the continent. These included the Arequipa craton in southern Peru and Bolivia, the Precordillera region of west-central Argentina, and Patagonia in southern Argentina. At the same time, some minor blocks consisting of rocks exhibiting a marine affinity were accreted to the continent in the southern Patagonian archipelago of Chile.

In the course of the subduction process that preceded these collisions, a series of north–south-trending belts of plutonic and volcanic rock formed offshore of the continent and parallel to the coast. Because of the later accretions of continental crust to the coastal margin, these belts were shifted more than 250 miles westward and today form prominent outcrops in northern Patagonia, the western Pampean Sierras, the Cordillera Oriental of Bolivia and northern Argentina, and the Cordillera Oriental of Colombia and Venezuela.

The collision of these blocks also produced a series of peripheral foreland basins, which were the result of crustal deformation and the stacking of slices of basement rocks in the orogenic areas. Examples of basins of the early Paleozoic age are the Beni basin in Bolivia and the Alhuampa and Las Breñas basins in northern Argentina. The late Paleozoic Claromecó foreland basin in northern Patagonia is now occupied by a sedimentary accumulation more than five miles thick that was formed at the same time as the Karoo basin in southern Africa, both basins resulting from the collision of the microcontinent of Patagonia against Gondwana.

The formation of Pangaea. The Paleozoic ended with the final amalgamation of Gondwana, which together with Laurasia to the north constituted the late Paleozoic supercontinent of Pangaea. Subduction beneath the western margin of Pangaea slowly ceased. The igneous rocks formed in the volcanic arc that developed along what is now the Cordillera Central between Chile and Argentina and then along the western continental margin, are transitional in nature—*i.e.,* the composition of the rocks changes from primarily andesitic to predominantly rhyolitic. These changes in mineral composition indicate the passage from a subduction-related compressive regime to one of extensive magmatic activity and crustal extension. Vast sheets of magma, consisting of flood basalts and of rhyolite deposits up to 2.5 miles thick, covered the west from southern Peru to the border between Argentina and Chile. Farther north this activity was partially obliterated in Cenozoic times by the uplifting of the Andes and by volcanic cover.

THE MESOZOIC AND CENOZOIC ERAS

Events in the Mesozoic. The mosaic of continental blocks accreted to form the Pangaea supercontinent was unstable and remained amalgamated for only a few million years. Extensive sedimentary cover indicative of arid conditions was accumulated unevenly in the late Paleozoic basins. Desertic sandstones, mudstones, and tuffs of Triassic age (245 to 208 million years ago) have preserved fossils of a rich fauna of dinosaurs and mammallike reptiles, as in the Ischigualasto basin of Argentina.

A series of Middle to Late Triassic basins also developed through horizontal crustal extension during the early phases of Pangaea's dispersal. These rifted basins largely followed the previous Paleozoic sutures along the western side of the continent. Crustal extension reactivated the inner part of the supercontinent as well, with an increase in subsidence in the Parnaiba and Paraná intracratonic basins, where deposits of Triassic age have been recovered from core samples.

Opening of the South Atlantic

The opening of the South Atlantic Ocean is recorded in a series of Mesozoic and Cenozoic basins that developed along the present Atlantic margin. Most of these basins have clastic red beds that date to the Late Jurassic and Early Cretaceous periods (about 163 to 97.5 million years ago). North of Pôrto Alegre, Braz., are found evaporite salt deposits created in marine basins with restricted circulation. Sediments formed under less restricted drift conditions began approximately 125 million years ago and are younger to the north, where they are mostly represented by clastic marine deposits. The basins of northern Brazil have carbonate deposits mixed with clastics. Deposits laid down in a restricted-circulation, anoxic (oxygen-poor) environment along the basins of Brazil and Argentina now contain abundant black shales rich in organic matter and are an important source of hydrocarbons.

Open marine conditions have prevailed in the Atlantic basins since mid-Cretaceous times. The first open oceanic circulation between the South and North Atlantic oceans was established along the passive margin of South America in the Late Cretaceous Period (97.5 to 66.4 million years ago), though marine sediments had accumulated and been lithified in these basins for some time prior to that.

The Andean orogeny. Coincident with most of the Cenozoic Era has been the Andean orogeny, the most significant geologic event of the era. The mountain ranges, however, display some of the same features found in the previous orogenies that developed along the western continental margin, such as the classical Andean volcanic belt, the east-vergence sub-Andean thrust and fold belt, and a series of cordilleras trending parallel to the Pacific oceanic trench. These features are a response to subduction of the ocean crust that was accelerated by the opening of the South Atlantic; and this subduction overshadows all other geomorphic processes along South America's Pacific margin.

The Andean orogeny has three distinct segments, each of which developed in a different geologic setting. The segments are differentiated by their relative abundances of Mesozoic-Cenozoic, metamorphic, and oceanic rocks and are divided into Northern, Central and Southern sectors.

The Northern Andes. North of the Gulf of Guayaquil in Ecuador and Colombia, a series of accreted oceanic terranes (discrete allochthonous fragments) have developed that constitute the Baudo, or Coastal, Mountains and the Cordillera Occidental. They were accreted during Cretaceous and early Cenozoic times. Structurally composed of oceanic volcanic arcs that were amalgamated after each collision by high-angle, west-verging thrusts, the Northern Andes are characterized by the heavily deformed metamorphic rocks and ophiolitic suites that developed during these collisional episodes. During mid-Cenozoic times, a continental magmatic arc was formed between the eastern and western cordilleras.

Farther east, the Andes of Venezuela (the Caribbean Andes) resulted from the collision of the Caribbean and South American plates during Cretaceous times. This complex setting developed a series of wrench faults and related basins east of Bucaramanga (Colombia) and north of the Orinoco River delta (Venezuela). One of these basins, now occupied by Lake Maracaibo, has the largest accumulation of hydrocarbon deposits so far discovered in South America.

Lake Maracaibo

The Central Andes. The Central Andes lie between the Gulfs of Guayaquil and Penas and thus encompass southern Ecuador, Peru, western Bolivia, and northern and central Argentina and Chile. They are characterized by their continental basement rocks and by an absence of oceanic and metamorphic rocks. The formation of the Central Andes was determined by subduction processes that occurred in the absence of major plate collisions. A period of crustal extension prevailed from the Jurassic Period (208 to 144 million years ago) to Early Cretaceous times, when important volcanic piles and plutonic rocks were emplaced. Back-arc basins developed in the sub-Andean regions, controlled by extensional faulting that occurred at about the same time the South Atlantic was opening.

The middle of the Cretaceous in the Central Andes was marked by a change in tectonic activity—from crustal extension to crustal compression. This change was related to an increase in the convergence rate between South America and the adjacent oceanic plate, which initiated the formation of a series of sub-Andean foreland basins from Colombia to central Argentina. Within these basins are now concentrated most of the petroleum resources of the Andean countries.

Since Cretaceous times the Central Andes have been characterized by considerable volcanism along the axis of

Geologic structure of South America.

the principal cordillera. Andesites, basalts, and rhyolites have been the major rock types to result from this activity, with some granitoids as well. Most of the gold and copper mined in Peru, Bolivia, and Chile comes from these formations.

The Southern Andes. The cordilleras south of the Gulf of Penas constitute the Southern Andes. These belts are defined by a long linear batholith (large exposed mass of coarse-grained igneous rock) that now extends unbroken to Estados Island in the South Atlantic. Outcrops of Early Cretaceous mafic and ultramafic rock found south of latitude 50° S along the axis of the cordillera have been interpreted as ocean floor of a back-arc marginal basin. Metamorphic rocks of Andean age are preserved only in the Darwin Cordillera along the Fuegian Andes of Chile. The eastern sub-Andean belt is composed of a series of back-arc and foreland basins, in which sediments more than five miles thick have accumulated.

Present geologic setting. The glaciations that encompass most of the Pleistocene Epoch (1,600,000 to 10,000

years ago) began in southern South America as early as the Late Miocene Epoch (*i.e.*, about 9,000,000 years ago), when ice caps first covered the Patagonian Andes. Maximum ice expansion was reached about 1,000,000 years ago during the Early Pleistocene, when ice sheets covered the Andes from Ecuador to Tierra del Fuego. In some areas, notably Patagonia, ice extended east to the Atlantic Ocean. About 10,000 years ago the glacial ice retreated, and the present landscape of South America began to take shape. South America's contemporary geology is characterized by continued volcanic and seismic activity along the Andes and relatively aseismic conditions to the east. (V.A.R.)

The land

RELIEF

South America has two major mountain systems of contrasting nature. Bordering the Pacific Ocean to the west, the geologically young cordilleras of the Andes extend along the entire continent from north to south. Stretching along the continent's northern and eastern sides are the ancient Guiana and Brazilian highlands, which are much lower in elevation and slope gently to the west; farther south are the Patagonian plateaus. Lowlands—the basins of the Orinoco, Amazon, and Paraguay-Paraná rivers and the plains of the Pampas—divide the highlands from one another. Taken as a whole, the relief of the continent shows a great imbalance: the major drainage divide is far to the west along the crest of the Andes. Thus, rain that falls only 100 miles (160 kilometres) east of the Pacific may flow to the Atlantic, 2,500 miles away.

The Andes Mountains. The ranges of the Andes Mountains, about 5,500 miles long and second only to the Himalayas in average elevation, constitute a formidable and continuous barrier, with many summits exceeding 20,000 feet (6,100 metres). The Venezuelan Andes—the northernmost range of the system—run parallel to the Caribbean coast west of Caracas, before turning to the southwest and entering Colombia. In Colombia the Andes—now trending generally to the north and south—form three distinct massifs: the Cordilleras Oriental, Central, and Occidental. The valley of the Magdalena River, between the Oriental and the Central ranges, and the valley of the Cauca River, between the Central and the Occidental ranges, are huge rift valleys formed by faulting rather than by erosion. An aerial view of the Andes in Colombia shows, within relatively short distances, a succession of hot lowlands interspersed with high ranges with snowcapped peaks.

The Northern Andes

In Ecuador the Andes form two parallel cordilleras, one facing the Pacific and the other descending abruptly eastward toward the Amazon basin, crowned by towering peaks. Between the ranges lies a series of high basins. These ranges continue southward into Peru, where the relief becomes considerably more complex; the highest of the Peruvian peaks is Mount Huascarán (22,205 feet) in the Cordillera Blanca.

Beginning to the south of Lima and extending through western Bolivia, the Andes again form two distinct ranges. Between them lies the Altiplano, a vast complex of high plateaus between 12,000 and 15,000 feet in elevation and as much as 125 miles wide. The Altiplano forms a maze of valleys, hills, and vast plains without equivalent except in Tibet. Water accumulates in closed basins to form marshes and lakes, the largest of which is Lake Titicaca on the border of Peru and Bolivia. This central region of the Andes has been dissected by several large rivers, all of which have cut spectacular gorges down the eastern slopes.

Farther to the south—along the border between Chile and Argentina—the Andes form a single but complex chain with many of the system's highest peaks, including Mount Aconcagua; south of Aconcagua, elevations gradually diminish. In southern Chile a part of the cordillera descends beneath the sea, forming innumerable islands with steep slopes. The Andes have been deeply carved by glaciers, particularly in the south. Glaciers still occupy some 1,900 square miles (4,900 square kilometres), constituting a huge ice cap with long terminal tongues running into lakes or into the sea.

The Andes are studded with numerous volcanoes that form part of the Circum-Pacific volcanic chain, often called the Ring of Fire. Earthquakes are frequent. Almost every major city has been devastated at least once by earthquake, even along the coastal plains, where clear signs of recent vertical movement are visible.

The plateaus. To the north and east, the Guiana and Brazilian highlands consist of ancient crystalline rocks greatly worn through prolonged erosion. The Guiana Highlands are mostly below elevations of 1,000 feet, with small rises separated by marshy depressions. Occasional dome-shaped granitic inselbergs (steep-sided residual hills)—some 2,000 feet in elevation—surmount the landscape. The southern edge rises abruptly to a series of mountain chains and high tablelands (*tepuis*), in which the highest peak is Mount Roraima (9,094 feet).

The Brazilian Highlands

Covering an area of about 580,000 square miles, the Brazilian Highlands (also called the Brazilian Plateau) rise to an average elevation of about 3,000 feet and are crowned by numerous ranges of hills. Included in this region is Bandeira Peak (9,482 feet), one of the highest points in Brazil. The São Francisco River, draining a large basin to the east, has cut deeply into the highlands. In the north the highlands slope gently to the sea, but in the east they drop abruptly, as much as 2,600 feet within a few miles. Skirting their southern edge, the Serra do Mar has summits of more than 7,000 feet in elevation. The sea has partly invaded the original coastal ranges and

Tablelands (*tepuis*) rising behind Hacha Falls on the Carrao River, in the Guiana Highlands of eastern Venezuela.

formed Guanabara Bay, which includes the harbour for Rio de Janeiro. Nearby are such steep-sided rocky masses as Sugar Loaf (Portuguese: Pão de Açucar; 1,296 feet) and Corcovado Peak (2,309 feet), which rise dramatically from the sea.

In the far south, Patagonia constitutes a series of vast tablelands that rise, terracelike, from the Atlantic to the Andes and are covered with rounded pebbles and crumbling sandstones. Geologically recent volcanic eruptions have spread sheets of basaltic lava over large parts of southern Patagonia and have dotted the sedimentary plateaus with volcanic cones.

The lowlands. The Orinoco River basin is nearly coextensive with the Llanos. It lies between the coastal ranges of the Venezuelan Andes and the Guiana Highlands and is covered with alluvia brought down by the Andean torrents.

The Amazonian depression, the largest river basin in the world, forms an enormous region, bounded by the Andes to the west, the Guiana Highlands to the north, and the Brazilian Highlands to the south. The ancient platform of Precambrian rock underlying the depression is covered with deep layers of alluvial sand and clay, so that it forms an immense plain of low undulations, the general incline being extremely slight. The river port of Iquitos, Peru, which is about 2,500 miles from the Atlantic Ocean, is at an elevation of only 384 feet, while Manaus, Braz., far downstream in the heart of the basin, has an altitude of 144 feet.

The basin of the Paraguay River, between the Bolivian Andes in the west and the Brazilian Highlands in the east, consists of a series of alluvial plains drained by a complex network of rivers interspersed with marshes. To the east, the marshes are called the Pantanal. They are only a few hundred feet above sea level, are subject to annual flooding, and form an immense swamp during the rainy season. The extensive plains west of the river, called the Gran Chaco, generally are arid.

The Pampas of Argentina, covering almost 300,000 square miles, consist of an enormous accumulation of loose sediments brought down from the Andes. These deposits, 1,000 feet deep at Buenos Aires and even deeper in other places, have completely buried the ancient features of the land. The landscape seems perfectly level, although it actually rises imperceptibly toward the west—from near sea level at Buenos Aires to 2,320 feet at Mendoza. Some hills, such as the Córdoba and San Luis ranges, are conspicuous features on the otherwise flat plains.

Detailed discussion of the Andes Mountains, Gran Chaco, and Patagonia can be found in *South American geographic features of special interest* at the end of this article.

DRAINAGE

Rivers. Drainage has been notably affected by the physical dissymmetry of the continent. The major basins lie east of the Andes, and the main rivers flow to the Atlantic Ocean. The four largest drainage systems—the Amazon, Río de la Plata (Paraguay, Paraná, and Uruguay rivers), Orinoco, and São Francisco—cover nearly three-fourths of the continent.

The Amazon basin

By far the largest system is formed by the Amazon River. Stretching some 4,000 miles across equatorial South America, the Amazon is second in length only to the Nile. The volume of water it carries surpasses that of all other rivers, constituting one-fifth of the total flowing fresh water of the world. About 6,350,000 cubic feet (179,800 cubic metres) of water per second is emptied into the Atlantic by the Amazon, which is more than 10 times the outflow of the Mississippi River. The Amazon drains some 2,722,000 square miles—about two-fifths of South America—and has more than 1,000 tributaries, several of which are more than 1,000 miles long. Rising in the central Peruvian Andes, it is named the Marañón in its upper course; after being joined by several rivers—including the Ucayali, from which the Amazon's length is measured—it escapes from the Andes through narrow canyons. Near Manaus, it is joined by the Negro River, which drains much of northern Brazil. The Amazon, then at full strength, winds through the low plains to pass between the Guiana Highlands and Brazilian Highlands before emptying into the Atlantic.

The second most important drainage system, estimated to cover at least 1,600,000 square miles, is formed by the Paraguay, Paraná, and Uruguay rivers. These empty into the Río de la Plata, which actually is an estuary or gulf and not a river. About 2,800,000 cubic feet of water per second discharge from the common mouth of these rivers, an outflow second only to that of the Amazon. The Paraguay River, with a length of 1,584 miles, rises in the Bolivian hills and empties into the Paraná River. The Paraguay is a river of the plains, flowing across a wide stretch of marshes (the Pantanal) in its middle course; its lower course, however, is drier. The Paraná has a total length of 3,032 miles; its upper course (generally called the Alto Paraná) flows mainly across high plateaus before its confluence with the Paraguay, after which the river flows through a broad floodplain before emptying into the Río de la Plata. The Uruguay River, at 990 miles, is the shortest of the three; it flows east of the Paraná before discharging into the Paraná delta.

The Orinoco River basin is the third largest drainage system, covering about 366,000 square miles. With a length of some 1,700 miles, the river first flows west and then north, plunging down a series of steep slopes. It then flows northeast and east along the edge of the Llanos, an almost flat basin that stretches westward to the Andes. Near the ocean, the Orinoco divides into a series of distributaries to form its delta. A unique feature of the Orinoco system is Casiquiare River, which allows water from the Orinoco to enter the Amazon system.

The basin of the São Francisco River, encompassing some 244,000 square miles, is South America's fourth largest drainage system. The river, which flows entirely within Brazil, has a total length of 1,811 miles. It rises in the state of Minas Gerais and flows northward for 1,000 miles before curving eastward to the Atlantic. The São Francisco has been an important artery of communication since colonial times and now is the location of several large hydroelectric projects.

The remainder of the continent's Atlantic-flowing rivers are of much less importance. Among the largest are the Magdalena in Colombia (navigable in its lower section) and the Essequibo, Maroni, and Oyapock in the Guianas.

Drainage to the Pacific is different because of the close proximity of the Andes to the Pacific coast and the scarcity of rainfall from southern Ecuador to central Chile. Consequently, the rivers are short, and few convey any large quantity of water. The major rivers are the Guayas in Ecuador, on which the port of Guayaquil is located, and the Santa in Peru. Some torrents have had great importance since early times, when good water management facilitated the development of ancient civilizations. In central Chile the valleys of the Aconcagua and Bío-Bío rivers have remained fertile agricultural regions.

Lakes. Most of South America's important lakes are in the Andes or their foothills. Because of the chain's complex topography, water has accumulated in closed basins to form natural reservoirs. Among permanent lakes, the largest is Lake Titicaca, which lies at an altitude of 12,500 feet between Peru and Bolivia. The lake is 120 miles long and up to 50 miles wide, although it was much more extensive in the past. Lake Junín in central Peru; Lake Sarococha, also in Peru, between Puno and Arequipa; and Lake Poopó in Bolivia also rank among the larger Andean lakes. They exhibit uniform physical conditions throughout the year, in terms of temperature and percentage of dissolved gases. In addition, they remain ice-free up to an altitude of 16,000 feet, and, as a result, the climate of their shores is temperate.

The Andean lakes

Another type of lake is found in Patagonia where, in the wake of melting glaciers, lakes formed downslope in

An Aymara Indian poling a reed boat on Lake Titicaca, Bolivia. The Cordillera Real in the Bolivian Andes rises in the background.

natural basins. Among these are Lakes Buenos Aires, Argentino, and Nahuel Huapí. Their eastern parts, which stretch to the end of the Argentine plateau, generally have gently sloping banks bordered by low mountains, while their western parts form a series of narrow, fjordlike arms that lie between steep slopes.

Marshes and swamps. Vast marshes are found in depressions in many parts of the continent. One of the widest marshy areas is the Pantanal, in the middle course of the Paraguay River; it is subject to flooding in December, reaching its highest watermark in June, when it becomes an immense swamp. Swamps of another type occur in the rain forests, mostly in the Amazon basin and in northwestern Colombia. In some places the ground is inundated throughout the year, whereas in other areas swampy conditions occur only at the time of the annual flood. Finally, wide, marshy areas border the mouths of the Orinoco and Amazon rivers, and mangrove swamps of various types are found along the lower river valleys and coasts from southern Ecuador northward, less continuously along the Caribbean coast, and south along the Atlantic coast to southeastern Brazil.

Detailed discussion of the Amazon River basin, the Orinoco River basin, the Río de la Plata system, and the São Francisco River can be found in *South American geographic features of special interest* at the end of this article.

SOILS

Because of its geologic history, topography, climate, and vegetation, some 27 distinct soil regions can be distinguished in South America, many of which have several subdivisions. The soils constitute three major groupings that correspond to the continent's three primary geographic components—the lowlands, the highlands, and the Andes.

Low natural fertility is a conspicuous feature of soils in the tropical regions of South America. About half of the continent's soils consist either of unconsolidated and nutrient-poor sediments (*e.g.*, kaolins [china clays] and quartz sands) found in river basins, latosols (red soils leached of silica and containing residual concentrations of iron and aluminum sesquioxides), red-yellow podzols (acidic soils with a bleached upper horizon, or layer, that are low in lime), and regosols (azonal soils consisting mainly of imperfectly consolidated material and having a complex morphology). About one-fifth of the continent is covered by desert soils of various types in which agriculture is risky without irrigation. Other regions, representing about 10 percent of the total area, are poorly drained, the soils being either gleys (clayey soils in which the substrate is bluish gray, generally sticky, and often structureless because of excessive moisture), groundwater laterites, grumosols (soils with a high content of expanding clays), or

Adapted from R. Ganssen and F. Hadrich (eds.), *Atlas zur Bodenkunde*

Soils of South America.

planosols (a type of soil found in humid climates in which soluble salts and minerals are leached out of the upper layers and are cemented or compacted at a lower level). In the Andes, slopes are often steep, and lithosols (shallow soils consisting of imperfectly weathered rock fragments) abound, accounting for another 10 percent of the continent's surface. In the inter-Andean valleys and on some of the foothills, nevertheless, eutrophic soils (deposited by lakes, and containing much nutrient matter, but often shallow and subject to seasonal oxygen deficiency) can be found.

The fertile soil regions

Fertile soils, therefore, extend over only about 10 percent of the surface of South America. The most important of these are brunizems (deep, dark-coloured prairie soils, developed from wind-deposited loess), chestnut soils, and ferruginous tropical soils. On the low coastal ranges, in the foothills of the western Andes, and on the nearby plains and terraces of Colombia and Ecuador, the soils consist mainly of red-yellow latosols, podzols, and alluvial soils. Soils in southern Brazil and Uruguay consist of brunizems, reddish prairie soils, and planosols. The Argentine Pampas, the largest fertile area on the continent, is uniformly covered with the so-called pampean loess, which is calcareous, rich in minerals, and partly of volcanic origin. Less rich soils are found in the uplands of northeastern and central Brazil, consisting mainly of sandy regosols in the north and red latosols in the south.

The agricultural development of South America closely reflects the distribution of soils according to their fertility. It is mostly confined to the eastern mid-latitude plains, in which is concentrated the production of cereal grains and cattle grazing; to the subtropical and temperate parts of the Andes, from Colombia to Chile, where grazing takes place and a variety of crops are cultivated; and to eastern and southeastern Brazil, where coffee, cacao, soybeans, and sugarcane are grown, while the interior plateaus are devoted to cattle grazing.

Soil erosion has ravaged a large part of the continent. According to some estimates, in several countries half or more of the presently arable land has been severely damaged or ruined by poor land management. In the Andes, land that once produced high yields of wheat is now abandoned. Mountain forests are still cleared for cattle grazing and cultivation, which greatly accelerates erosion and ruins the soil of the region for years thereafter. Soil damage has been less severe in areas of relatively flat terrain. Campaigns for soil conservation or restoration have been implemented in most countries.

CLIMATE

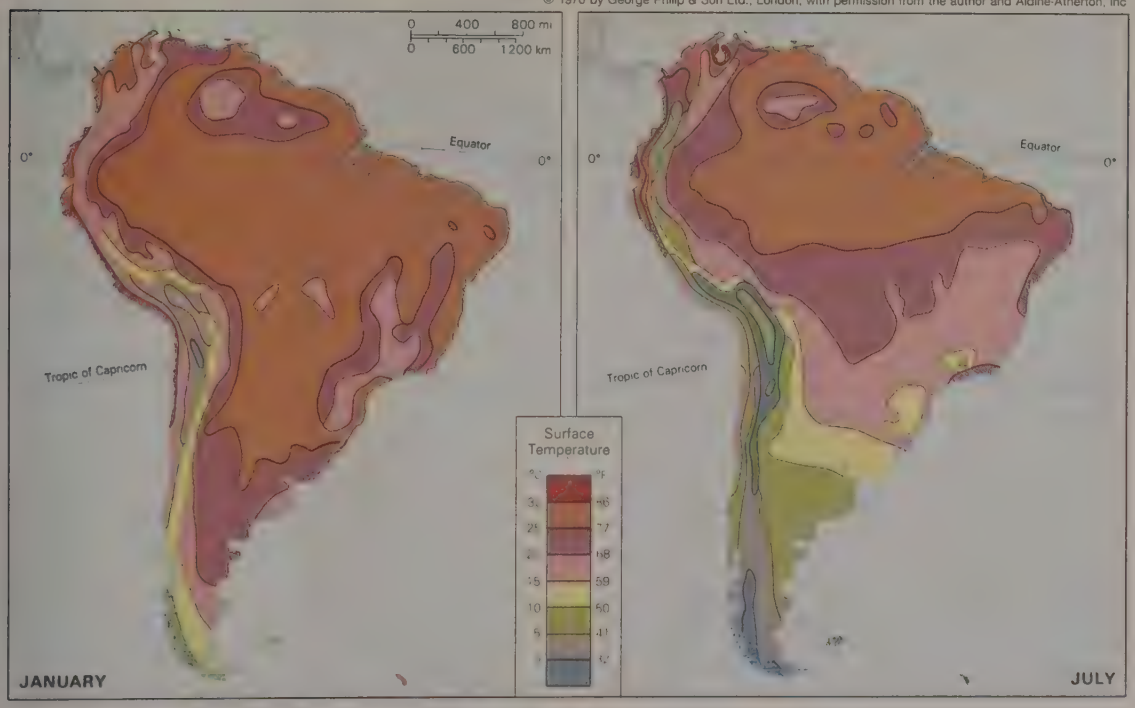
South America extends over a wide range of latitude, and encompasses a great variety of climates. Although it is the only continent (other than Antarctica) to reach such a high southern latitude, South America's broadest extent is in the equatorial zone, so that tropical conditions prevail over half of the continent.

Factors influencing climate. Three principal factors control the broad features of South America's climate. The first and most important of these are the subtropical high-pressure air masses over the South Atlantic and South Pacific and their seasonal shifts in position, which determine both large-scale patterns of wind circulation and the location of the rain-bearing intertropical convergence zone (ITCZ). The second is the presence of cold ocean currents along the continent's western side, which affect both air temperatures and precipitation along the Pacific coast. Finally, the orographic barrier of the Andes produces a large rain shadow over much of the southern part of the continent.

Air circulation patterns

The South Atlantic and South Pacific high-pressure cells take the form of great semipermanent anticyclones (centres of high atmospheric pressure around which winds circulate), the positions and mean intensities of which change with the seasonal north-south migration of the Sun. The eastern part of the South Pacific anticyclone dominates the climate of most of South America's west coast, producing stable, subsiding air that yields minimal precipitation. The cold Peru (Humboldt) Current, flowing northward along the coast from southern Chile to the Equator, cools and further stabilizes the Pacific air that invades the continent. One of the world's driest regions, the Atacama Desert along the northern coast of Chile, results from these conditions. The east coast (north of Patagonia), by contrast, receives greater amounts of precipitation from the humid winds emanating from the South Atlantic high.

The ITCZ is responsible for the seasonal character of precipitation in South America's extensive tropical wet-dry climatic zone. In this region, low-pressure cells persist between the subtropical anticyclones of the Northern and Southern hemispheres, and the trade winds of both hemispheres converge. A migrating zone of unstable atmospheric conditions results, bringing periods of prolonged,



Average temperatures for January (left) and July (right) for South America.

abundant precipitation. The ITCZ is a product of the subtropical highs, and it also follows the annual migration of the Sun. Thus, the ITCZ reaches its most northerly position during the Southern Hemisphere's winter, which is the driest period for most of tropical South America.

The southern portion of the continent is unaffected by the ITCZ and falls instead under the influence of the mid-latitude westerlies, which are particularly strong in the Southern Hemisphere because of the large extent of ocean area there and the unimpeded air flow this allows. As the westerlies rise over the Andes, most of their moisture is lost in orographic precipitation. A typical rain shadow develops on the lee side of the chain, as in the vast desert and semidesert region of Patagonia.

Finally, altitude is an important factor. Vertical climatic zones, ranging from humid tropical at lower elevations to Alpine and Arctic on the high peaks, are particularly well-defined in the Andes.

Climatic regions. South America can be divided into four major climatic regions—tropical, temperate, arid, and cold—their parameters determined by the factors described above.

Tropical climates. Among the tropical climates, the tropical rainy, or rain forest, type occurs on the Pacific coast of Colombia, in the Amazon basin, on the coast of the Guianas, and on part of the coast of Brazil. The average daily temperature is about 86° F (30° C), with monthly and annual variations of less than about 5° F (3° C). Heavy rainfall, well-distributed throughout the year, averages about 98 inches (2,500 millimetres) annually in Belém (Brazil), about 108 inches in Iquitos (Peru), and 71 inches in Manaus (Brazil). The Chocó region of Colombia—one of the wettest areas in the world—receives in excess of 400 inches, and it rains more than 300 days per year. In the Amazon region, rains do not fall evenly over the basin. The southern part receives most of its rainfall during the Southern Hemisphere summer (October to April), while the northern part has its rainy season during the Northern Hemisphere summer (May to September). The "dry" season is neither lengthy nor noticeable; humidity is always high.

Tropical wet-dry climatic regions

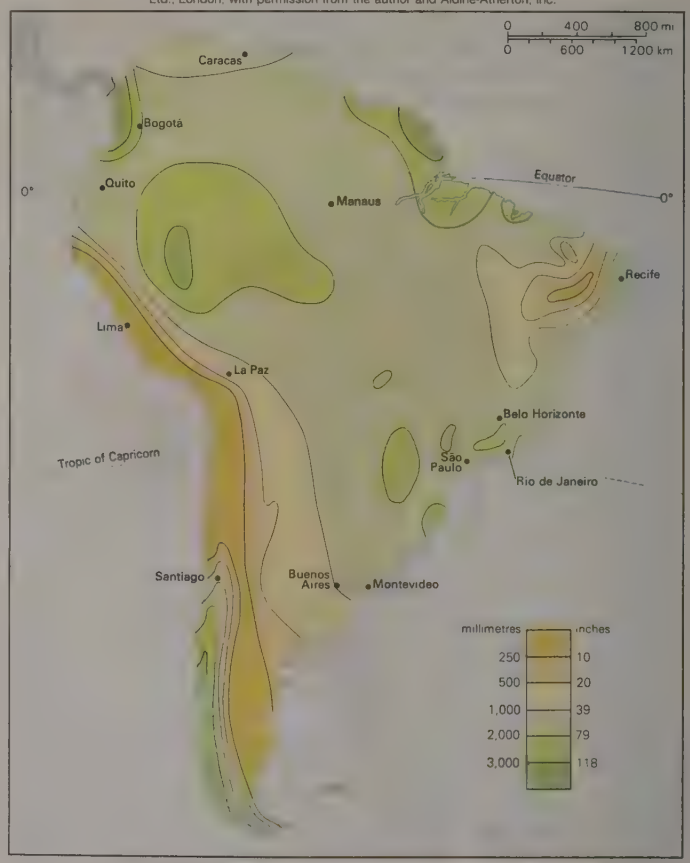
The second type of tropical climate—the tropical wet-dry, or savanna (grassy parkland), type—is characterized by high temperatures (all monthly means above 64° F, or 18° C) but receives less precipitation and experiences a prolonged dry season. It is found around the tropical-rainy belt, in the Orinoco basin, on the Brazilian Highlands, and in part of western Ecuador. Temperatures are still high and annual variations small, but daily temperature extremes are greater, typically ranging from a low of 65° F (18° C) to a high of 95° F (35° C).

Temperate climates. The so-called temperate climates actually have a greater range of temperatures than do the tropical climates and may include extreme climatic variations. These climates, characterized by lower winter temperatures, are found south of the Tropic of Capricorn (in Paraguay, parts of Bolivia, Brazil, Argentina, and Chile) and in the Andes. On the Atlantic side, temperatures in the warmest month average 77° F (25° C), but cold-month averages vary from 63° F (17° C) in the north (Asunción, Paraguay) to 50° F (10° C) in Buenos Aires, Arg. Rainfall exceeds 1.5 inches each month in the east but decreases to the west. In central Chile, between latitudes 32° and 38° S, the climatic features are similar to those of the Mediterranean, with mild winters and winter rains; summers, however, are cooler (69° F, or 21° C, in Santiago, Chile, in January—9° F, or 5° C, cooler than in Mediterranean locations). In southern Chile, winter temperatures are lower but not as low as the latitudes would indicate. The islands and channels have a relatively uniform climate throughout the year, and winters are much less severe than in Labrador, for example, which is at a comparable latitude and maritime location north of the Equator. The presence of glaciers is the result of cold, snowy winters and cool, cloudy summers during which ice does not completely melt. Rainfall is abundant (102 inches in Valdivia, Chile, and probably twice this figure on the western slopes of the mountains), and the coast is one of the wettest regions in South America. A short distance inland, however, after passing into the lee of the Andes, rainfall decreases considerably (20 inches at Ushuaia, Arg.). Thus, in Patagonia an unusual situation exists in which these variations in rainfall result in greater differences in climate from west to east than from north to south.

Arid climates. Arid climates are found in four areas. Patagonia and northwestern Argentina constitute the largest of these. Rainfall is low, only about four inches in San Juan in the north and about seven inches farther south in Neuquén. The annual range in average monthly temperatures in Patagonia—the greatest in South America—is more than 36° F (20° C), the result of warm summers and cold winters. Another arid zone, the Atacama Desert, is found in a narrow strip along the Pacific coast between latitudes 5° and 31° S. The cold seas associated with the Peru Current and the proximity of the high Andes produce an inversion of normal atmospheric temperatures, as air in contact with the water cools more rapidly than the upper strata of air. The result is a nearly continuous layer of stratus clouds about 1,200 feet thick, lying at altitudes varying between about 1,000 and 3,000 feet, that prevents air near the ground from being warmed. Temperatures, consequently, are relatively low: Lima has an average annual temperature of 64° F (18° C), ranging from about 72° F (22° C) in February to about 59° F (15° C) in August. The coast of Peru thus is the cloudiest—and one of the driest—deserts in the world, with no sunshine for at least six months of the year. It almost never rains, except under abnormal circumstances, but condensation of fog (called *garúa* by the Peruvians) provides a limited amount of moisture. Another desert extends from northeastern Colombia to Venezuela, covering a zone where rainfall is scarce and droughts are prolonged.

The coast of Peru

Finally, an arid zone occurs in northeastern Brazil, between the Parnaíba and São Francisco rivers. The interior highlands act as a wedge separating the sea winds from the northeast and those from the southeast, which carry their moisture beyond the region. Average annual rainfall is less



Average annual precipitation in South America.

than four inches, and the dry season may last as long as seven months. The worst feature of the area's climate is the irregularity of the rainfall, as a result of which severe droughts plague the region.

Cold climates. Areas where average annual temperatures are less than 50° F (10° C) are characterized as having cold climates. These occur in the southernmost parts of Argentina and Chile and in the high Andes above about 11,500 feet. Mean temperatures are relatively low, but daily variations are wide. There is a marked difference in humidity between the northern and southern parts of the upper Andean zone. In Colombia and Ecuador the climate at such altitudes is cool and damp. Temperatures, always low, may on the average vary daily from 54° F (12° C) during the daytime to 28° F (−2° C) at night. Rainfall generally is high and well distributed throughout much of the year, although most of the Ecuadorian Andes have a dry period from June to August. Clouds and mist are dense in much of the region, and sunlight penetrates only for short periods. From central Peru to Bolivia and Chile, temperatures are still lower. Near Lake Titicaca, the average annual temperature is only about 34° to 36° F (1° to 2° C); November is the warmest month, with an average temperature of 41° F (5° C), while the coldest month, July, has an average of 28° F (−2° C). Daily variations are considerable; typically, a daytime maximum of 68° F (20° C) may drop to a nocturnal minimum of 5° F (−15° C). Annual rainfall varies from 24 to 56 inches but is concentrated during the southern summer. The dry season is long and characteristically accompanied by drought. Winds are continuous and often violent, accelerating the coldness and the dryness of the climate, which produces a harsh and hostile environment. As in any mountainous region, climate varies largely according to local conditions.

(J.P.D./C.W.M.)

PLANT LIFE

South America, with its distinctive plant and animal life, covers most of the biotic region called the Neotropics (the faunal realm also is called the Neogaean). This region extends southward from the Tropic of Cancer to include all of Central and South America—even that southern portion that does not have a tropical climate. With Australia it is, because of its isolation from the rest of the world during the Tertiary Period (66.4 to 1.6 million years ago), the landmass with the strongest biological originality.

Affinities with other continents

Vegetation and animal life manifest some relationships with other continents as a result of past geologic events. Ancient groups of plants and animals including mollusks, chilopods, some fishes, reptiles, and amphibians show

Vegetation zones of South America.

affinities with the animal life of Africa, Australia, and New Zealand. More recent elements, mostly vertebrates, migrated from or through North America.

The pattern of distribution within the continent is complex because of the variety of climatic and ecological zones. The northern tropical regions are the richest in diversity, while the southern part and the western Andean highlands are much impoverished, despite some differentiation.

Vegetation zones. The proportion of endemic plants in South America is very high, even at the family level. Among angiosperms (plants having seeds enclosed in an ovary) no fewer than 25 families and 3,500 genera are endemic to the tropical and temperate zones. Others are related to African plants or belong to southern plant groups also distributed in southern Africa and in Australasia. Vegetation is by no means uniform throughout the continent; its distribution is determined by climatic, geographic, soil, and sometimes anthropic (human-related) differences.

Tropical and subtropical rain forests. Rain forest covers the largest part of the Amazon region, most of the Guianas, southern and eastern Venezuela, the Atlantic slopes of the Brazilian Highlands, and the Pacific coast of Colombia and northern Ecuador. The huge Amazon region is the largest and probably the oldest forest area in the world; it also ascends the slopes of the Andes until it merges with subtropical and temperate rain forest. On its southern border it merges with the woodlands of the Brazilian state of Mato Grosso, with galleries of its trees extending along the rivers. Consisting of enormous trees, some exceeding a height of 300 feet, the rain forest is composed of an almost incredible number of species growing side by side in the greatest profusion and arranged in different strata. In the region of Manaus, Braz., for example, 1,652 plants belonging to 107 species in 37 different families were found on about 1,900 square feet. Amazonian trees number about 2,500 species.

The forests of the *igapós* (swamps, where the ground is inundated or very marshy throughout the year) cover the lowlands. Characteristic trees are, among others, *jacareúbas* (*Calophyllum brasiliense*), which is a tall tree with hard reddish brown wood used for heavy construction, *araparis* (*Macrolobium acaciaefolium*), *abiuranas* (*Lucuma* species), *piranheiras* (*Piranhea trifoliata*), and *louros-do-igapo* (*Nectandra amazonum*). Undergrowth is dense.

The *várzea* regions are those that are inundated only at the annual flood. Trees are higher and quite diversified; they include *oeiranas* (*Alchornea castaneifolia*), a euphorbia (*i.e.*, characterized by a milky juice), and the trumpet tree (*Cecropia peltata*), a rapid-growing tree of the mulberry family with a light wood. Palms and hevea (a kind of wild rubber plant) grow in these forests. The forests of the nonswampy areas are rich in hardwoods, of which acapu (a tree with dark brown wood), *pau-amarelo* (*Euxylophora paraensis*), *pau-santo* (*Zollernia paraensis*), massaranduba (a Brazilian tree with light reddish brown wood), jarana (a tree with hard, heavy, durable wood), and matamata (a tree with hard, heavy, durable wood, used for pilings) are the best known. Hevea and the Brazil nut tree (*Bertholletia excelsa*) are characteristic of these forests where spiny palms cover the ground.

Epiphytes (nonparasitic plants that grow on other plants, deriving moisture and nutrients from rain and air) are numerous, mostly Bromeliaceae (a family having spiny leaves), orchids, and ferns. Lianas abound, particularly in drier forests. Epiphytes

Tropical deciduous forests. These forests, dominated by trees of moderate height, notably of leguminous species, are found widely dispersed through northern South America, where the climate is characterized by a prolonged dry season, notably in Venezuela, Colombia, and the Brazilian Highlands.

Caatinga. Caatinga (white forest) refers to the generally stunted, somewhat sparse, and often thorny vegetation of the dry interior of northeastern Brazil. Trees, leafless for long periods and able to resist drought, also are characteristic, particularly in the basin of the São Francisco River. Dominant species are leguminous trees, particularly *catingueiras* (*Caesalpinia*), *juremas* (*Mimosa*), and *joazeiros* (*Zizyphus joaseiro*), members of the Euphorbiaceae (spurge) family, and Bombacaceae (a family of tropical trees with palmate leaves and large, dry or fleshy fruit). Undergrowth consists of thickets, bromeliads (plants with basal, often spiny leaves), and innumerable cacti, among which is the *xiquexique* (*Cereus gounellei*), the complicated intertwinings of which cover the soil. Where more water is available, caatinga species may grow 30 feet high and form impenetrable thickets.

South Brazilian forests. These parklike forests, sometimes very dense but interspersed with savanna, occupy vast expanses from the border of the Amazonian rain forest to the marshes of the upper Paraguay River. The typical landscape is a grassland strewn with smaller trees. In effect, it includes a mosaic of associations, from hygrophilous (living or growing in moist places) to xerophilous (adapted to dry conditions) forests and even desert.

Notable is the forest region of araucaria, or Paraná pine (*Araucaria angustifolia*), which covers a vast area between the Paraná River and the Atlantic Ocean, stretching from Curitiba, Braz., to northern Argentina. Araucarias (which are not true pines) dominate a dense forest of numerous species including hardwoods, yellowwood (Podocarpus), and the South American holly (*Ilex paraguariensis*), from which the beverage maté is made.

Xerophytic associations. Thickets of small trees and

Rain-forest vegetation along the northern coast of Ecuador.

Caatinga vegetation in the dry interior of northeastern Brazil.

shrubs, often thorny, among which species of *Prosopis*, *Acacia*, and *Mimosa* predominate, cover regions that experience alternate dry and relatively wet seasons; these regions particularly include coastal Venezuela, northeastern Colombia, southwestern Ecuador, and northern Peru.

In Peru this association merges with the desert, which extends along the coast to northern Chile, having a width of from 50 to 100 miles. Only a few shrubs and some terrestrial (as distinct from epiphytic) bromeliads grow in this area, which becomes greener only in the Andean foothills, where cacti and other xerophytic plants are to be found, and along the valleys of rivers flowing down from the Andes. In some areas, called lomas in Peru, winter mists bring some humidity, and a specialized type of vegetation, consisting of annual and bulbous plants, grows for a short period.

Lomas vegetation

Subantarctic beech forests. Temperate rain forests—similar to those found in British Columbia and in the northwestern United States—grow in southern Chile at low and moderate altitudes, thanks to abundant rainfall. The most typical trees belong to the genus *Nothofagus* (timber trees found in the cooler parts of the Southern Hemisphere), the northern species of which are evergreen and the southern species deciduous. Various conifers, notably the alerce and araucarias, mingle with the leafy trees. A dense undergrowth of shrubs, lianas, bamboos, ferns, mosses, and epiphytes grow in the northern districts but disappear toward latitude 49° S. In southern Chilean Patagonia, forests consist of twisted, creeping trees merging into a kind of heath.

Savannas. True savannas are found mostly in the Llanos of Venezuela and northeastern Colombia. This vast area is covered with grasses and sedges, but trees (mainly palms) also are found, especially along streams.

Pampas. The flat plains called Pampas, which constitute the greater part of eastern Argentina, are covered with grasses. The Pampas originally were covered with trees, but humans have removed the trees and have acclimatized various grass species. Exotic pines, eucalyptus, oaks, and poplars constitute introduced trees. To the south the Pampas merge with the Patagonian steppe, where tussock grasses are mixed with scattered low bushes and spiny plants. The vegetation becomes much poorer to the south.

Mountain vegetation. In the high Andes, a temperate zone extends from the upper limit of the subtropical rain forest (about 6,000 feet) up to the timberline, which reaches an altitude of about 11,000 feet in Ecuador and Peru. This zone is very humid on the Amazonian side, where both the epiphytes and the undergrowth are dense.

The upper zones have a peculiar vegetation that reaches the snow line. In the wet northern Andes in Colombia and Ecuador, Alpine meadows called *páramo* consist of grasses and other herbaceous plants, often with bright flowers; these are surmounted by taller plants, especially the showy frailejones (*Espeletia*), which grow 15 to 20 feet high and are crowned by large bouquets of long hairy leaves.

In the south *páramo* vegetation merges with that of the high plateaus, notably of the Altiplano of southeastern Peru and western Bolivia. Typical vegetation consists of rough grasses, between which grow a variety of herbaceous, cushion, and rosette plants, shrubs, and cacti. Vegetation extends to the limit of permanent snow but becomes scarce at higher altitudes where soil is often barren.

Human influences on vegetation. Human activity has transformed the original vegetation cover to a large extent throughout South America, particularly in forested areas. The forests of eastern Brazil were ravaged in the process of clearing the ground for crops, especially sugarcane. The forests of araucaria in the southern states of Brazil have been rapidly vanishing, as they have been exploited for timber. The slopes of the Andes are so severely deforested that it is not apparent that they once were covered with trees. In the Amazon region, hundreds of square miles of tropical rain forest are cut annually, and the forest no longer is the enormous inviolate mass it once was. In Patagonia the practice of burning to convert remaining patches of forest into pasture steadily increases. Animal herders have severely damaged grasslands through overgrazing, from the Venezuelan Llanos through the high Andes, to Tierra del Fuego. The destruction of habitats continues to accelerate throughout the continent, despite the growing concern of those favouring conservation.

Destruction of the forest cover

ANIMAL LIFE

South American animal life is particularly rich and well diversified as a result of the wide range of habitats. A number of animal groups well distributed over the rest of the world are nevertheless missing because of South America's lengthy isolation. Many animals belong to exclusive groups, and even at the family level the percentage of endemic forms is high. Speciation has reached a higher degree in South America than in other parts of the world.

Principal faunal types. *Fish and bird life.* Freshwater fishes are numerous, with about 2,700 species, though they derive from only a few ancestral groups. Amazonian fishes may approach 1,500 species in number. Among the dominant groups are characins (800 species), which include the flesh-eating piranha; gymnotids, South American cyprinoid fishes that include the electric eel; catfishes; cyprinodonts, a large family of small scaly-headed soft-finned fishes; and cichlids, a family consisting chiefly of fishes that somewhat resemble sunfish.

Birds are represented by 89 families and some 3,000 species—a much higher figure than in Africa or Asia, which justifies the application of the name bird continent to South America. Twenty-five families are endemic to the Neotropical region. Unique birds include rheas (large, tall, flightless birds that resemble ostriches), curassows (large arboreal birds distantly related to the domestic fowl), hoatzins (a brownish crested bird, having claws on the digits of the wing when young), oilbirds, motmots (bright-coloured birds related to kingfishers), jacamars (small, bright-coloured birds), toucans, manakins, and cotingas (related to manakins), and many passerine (perching) birds. Hummingbirds have evolved to fill a variety of habitat niches, with more than 120 species in Ecuador alone. Parrots, pigeons, cuckoos, tyrants (a kind of flycatcher), woodhewers, and orioles are among the dominant groups. Remarkably, the proportion of nonpasserine to passerine birds is greater in South America than in any other part of the world.

Hummingbirds

Mammals. Mammals include types that immigrated to the continent before its complete isolation in the early Tertiary Period. Among these are marsupials (pouched animals), sloths, anteaters, and armadillos; other kinds, now extinct, persisted until the Pleistocene Epoch. More recent elements include hystricomorph rodents (a suborder including porcupines and guinea pigs) and monkeys among the oldest arrivals, and tapirs, deer, carnivores, and bats among the newer arrivals.

Amphibians and reptiles. Amphibians are well represented by caecilians (small wormlike, burrowing amphibians), salamanders, toads, and a number of varieties of frogs, including clawed frogs, the most aquatic of all. The tree frogs, arboreal amphibians, are particularly abundant through the Amazon basin and are very different from their African and Asian counterparts, although the frog faunas of Australia and South America often are strikingly alike. Reptiles include a great variety of turtles and tortoises, crocodiles, caimans (endemic crocodilians), geckos, many iguanas, teiids (a family of mostly tropical American lizards), *Amphisbaena* (a genus of harmless, limbless lizards), and many snakes, including boas, colubrids (a very large family of nonvenomous snakes), coral snakes, and vipers.

Arthropods. Most South American insects, spiders, crabs, centipedes, and millipedes are found nowhere else in the world. Thousands of species, especially insects of the tropical rain forest, have yet to be discovered. South America has the richest array of butterflies of any continent, including the spectacularly coloured members of the Morphidae subfamily; the social insects—termites, ants, wasps, and bees—also are well represented. Many of the best-known arthropods (*e.g.,* mosquitoes, sand flies, and kissing bugs) are responsible for the transmission of human diseases.

Ecological communities. Animals are distributed according to the pattern of vegetation zones, and several well-defined communities can be distinguished. They include regions as diverse as the Amazonian forests and the high Andes.

The Amazonian and Guianan forests. The most diverse community is found in the Amazonian and Guianan forests, where the abundance of water and trees makes life easy. Rivers are the realm of large numbers of invertebrates and fishes, such as *pacu* (*Metynnis*), which is a big brownish flat fish, the meat of which is highly valued; *coumarou* (*Curimato*), which is a toothless vegetarian fish resembling the marine mullet; electric eel (*Electrophorus electricus*); pirarucu (*Arapaima gigas*), which can attain a length of 15 feet and a weight of 200 pounds; and piranha, having teeth so sharp that they can cut through flesh like a razor; as well as a wealth of small fishes, many of which are vividly coloured. The manatees (a chiefly tropical, aquatic, herbivorous animal with a broad tail) and the *inia,* a primitive dolphin, frequent the larger rivers of the region. The Amazon river turtle (*Podocnemis expansa*) persists despite intense exploitation. Crocodiles and caimans inhabit the main waterways.

Arboreal adaptions

Amazonian forests constitute an environment to which most animals responded by becoming arboreal. Tree frogs can move across the surface of the leaves thanks to adhesive pads on their feet; lizards have very elongated fingers; monkeys, *sarigues* (a close relative of the opossum), and kinkajous (a nocturnal, carnivorous mammal) have prehensile tails. Birds are numerous and, because of the enormous amount and variety of available foods, well diversified. Antbirds, tyrants, cotingas, *tangaras* (brilliantly coloured birds related to the finches), hummingbirds, toucans, woodpeckers, barbets (loud-voiced tropical birds closely related to honey guides), parrots, and tinamous (quaillike terrestrial birds) are the dominant groups. Many of them never leave the forest canopy, where they display their brilliant colours, which contrast with the more modest plumage of those birds that live in the undergrowth. Mammals are represented by a number of terrestrial or half-aquatic species, such as very small deer; some large rodents (including the agouti, paca, and capybara); tapirs; and carnivores (including the jaguar). Primates range from pygmy marmosets to larger durukulis (small, round-headed, stocky-bodied, bushy-tailed monkeys), woolly monkeys, spider monkeys, and howler monkeys. Bats also are numerous, including species that feed on fruit and others that eat fish. Sloths feed on the leaves of certain trees, among whose branches they remain much of their lives. The predators are represented by carnivorous mammals, a series of snakes—including anacondas and boas—and large raptors (birds of prey), such as the harpy eagle (*Harpia harpyja*), the most powerful bird of prey to be found in the world. Insects, including a great variety of butterflies and ants, are innumerable.

East-central plateaus and lowlands. The Brazilian Highlands have an impoverished animal life, from which species that are strictly adapted to the dense forest are excluded. The plains of Uruguay and the Gran Chaco have a varied animal life that includes some particular species, such as the maned wolf. The marshes are inhabited by a wealth of waterfowl, as well as by a species of lungfish (*Lepidosiren paradoxa*) that is related to its African and Australian counterparts.

The Argentinian Pampas. The Pampas of Argentina are inhabited by only a limited number of indigenous animals. Among the birds are rheas and a series of smaller birds, including the popular ovenbird (*Furnarius rufus*), the name of which comes from its globe-shaped nest made of mud. Endemic mammals include the mara (*Dolichotis patagona*), a long-legged, long-eared rodent; the plains viscacha (*Lagostomus*), a burrowing rodent related to the chinchilla; the guanaco (*Lama guanacoe*), a South American mammal related to the camel but resembling a deer; and Pampas deer (*Blastoceros campestris*). The restricted number of the larger herbivorous mammals is quite remarkable and illustrates the scarcity of recent mammalian types in the Neotropical region.

The southern Chilean forests. The forests of southern Chile are inhabited by a specialized animal life, with a high percentage of endemic species. Parakeets and hummingbirds are found as far south as Tierra del Fuego. A marsupial, the rincolesta of Chiloé (*Rhyncholestes raphanurus*), is one of the most primitive mammals still in existence.

The high Andes. The high Andes have an impoverished animal life. Species there have had to adapt to the harsh and cold environment, scanty vegetation, and low oxygen pressure. The great number of lakes in the region has attracted many aquatic birds, including flamingos, which nest up to elevations of 16,000 feet in northern Chile, and amphibians such as the giant toads of Lake Titicaca, which spend their entire life in water. Mammals are represented by the guanaco and vicuña (both wild ruminants related to the domesticated llama), deer, and numerous rodents, including viscachas, chinchillas, and guinea pigs. Predatory species include foxes, pumas, and many birds of prey, notable among which is the condor, the giant of living birds, with a wingspan of more than 10 feet.

Andean mammals

The arid west coast. The limited variety of animals that inhabit the arid coast of Peru and northern Chile is especially striking when compared with the richness of offshore marine life. The cold upwelling water of the Peru Current, rich in salts, are swarming with life, from plankton to fishes, including the Peruvian anchovy (*Engraulis ringens*); these small forms of life provide food for higher levels of the marine community, represented, for example, by sea lions and birds, many of which are endemic to the area. Birdlife includes a penguin, many species of gulls and terns, shearwaters, petrels, cormorants, pelicans, and boobies (a kind of gannet). Three kinds of these birds—the guanay (or Peruvian cormorant; *Phalacrocorax bougainvillii*), the variegated booby (*Sula variegata*), and the brown pelican (*Pelecanus occidentalis*)—nest by the millions on small islands off the coast, where their droppings accumulate to form guano, a highly prized source of fertilizer.

Human influences on wildlife. Overhunting and habitat destruction have seriously depleted populations of wild animals in much of South America. Almost all wild species are less abundant than they were before the mid-20th century, and some are threatened with extinction. Laws designed to protect wildlife frequently are not observed. In addition, many rural people, especially in tropical-forest areas, still depend on game as a source of food; and the sale of live animals for pets or laboratory use has further depleted stocks. Populations of animals not considered economically valuable have been reduced as their forest habitats have been removed.

Nature reserves, established to protect animals in their habitat, are now found in most South American countries. Argentina pioneered wildlife protection on the continent by creating Nahuel Huapí National Park. At Iguaçu

(Iguazú) Falls—located on the Iguaçu River on the border between Brazil and Argentina, just before the confluence of the Iguaçu and Paraná rivers—two national parks, one in each country, protect wildlife and the surrounding rain forest. Manu National Park in southeastern Peru protects one of the richest collections of plant and animal life in the Amazon basin, including more than 1,000 species of birds. Venezuela's effort to protect habitats led to the establishment (1962) of Canaima National Park in the Guiana Highlands, which with an area of nearly 11,600 square miles is the largest park on the continent. Overall, South America has about 58,000 square miles of parks, but the inviolability of many of these sanctuaries against the pressures of economic development has not been clearly established in all countries. (J.P.D./D.W.Ga.)

The people

ETHNIC ORIGINS AND MIGRATIONS

Four components of the population

Four main components have contributed to the present-day population of South America—American Indians (Amerindians), who were the pre-Columbian inhabitants; Iberians (Spanish and Portuguese who conquered and dominated the continent until the beginning of the 19th century); Africans, imported as slaves by the colonizers; and, finally, postindependence immigrants from overseas, mostly Italy and Germany but also Lebanon, South Asia, and Japan.

Indians. Before the beginning of the epoch of European exploration and conquest in the early 16th century, South America was almost completely occupied by diverse peoples. Nearly all of these cultural groups practiced agriculture, and most exhibited an extraordinary understanding of their physical environment that had been developed over thousands of years. Although areas such as deserts, mountain peaks, and tropical rain forests appeared to be uninhabited, most of these places were occupied at least occasionally. The societies with the greatest complexity of social organization and densest population tended to be located along the Pacific coast, in the adjacent Andes, and along the major rivers of the Amazon basin. Less complex societies were located away from the rivers and mountains, and nomadic hunting groups were found in the Pampas, Patagonia, and southern Chile.

Agriculture-based village culture and social organization came first to the tropical lowlands of the Amazon basin and valleys of coastal Ecuador and Colombia (*c.* 3000 BC). This culture included religious temple-mound complexes, fine ceramics (based partly on earlier technology for making fire-engraved containers out of bottle gourds), and farming such crops as cassava (manioc) and corn (maize) on periodically flooded plains and levees. These areas eventually became organized into complex chiefdoms containing dense populations, supported in some cases by raised fields—broad planting surfaces separated by ditches that enhanced the fertility of the soil while limiting the possibility of fungal diseases and waterlogging.

The practice of agriculture spread to the desert coast of Peru and Chile and then into the higher elevations of the Andes, and new technologies appeared. In coastal areas, elaborate irrigation networks supported ceremonial centres and (later) true cities such as Chan Chan (near present-day Trujillo on the northern coast of Peru), the capital of the Chimú state. Coastal Peruvian and Ecuadorian cultures (such as Moche and Nazca) produced superb ceramic art and finely woven textiles. In coastal Chile the Mapuche (Araucanian) culture effectively occupied its region through farming and hunting.

In the highlands, fertile soils of volcanic ash were cultivated with the digging stick and a type of foot plow called the *chaquitaclla*. Highland soils also were improved by constructing long earthen irrigation canals or (in the Central Andes) some of the world's most elaborate and beautiful stone-walled terracing. In most parts of the Andes, areas of high population density were organized into chiefdoms—such as the Chibcha of Colombia and the mound (tola) builders of Ecuador—led by powerful, paramount lords. Early cities and empires first developed around Huari (Wari) in south-central Peru and Tiahuanaco in western Bolivia, but the last and best-known empire was that of the Inca (Inka). Called Tawantinsuyu, the Inca state expanded from its homeland in the Cuzco Valley of south-central Peru north to what is now southern Colombia and south to the Maule River in central Chile (the northern limit of the Mapuche culture). The Inca easily conquered the desert coastal cultures by threatening their water supplies but never succeeded with the chiefdoms of the Amazon basin and of coastal Ecuador. Thus, when Inca expansion was halted by the Spanish in the 1530s, the empire was long but narrow, confined to the Andes and Pacific coast. This empire did not include all of the advanced agricultural cultures of the continent, which continued north into Venezuela, east into the Amazon basin, and south into the Mapuche area.

The Inca

Certain areas of South America—notably in the more remote parts of the interior, away from the main rivers—were occupied by simpler village cultures based on shifting cultivation, an agricultural practice still used in many of these areas. Nomadic hunter tribes were located in areas of present-day Uruguay and Argentina and in the extreme south (Tierra del Fuego and Cape Horn). Although these cultures appeared to be simple in organization and technology, they were well adapted to hunting wild animals (*e.g.*, the guanaco), fishing, and gathering edible plants in a harsh environment.

The number of Indians at the time of the conquest is uncertain: estimates vary from 8 to 100 million for North, South, and Central America combined (for the Inca, from 3 to 32 million). More recent estimates that put South America's preconquest population at about 20 million seem more realistic.

Equally controversial is the origin of South America's Indians. Most anthropologists believe that they are descended from people who migrated to North America from Asia between about 60,000 and 20,000 years ago, having crossed the Bering Strait separating northeastern Asia and northwestern North America. It is not known when humans first arrived in South America, although it is fairly certain that people were present in Chile by 11,000 BC.

Iberians. Until the end of the era of Iberian domination, only the Spanish and Portuguese were admitted to their South American colonies. The rigid exclusion of all other foreigners had but few exceptions, though a small number of non-Iberian Europeans settled as a result of illegal or tolerated immigration. Most of the Spaniards came from Castile and the southern regions. Little is known about the principal regions from which the Portuguese came. It is estimated that the total number of *licencias* (authorizations to emigrate) granted by Spain was about 150,000 for the entire colonial period, which lasted from the 16th to the 19th century; it is possible that the number of illegal immigrants also approached this number. Of these, no more than two-fifths of the emigrants went to South America. Up to one million Portuguese may have migrated to Brazil, drawn primarily by a gold rush in Minas Gerais in the 18th century.

Africans. A few African servants accompanying the early Spanish or Portuguese explorers were the first slaves to enter the continent. Larger-scale importation of slaves from Africa developed after the slave trade was established early in the 16th century, though reliable quantitative information is lacking. Estimates of the number of Africans brought to South America are four million for Brazil and three million for all of Spanish America, of which most went to areas of present-day Venezuela, Colombia, coastal Ecuador and Peru, and northwestern Argentina; a number also went to the large Spanish colonial cities as urban servants. In addition, many Africans were brought to the British and Dutch Guianas (present-day Guyana and Suriname, respectively). African slaves were considered to be more resistant than American Indians to tropical diseases, especially in plantation areas. Most of the slaves imported into South America came from Portuguese or Spanish trading posts along the west coast of Africa, including areas near present-day Angola. The slave trade ceased in the early 19th century.

The slave trade

Postindependence overseas immigrants. Most of the South American countries gained independence in the

early 19th century, thus bringing an end to the legal exclusion of foreigners. Mass immigration to the continent, however, did not begin until after 1850, acquiring momentum in the last three decades of the century and continuing until 1930, when it decreased abruptly. Some 11 to 12 million people arrived in South America; the great majority of these went to Argentina (more than half) and Brazil (more than one-third). Although many later left, the demographic and sociocultural impact of this influx was tremendous in Argentina and (to a lesser extent) in southern Brazil. Immigration to other countries was numerically insignificant (although socioculturally meaningful), except in Uruguay, where because the preexisting population was not numerous, the proportion of foreign-born was high—about one-fifth in 1908 and even higher in the 19th century. In Argentina the proportion of foreign-born reached nearly one-third of the total population and stayed at that level for many years. In both cases the contribution of post-independence immigration was proportionally much higher than in the United States at the peak of mass immigration.

The great majority of the immigrants were Europeans—Italians (forming nearly half of the immigrants in Argentina, one-third of those in Brazil, and probably the majority of immigrants in Uruguay), the Spaniards (one-third in Argentina), and the Portuguese (nearly one-third in Brazil). Other small but socially relevant immigrant streams arrived from central and eastern Europe. This source of immigration became more important in the 20th century and especially during the 1930s and '40s, when it included more middle-class and educated people, among whom were many Jews and other refugees. After World War II another smaller wave of immigration arrived from Europe (principally Italy and Spain), directed mostly to Venezuela and Argentina.

Asian immigrants

Other important waves of immigration arrived from East and South Asia and the Middle East. Chinese labourers came in the 19th century to help build South American railways and established Chinese districts in such cities as Lima. Labourers from South Asia were brought by the British to Guyana, and similar migrants went to Suriname, supplemented by workers from the East Indies (Indonesia). Lebanese migrated to South America from the Ottoman Empire prior to World War I; known locally (and incorrectly) as "Turks" (*turcos*), these Lebanese became important in commerce and even politics in such cities as Guayaquil, Ecuador. Since World War II, Koreans have migrated to Argentina (under a negotiated treaty) and under less formal conditions to countries as diverse as Paraguay and Ecuador, where they often have become involved in commerce and industry. The largest Asian group by far, however, has been the Japanese. Before World War II large numbers of Japanese settled in Brazil, Bolivia, and Argentina. People of Japanese ancestry now are found primarily in the Brazilian states of São Paulo, Santa Catarina, and Rio Grande do Sul, as well as in Argentina and Peru; and collectively they constitute the largest concentration of ethnic Japanese living outside of Japan.

POPULATION AND ECOLOGICAL DISTRIBUTION

The present population. The present population of South America is the result of four centuries of ethnic mixture among these four components—indigenous peoples, Iberians, Africans, and overseas immigrants—and their various descendants. The mixing process began when the first Iberians reached South America. The previous traditions and basic values and attitudes of the Iberians—coupled with other characteristics of their conquest and colonization—facilitated intermixing not only with the Indians but in general among all the various ethnic groups, although the intensity, extent, and frequency of this mixing varied both among different groups and at different times.

Legal marriage between Iberians and Indians was tolerated, often permitted, and even, in some special circumstances, promoted. It was possible—and in certain epochs easy—to recognize mestizo (generally, mixed European and Indian) children, though frequently a mestizo was considered automatically illegitimate. Social custom did not permit intermarriage between Europeans and Africans and between Africans and Indians and their offspring, although social custom failed to prevent generalized interbreeding. This prolonged process created a great variety of physical types, resulting in the emergence of a complex terminology to describe them.

The more important designations are *mestizo* (called *caboclo* in Brazil), *mulatto* (European-African), and *zambo* (African-Indian). During the postindependence period of European immigration, other national groups contributed to further ethnic mixture. As a result, Argentina and Uruguay completely modified their ethnic composition.

Culture areas. Many South Americans resist recognizing ancestry as being socially significant, especially as language, religion, and other cultural aspects tend to cross ethnic lines. In practice, however, an individual's ethnic background can be a factor in determining social status or economic opportunities. Ethnic distinctions tend to be geographic in nature and can be divided into three broad types of regions—Indian-American (indigenous American), African-American, and European-American—based on a predominant ethnic element in what otherwise are mixed populations. These regions have been defined to a large extent since the end of the colonial period. The people within them, however, are not of uniform ancestry but rather are clustered into different cultural groups.

Three cultural regions

Indian-American regions. Included in this designation are the Amazon and Orinoco basins, Paraguay, northern and central Chile, and the highlands of Venezuela, Colombia, Ecuador, Peru, and Bolivia. These were the areas of pre-Columbian chiefdoms and states at the time of the Spanish conquest. It was possible to found the social and economic organization of the Spanish empire on the relatively advanced institutions of these cultures; at the same time, Indian labour could be easily exploited. The original Indian population suffered from what has been regarded as a demographic disaster—during the first century of Spanish domination the Indian population declined up to 95 percent in some areas—but a substantial number of Indians survived, and mixing between Indians and Europeans often was intense. Indian populations in the highlands began to recover during the 18th century. The European component of the population was confined to towns and cities in colonial times, followed by more recent migrations to areas of the Amazon basin during the rubber boom of the early 20th century. African populations were limited to plantation zones in warmer mountain valleys. In Chile a pronounced shift toward identification with European culture took place, even though the population had a substantial proportion of Indians.

African-American regions. This category includes the coastal areas of the Guianas, Venezuela, Colombia, Ecuador, and Peru; most of eastern Brazil; and northwestern Argentina. Most of these areas are not considered "black" today but rather are identified in regional terms. Thus, coastal Ecuadorians in general are called *montuvios,* coastal Peruvians *criollos,* and northwestern Argentines *criollos* or *gauchos.* Many African-American Colombians who were designated as *mulattos* on colonial censuses were called *mestizos* on later censuses. Changes in African cultural identity were facilitated by the rapid adoption of European religion and language in slave populations.

European-American regions. Most of the people included in this grouping live in a belt extending from southern Chile through Patagonia and the Pampas to southern and southeastern Brazil. Part of this area contained hunter-gatherers at the time of the Spanish conquest, and these peoples strongly resisted European domination until they were decimated by modern warfare in the 19th century. The Brazilian area contained Indians who had been displaced westward by slave raids during colonial times. People of European and Japanese ancestry were drawn into these regions in the 19th and 20th centuries by the possibility of developing forms of commercial agriculture—especially wheat and dairy farms and cattle and sheep ranches—similar to those in their homelands.

Diversity

Linguistic patterns. The linguistic diversity and multiplicity of South America probably is unmatched anywhere else in the world. Thousands of languages and dialects

have been cataloged, including all those existing since the European conquest. Classification systems vary a great deal—from more than 100 "linguistic families" and many unrelated languages at one extreme to extremely simplified schemes at the other. There also is considerable disagreement on the composition of these "stocks" and how many languages should be classified. Most are now extinct, either because the peoples who spoke them have disappeared or because of acculturation into a European language or, in some instances, into another indigenous tongue.

The survival of Indian languages in the Indian-American areas has depended on a variety of factors. Colonial authorities helped spread Quechuan languages (those spoken by the Inca) because they were convenient for missionary activities and for government, and these languages often displaced local indigenous languages. Elsewhere, local languages gave way to new languages such as the *língua-geral* of Brazil (combining Tupí-Guaraní and Portuguese). In many cases populations became bilingual, with an Indian language spoken at home and Spanish used for public transactions; examples include the Spanish-Guaraní speakers of Paraguay and the Quechuan-Spanish speakers throughout the Andes.

The largest surviving indigenous language groups are Quechuan, Aymaran, Tupí-Guaraní, and Mapuche. Quechuan languages are in use primarily in the Andean highlands (southern Colombia to Bolivia) but also in large areas of the Amazon basin and in northwestern Argentina. Quechuan, collectively the third largest language group in South America after Spanish and Portuguese, is not spoken by all Andean highlanders but is limited to certain sharply defined geographic domains. Aymaran languages are spoken in northwestern Bolivia, southeastern Peru, and small areas of northwestern Argentina and northern Chile. Most people in Paraguay speak Spanish and a dialect of Tupí-Guaraní and consider themselves to be mestizo Paraguayans rather than Indians. Mapuche speakers, who constitute the largest Indian population in Chile, are restricted to the south-central part of the country, with smaller groups found in Argentina, especially in Neuquén province.

A great many other Indian languages also are spoken by members of numerous smaller groups, many of which are extremely localized and some of which are on the verge of extinction. These groups are found primarily on the periphery of lowland regions, in areas once isolated from slave trading and the rubber trade. Relatively few lowland groups are located in Brazil, the rest being found in the Hispanic countries. Among the larger groups of the Amazon basin (excluding Quechua speakers) are the Chiquitanos of eastern Bolivia, the Arawaks (Campa, Machiguenga, etc.) and Shipobo of east-central Peru, the Cocama-Cocamilla of northeastern Peru, the Jívaroans along the Ecuador-Peru border, the Tikuna of the Brazil-Colombia-Peru border region, the Yanomamo of the Venezuela-Brazil border region, and the Makushí along the Brazil-Guyana border. Groups south of the Amazon basin include the Chiriguano of southeastern Bolivia and northwestern Argentina and the Toba of northern Argentina. North of the Amazon basin are the Arawaks of Guyana, the Goajiro and Sinu (Cenú) of northern Colombia, and the Emberá along the Colombia-Panama border. The Quillacingas of Colombia occupy lands just to the north of the Quechua domain.

Shamanism

Religious patterns. South American Indians traditionally practiced shamanism, a belief system in which chosen individuals attempt to use esoteric knowledge to cure illness and to avert harm. Indigenous cultures also practiced rites of passage and seasonal rites, animal (and occasionally human) sacrifice, and ceremonial drinking. The Inca built temples, maintained a priesthood and a class called Chosen Women who were dedicated to the service of the gods, and performed pilgrimages.

The Iberian invaders considered most Indian practices to be superstition rather than heresy, and over time they were able to convert the indigenous population to at least an external observance of Roman Catholicism. Perhaps 85 percent of the South American population now professes Catholicism. In Brazil, tens of millions of people combine Catholicism with African elements in such cults as Macumba and Candomblé. New movements such as liberation theology have enhanced the popularity of Catholicism in many communities. Protestantism long has been present in the Guianas, and it has become more widespread in the late 20th century, especially in Chile, southern and southeastern Brazil, and among the Aymara of Bolivia and Quechua speakers of central Ecuador. The largest Jewish community is in Argentina in Buenos Aires.

Sociological changes. All or most legal discrimination against the Indians and other ethnic sectors of the population was nominally abolished either at the time when the individual countries became independent or during the 19th century. The real conditions of the Indians (and to a certain extent of the Africans after the abolition of slavery in Brazil in 1888), however, remained the same or became worse, since, on one hand, liberal legislation tended to eliminate all communal property and the legal existence of the Indian communities, while, on the other, various forms of exploitation continued unchanged. These de facto conditions also were reinforced by 19th-century pseudo-scientific doctrines, one of which claimed that Indians and Africans were biologically inferior races.

In the 20th century, however, a partial change in intellectual attitudes and political conditions has resulted in initiatives toward ameliorating the conditions of these groups. In Brazil, for example, institutions such as the Protective Service for the Indians (Serviço de Proteção do Indio) and the National Indian Foundation (Fundação Nacional do Indio) have been established, although such organizations often have become agents for the relocation and control of Indian groups rather than for their interests and survival. Christian missionaries sometimes have acted as representatives of Indian rights. Indians of the Andean highlands have benefited from land reforms enacted since 1950 in Bolivia, Peru, and Ecuador, although these reforms often have defined rural peoples as "peasants" rather than as Indians. Such groups as the Agaruna and the Shipibo in eastern Peru have been able to take advantage of programs by which some Indians actually have become the landlords of mestizos. National parks and protected areas have been established for such peoples as the Yanomamo of Brazil and Venezuela and the Huaorani of Ecuador.

Indian-rights movements

Large-scale Indian-rights movements have appeared in the highlands, which have attempted to link different Quechua-speaking groups into broader unions in order to obtain land and political recognition; often these movements have claimed that Indian groups constitute nations in their own right. Lowland Indians also have organized—as in the Kayapó of Brazil and the Shuar of Ecuador—and larger, pan-Indian movements have emerged that have striven to unite disparate groups at the national and international level. Coupled with the rise of these movements has been a growing interest in Indian languages, technology, music, and medicine and an effort to use indigenous knowledge to provide appropriate economic development and help conserve the South American landscape.

(G.Ge./Gr.W.K.)

DEMOGRAPHIC PATTERNS

The continent's demographics reflect an unusual settlement history: South America is a "hollow continent," with most of the population concentrated around its margins. The highest population densities are found in the old Indian core areas of the Andes, the former slave areas of northeastern Brazil, and the areas of European immigration in southern Brazil, Uruguay, and Argentina. The interior is relatively empty because of the decline in Indian populations, poor communications with coastal areas, and the absence of economic opportunities capable of attracting large numbers of immigrants. Another characteristic of South American demography is a high rate of population growth in tropical regions coupled with moderate growth in the temperate southern cone. The high tropical growth rates, however, have begun to diminish.

Both South American demography and history can be explained through the changing patterns of birth and death rates and immigration caused by the Iberian conquest and by subsequent economic development. After the conquest, diseases such as smallpox, measles, malaria, and yellow

fever decimated all Indian populations, leading to a long-term pattern of high death rates and declining or stagnant populations, even where fertility was high. Beginning in the area of European migration and extending throughout the continent after World War II, innovations in public health, such as safe drinking water and vaccines, have resulted in a dramatic drop in death rates everywhere except remote rural areas and urban slums.

The demographic transition and fertility. The resultant population explosion has been caused by a traditionally high fertility rate and a modern low mortality rate. The situation can be thought of as the second of three stages. The first stage, which characterized most of South America during the 18th and 19th centuries, involved a rough population balance maintained by high death and birth rates. The second, transitional, phase has consisted of a population explosion brought about by declining mortality and continued high fertility. The third constitutes a modern stage where low fertility brings population stability.

Fertility rates are a result of many factors, including the availability and cultural acceptability of birth-control measures. In general, economic factors increasingly have come to dominate in decisions regarding family size, including the benefits of young children to families and the costs of rearing children to adulthood. Children traditionally have had considerable value in helping families in their farming or urban-craft livelihoods and in providing security for the elderly. The costs of maintaining children in such circumstances were low, and women had few opportunities outside the household to compete with child-raising.

Changes in fertility in South America have occurred with the expansion of mandatory education, which simultaneously has raised the cost of rearing children, reduced their benefits to families, and provided young women with the education needed to seek employment. A decline in birth rates has occurred despite opposition to birth control on the part of the Roman Catholic church. Birth rates declined first in the more prosperous areas of the southern cone, but all regions have experienced the effects of growing educational and employment opportunities for young women in an increasingly urbanized environment.

Effects of rapid population increase. Rapid population increase has had important demographic and social effects. Two examples are especially illuminating.

At the peak of population growth during the second stage, the proportion of children tends to be high, while in the third stage it is low. In South America the proportion of the population under 15 years is relatively high. As a consequence, the group of people in their productive (working) years is greatly reduced. This high ratio creates

Population density of South America.

a heavier burden for the working group, while the economy is not able to raise the productivity level needed to compensate for it.

Urban growth

Another crucial consequence is the so-called urban explosion. Argentina and Uruguay have become two of the most urbanized countries in the world, but their urban growth has been the result of mass foreign immigration. The dramatic increase in urban concentration began approximately in the 1930s. In all of Latin America, the proportion of urban centres with more than 10,000 inhabitants increased from one-fourth in 1950 to about three-fourths in 40 years.

South America now is one of the most urbanized regions in the world, following the industrially advanced areas. Although the rate of growth in larger cities has decreased since 1950, the urban population has continued to be concentrated in the larger cities: a large proportion of the urban, and in some cases of the total, population lives in a single urban centre. This situation prevails in Uruguay, Argentina, Chile, Paraguay, and Peru.

Much of the growth of South America's largest cities has come about from natural increase. Migration has remained important, however, because of unfavourable conditions in the countryside. Land ownership often has been concentrated in a few hands, while "urban bias" in national policy has been reflected in price controls for or subsidized imports of foodstuffs, concentration of health, recreational, and educational facilities, and the expansion of government bureaucracies in large cities. Attempts to reverse urban bias have met with strong political opposition. There also have been pressures from rural guerrilla movements, especially in Peru, which has caused an especially rapid migration to Lima.

The unequal distribution of population in South America—the "hollow continent" phenomenon—is likely to continue and even become more pronounced. Although certain frontier areas, such as Rondônia state in Brazil and the coca-growing regions of the Andes, have attracted substantial in-migration, these flows have been far less than the out-migrations to towns and cities in already densely populated areas. Development of the interior increasingly has relied on labour-saving technology, resulting in little incentive for migration. As the largest cities face mounting problems, the likely solution will be the urbanization of nearby rural centres. (Gr.W.K.)

The economy

As a group, the economies of South American nations have changed profoundly since the 1970s. This has come as a result both of external conditions beyond the control of these nations and of internal policy decisions made to produce change. At the most fundamental level, these countries mainly are exporters of relatively low-value primary products and semiprocessed materials and importers of higher-value manufactured goods. Great efforts have been made across the continent to expand the manufacturing sectors and to reduce dependency on imports.

From the 1930s until the late 1980s, the majority of South American nations pursued economic development strategies based on a system of import substitution. National governments used such measures as tariff and price policies to encourage domestic industries and protect them from external competition. They also created joint ventures with private capital and established state-owned enterprises, especially in the heavy industries, utilities, and transportation. They provided high subsidies for social programs in areas such as education and public housing. Furthermore, national spending on armaments and "defense" soared during periods of military rule.

Nations borrowed from foreign private banks and international lending institutions, such as the World Bank and the Inter-American Development Bank, to fund existing programs while also trying to expand their economic productivity through investments in areas such as transportation, energy generation, industrialization, and agricultural modernization. However, many countries lived well beyond their means through the wholesale borrowing of funds at high interest rates on the world market. Consequently, they were forced to borrow more and more money just to service the interest payments that accumulated annually on their outstanding debt, thus creating the so-called "debt crisis."

The debt crisis

With the debt crisis, economic chaos befell many South American nations. After decades of substantial progress in its economic development, the region as a whole regressed significantly in the 1980s. Between 1980 and 1990, gross domestic product (GDP) per capita measured in constant dollars declined for every South American nation except Brazil, Colombia, and Chile. For a part of this same period, inflation rates skyrocketed in many nations, exceeding 3,000 percent per year in some instances. Currency devaluation, economic austerity programs, and governmental disinvestment were the most commonly used remedies to check these problems.

The severity of their problems and the demands of their lenders have prompted most South American countries to initiate fundamental restructurings of their economies. These reorganizations are in accord with neoliberal, or "free-market," economic theory, which has come to dominate the region's economic planning and decision making in the 1990s. Emphasis has been placed on stimulating economic growth while selling state-owned enterprises to private investors and eliminating or severely curtailing support for social programs. The long-term goal is to increase productivity, reduce governmental expenditures, and diversify economic activities. Regional economic integration also has taken on new importance. The impact of these changes is not yet clear, but their most dramatic effects are felt by those lowest on the socioeconomic ladder. (E.C.G.)

Toward a free-market economy

RESOURCES

Mineral resources. South America is relatively rich in mineral resources. However, they are highly localized: few nations have a good balance of fuels and raw materials within their boundaries, and two countries, Uruguay and Paraguay, are nearly devoid of mineral wealth.

Mineral fuels. Large quantities of oil and natural gas are found in several areas within South America. The greatest quantities are located in the sedimentary materials surrounding Venezuela's Lake Maracaibo and the adjacent Caribbean coastal margin. Venezuela also has major deposits of oil and natural gas in the area surrounding El Tigre. Venezuela is one of the world's largest oil producers and exporters. Since 1972 Ecuador has also become a major oil exporter, utilizing newly discovered fields in the Amazonian region east of the Andes. Oil fields were brought into production at the same time in the Peruvian portion of the Amazon basin west of Iquitos. Bolivia produces oil and natural gas in its eastern lowlands around Santa Cruz, while Argentina and Chile share significant deposits bordering the Strait of Magellan in Patagonia and Tierra del Fuego. Additionally, Argentina has traditional oil-producing regions around the Patagonian city of Comodoro Rivadavia. Brazil has limited offshore oil and gas reserves. Colombia has long been self-sufficient in oil and gas production, with primary areas in the central Magdalena River valley and the Putumayo area adjacent to its border with Ecuador.

South America is poor in coal. Colombia exports coal from La Guajira Peninsula and the lower Magdalena River basin south of Barranquilla, and Argentina has limited quantities of good-quality coal at El Turbio in the extreme south. Brazil produces relatively small quantities of coal in its southern states, while areas in northwestern Venezuela and inland from Concepción in Chile also have coal mines.

Iron and ferroalloys. South America contains about one-fifth of the world's iron ore reserves. The most important beds are located in Brazil and Venezuela, supplying domestic iron and steel industries as well as significant exports. The great majority of the continent's reserves are in the Brazilian states of Minas Gerais, Pará, and Mato Grosso do Sul, where lodes of magnetite and hematite ores contain up to 50 to 65 percent iron content. In Venezuela, sites like Mount Bolívar and El Pao in the Sierra de Imataca at the base of the Guiana Highlands have re-

Iron ore deposits

Basic structural regions and principal mineral and hydroelectric sites of South America.

serves of ore containing a high percentage of iron. High-quality beds of this type are also found at Mutún, Bol., and in the central part of the Chilean Andes. Oolitic iron ore (*i.e.,* ores consisting of small round grains cemented together) is found at Sierra Grande in Argentina and Paz del Río in the Cordillera Oriental of Colombia. In addition, important iron ore deposits are located at Marcona, Peru, and along a narrow belt from Taltal to Ovalle in northern Chile. Lateritic deposits of ferrous hydroxides are widespread, mainly in Colombia, Brazil, and Argentina.

Among ferroalloys, manganese occurs in sedimentary forms in the Brazilian states of Amapá and Minas Gerais, as well as in highland Bolivia. It is also found in much lesser quantities in Argentina, Chile, Ecuador, and Uruguay. Chile has the second largest reserves of molybdenum in the Americas, trailing the United States.

Copper reserves

Nonferrous base metals. Nonferrous metals are abundant in South America. The continent's copper reserves represent more than one-quarter of the world's known reserves, nearly all of which are found in Chile and Peru. In Chile the Chuquicamata deposits of the northern Atacama Desert contain the largest amounts of copper known in the world and have ores containing 2.5 percent copper. Peru's most important deposits are found in the country's central Andean ranges near Yauricocha, Morococha, Casapalca, Cerro de Pasco, and Huarón, as well as in the south, where the Toquepala mine opened in 1960. Copper also is found in Argentina and highland Bolivia and at Caraíba in the Brazilian state of Bahia.

Bolivia ranks among the world's four or five largest tin producers. Sedimentary deposits and veins of tin occur in the country's eastern Andes in a narrow belt extending roughly from Oruro to Potosí. Significant tin deposits also occur in Brazil's western Amazon basin near the Madeira River. Lead and zinc are dispersed among many countries but are found in greatest abundance in the central Andes of Peru; in the state of Minas Gerais, Brazil; in highland Bolivia; and in the northern Argentine Andes. Bauxite is exploited in Guyana and Suriname; there are also major production centres near Cuidad Guayana in Venezuela and in several places in the eastern Amazon basin of Brazil. Small quantities of mercury occur in the central Andes of Chile and near Huancavelica in Peru. Antimony is found in Bolivia and in lesser quantities in central Peru.

Gold and silver

Precious metals and gemstones. Despite the fact that South America was Europe's treasure trove for gold and silver from the 1530s through the late 1700s, in the late 20th century the region contributes only a small percentage to the world's production of these precious metals. Brazil is South America's leading gold producer, with deposits in the Amazon basin accounting for much of the output. Traditional mining centres in Minas Gerais,

Goiás, and Mato Grosso have diminished in importance. Placer deposits in Colombia's Atrato River basin are significant sources of gold, and the metal is still produced also in Venezuela and in classical gold-mining centres in the central Andes of Peru, in the Andes of Chile, and in the Carajás area in Brazil. Peru has historically been one of the world's main silver exporters, primarily from mines extending from Cerro de Pasco to Huancayo in the Andes, but production has decreased since the early 1970s. Ecuadorean silver is located primarily in the Andes, while Colombia, Argentina, and Bolivia also exploit this metal in their highland areas. Platinum is found in the Cordillera Occidental of Colombia as well as in smaller quantities in association with the copper-mining activities of central Peru.

Many parts of South America, mainly in Brazil, are famous for their gems. The ancient bedrocks of the Brazilian Highlands, especially in the states of Minas Gerais and Goiás, are rich in precious and semiprecious stones, including diamonds. However, Brazil contributes only a small percentage to world diamond production.

Other precious or semiprecious stones abound in the same region, notably topazes, tourmalines, beryls, aquamarines, chrysoberyls, garnets, opals, and sapphires, as well as quartz of sufficiently high grade for use in the electronics industry. Colombia is famous for its emeralds, found primarily in the Muzo mines of the Cordillera Oriental.

Various elements used in industry, such as beryllium, niobium (columbium), tantalum, thorium, lithium, rare-earth metals, and mica, are extracted in South America. Brazil, from the Northeast through Minas Gerais, and Argentina's Sierra de Córdoba are important sources for these minerals.

Nonmetallic deposits. South America has few significant reserves of phosphates or potash, the primary bases for many fertilizers. The Atacama Desert of northern Chile has large deposits of nitrates, which were used for fertilizers and in the munitions industry until they were largely replaced by synthetic fertilizers and atmospheric nitrogen; however, they continue to be used as a source of iodine. Limestone is quarried in Ecuador, Brazil, Chile, and Colombia, while Uruguay and Colombia are significant producers of marble. Brazil has the continent's only significant deposits of graphite.

Biological resources. South America's abundant and diversified biological reserves have been described previously. These resources, however, are unevenly distributed throughout the continent; for example, the only large areas suited to wide-scale agriculture are found in the Argentine Pampas, central Chile, southeastern Brazil, and the littoral of Uruguay.

Botanical resources. Pre-Columbian cultures domesticated numerous plants, such as corn (maize), potatoes, cassava, and beans, which, when introduced into the Old World, became dietary staples there and revolutionized the world's food supplies. In addition, a great number of South American plants provide valuable drugs, including quinine (obtained from the bark of several trees of the genus *Cinchona,* indigenous to the eastern slopes of the Andes) and cocaine (extracted from the leaves of the coca shrub, found in the eastern Andes from Peru to Bolivia).

Domesticated plants of pre-Columbian cultures

The extensive forests that cover about half of the continent constitute South America's richest natural resource. With more than 1.5 million square miles of tropical rain forest, Brazil is the most densely forested country in the region. However, since the 1980s rapid deforestation in the Amazonian rain forest has become a worldwide concern because of its effects on the environment, including the loss of biodiversity and potential climatic change. Softwood forests, though much more limited, are extensive south of the Bío-Bío River in Chile and in the southern Argentine Andes, as well as from Paraná southward in Brazil. Tropical grasslands, such as the savannas of the Llanos of Colombia and Venezuela, Brazil's Mato Grosso Plateau, and the Argentine Pampas, a midlatitude grassland, represent South America's second major botanical resource.

Animal resources. Animal resources constitute a major portion of the economies of most South American countries. In pre-Columbian times, relatively few animals were domesticated, and almost none of them extended beyond the geographic limits of their wild ancestors. An exception was the Muscovy duck. Llamas and alpacas were domesticated in the high Andes in Inca times and probably earlier. Guinea pigs were domesticated as a meat source in pre-Inca times in the Andean highlands from Colombia to Argentina. Among animals introduced to the continent were cattle, horses, goats, sheep, and pigs, all of which adapted rapidly and thrived in the New World. Cattle have become especially important in areas such as the Llanos in Venezuela and Colombia, the Argentine Pampas, and the rolling plains of Uruguay, while sheep and goats predominate on the drier, colder grazing lands of the high mountainous areas and Patagonia. Game is plentiful in most habitats, though mammals are few and specialized. Deer are represented by several species. A variety of animals are exported as pets or for zoos.

Several Neotropical animals provide world-famous fur or wool. Chinchilla, native to the high Andes from Peru to northern Argentina, were hunted for their delicate gray fur to the point of near extinction. Vicuñas continue to be hunted despite protective laws and a ban placed on

Large iron mine in the Serra dos Carajás, Pará state, Brazil.

the trade of their fur. Efforts are being undertaken to increase their numbers by "ranching" vicuñas. The giant otter of the Amazon, several spotted cats such as the ocelot and jaguar, and rodents like the nutria also provide highly prized furs.

Aquatic animals

The colonies of seabirds along the Peruvian and Chilean coasts produce an accumulation of dung (guano) which is an important fertilizer. Pinnipeds (a suborder of aquatic carnivorous animals, including seals and walruses) are exploited for their oil and furs, particularly in Uruguay. Fur seals and sea lions are found along the southern coasts of South America, although their numbers have been reduced by hunting. (E.C.G./J.P.D.)

FORESTRY, FISHING, AND MINING

Although the Neotropical forests are renowned for their biological diversity, the bulk of their trees consists of fewer than 200 species. The mixed character of these forests is a major obstacle to large-scale exploitation of timber. Nonetheless, timber harvesting has expanded dramatically since 1950, especially in the Amazon basin. Many species are used as cabinet woods, including the highly prized mahogany from Venezuela, Brazil, Peru, and Bolivia and several leguminous species such as rosewood. Some species are exploited as general utility woods and are mainly used domestically, often as fuel. Other species, such as the quebracho tree found in the Gran Chaco of Argentina and Paraguay, which produces tannin, have significant commercial value. Commercial tree plantations have become important sources of forest products, especially in Argentina and Chile. Additionally, eucalyptus groves have been planted throughout the region since their introduction in the early 1800s and provide both building material and fuel.

Commercial tree plantations

Freshwater fish, abundant in many South American rivers, have been exploited as a food source since the earliest times, especially in the Amazon region and in the Guianas. Trout were introduced by Europeans into Andean lakes and rivers, sometimes to the detriment of endemic species, while reservoirs in northeastern Brazil and elsewhere have been stocked with tilapia from Africa. Most freshwater fishing is for local consumption.

Marine fisheries became important in the 1960s, when Peru emerged as one of the world's major fishing nations, based on its anchovy fisheries. However, overexploitation has severely depleted this resource. Chile has developed a large commercial marine fishing industry as well as salmon, trout, and shrimp "farms" aimed at the export market. Since 1980 Ecuador has been a leader in shrimp exports.

Mining, including the extraction of hydrocarbons, constitutes a significant portion of the gross national product of several countries, most notably Venezuela and Chile. Oil and natural gas are the most valuable minerals recovered. Venezuela is the region's largest petroleum producer, while Brazil leads in iron ore tonnage, accounting for more than four-fifths of the output. Brazil also is the largest producer of bauxite and tin concentrates, although Bolivia's tin output represents a large share of South America's total. Chile produces approximately three-fourths of the continent's copper output.

AGRICULTURE

Agriculture constitutes a large portion of South America's economy. Livestock production also occupies large parts of rural South America, especially cattle ranching. Most of the commercial livestock production, especially for the export sector, occurs on huge estates that have been the source of economic and social dominance for their owners for many generations.

Only about one-eighth of South America's land is suitable for permanent cropping or grazing. It is broadly agreed that agricultural land use throughout the continent is less efficient than it might be. Farm and ranch productivity could be enhanced by measures such as providing adequate agricultural credit, improving marketing, storage, and transportation systems, and expanding the educational system in rural areas. Such changes would benefit the large number of small farmholdings (*minifundias*)—three-fourths of South America's farmers own less than 25 acres (10 hectares)—making it possible for those farmers to improve their living standards and contribute to national development. The changes also would help to alleviate the widespread under- and unemployment prevalent in the densely populated rural areas. Unemployment is a problem in such areas, even though less than one-third of South America's working population is employed in the agricultural sector, as compared with nearly one-half of the population for the world as a whole.

Inefficient land use

The agricultural sector is affected negatively as well by the unfavourable terms of trade between agricultural commodities and manufactured goods that have existed in general since World War II. The rise in the cost of farming has outstripped the rise in the prices paid for agricultural commodities, and this imbalance substantially lowers the investment potential in the agricultural sector.

Principal crops. *Food crops.* Corn (maize), a native of tropical America and now a staple in countries around the world, is the most widely cultivated crop throughout the continent. Argentina became a major exporter of corn during the 20th century. Beans, including several species of the genus *Phaseolus,* are widely cultivated by small-scale methods and form an important food item in most countries. Cassava and sweet potato also are indigenous to the New World and have become the basic foodstuffs of much of tropical Africa and parts of Asia. The potato, which originated in the high Andes, became a dietary staple of many European nations. Several other plants were domesticated in South American environments, such as quinoa and canahua, both small grains used as cereals, and tuberoses such as ullucu and oca. Squashes and pumpkins are pre-Columbian crops that have spread throughout the world, as is the tomato, indigenous to South America's west coast. Cashews, cultivated in most tropical countries, and Brazil nuts, harvested from trees in the Amazon basin, are widely regarded as delicacies, but both the cashew fruit and the nuts also are local favourites. Cacao, native to the Amazon region and the source of cocoa, was prized by indigenous peoples and is still cultivated in many parts of South America, particularly in the state of Bahia, Brazil. Avocados also originated in the same region. Pineapples, probably indigenous to southern Brazil and the Paraná River basin, were cultivated throughout tropical South America and the West Indies prior to the arrival of Columbus. Papaya and guava are also from tropical America.

Introduced species

Europeans introduced a number of plants to the continent. Sugarcane has been cultivated in the humid tropics of South America since early colonial times, especially in northern Brazil, where it became the mainstay of the economy. In similar environments bananas have long been an important local food item, and since the early 1970s Ecuador has become one of the largest banana exporters in the world. Mangoes, oranges, lemons, and grapefruits are grown widely throughout tropical and subtropical environments in South America. While their origin is much disputed, coconuts are common in most tropical coastal areas in the region. Among the cereals, rice, which was introduced from Asia, has become a dietary staple in several countries. It is grown extensively in the irrigated desert oases of the Peruvian coast and in savanna and rain forest climatic areas of Brazil and Colombia. Wheat, along with other cereals, was introduced by the Spanish by the 1550s throughout Andean South America, where it is still grown. However, it is most successfully produced on the Pampas of Argentina and the littoral of southwestern Uruguay, where it was introduced after the mid-1800s. Soybeans were introduced in the Argentine Pampas in the 1950s and in southern Brazil in the 1960s and are now an extremely important commercial crop.

Specialized cash crops. Coffee was imported from the Old World in the 1800s and grown in the highlands of Venezuela, Colombia, and Ecuador. It is exported in great quantities from the main producing areas of Colombia's Cordillera Central, the source of some of the world's highest-quality coffees, and from several Brazilian states, including Paraná and Minas Gerais. The most notable native beverage, yerba maté, is brewed from the leaves of a plant indigenous to the upper Paraná basin. It is still

Agricultural regions of South America.

gathered in its wild state in Paraguay, Brazil, and Argentina, as well as grown on plantations in the latter two countries. Tobacco is cultivated in many countries but is produced commercially mainly in Brazil and Colombia. The two commercially most important native South American spices—allspice and red, or chili, pepper—are exported from Brazil.

South America also has a great variety of oil-producing plants, such as the babassu palm, native to Brazil, whose nuts are used for making soap. Vegetable waxes are produced mainly from the waxy secretions found on the leaves of the carnauba palm of Brazil. Vegetable ivory is taken from the hard seeds of the tagua palm, found in much of northern South America but particularly in lowland Ecuador.

Cotton, which has been used for cloth since prehistoric times, is grown in large quantities in northeastern Brazil, coastal Peru, and in the Chaco province of Argentina. Kapok and plants producing stem or leaf fibres, such as sisal, are extensively grown. The iraca, a plant with the appearance of a stemless palm, is cultivated in southern Colombia and northern Ecuador. Its fibres, extracted from young leaves, are woven into the once-famous "Panama" hats.

Natural latexes

Several plants furnish latex, from which rubber is extracted. Para rubber (seringa) and related species native to the Amazon basin were known by Indian groups and formed the basis for the Brazilian "rubber boom" of the late 1800s. Balata yields a nonelastic rubber used in golf balls and baseballs. Chicle, a latex gum extracted from the sapodilla tree, is used in the preparation of chewing gum. Artificial rubber has greatly reduced the demand for many natural latexes.

Livestock. Because cattle were of enormous cultural and economic importance for the Hispanic colonial economies, South America has a significant percentage of the world's total cattle population. Hybridized cattle breeds of the highest quality, such as Herefords, Angus, and Charollais, are found on the rich midlatitude pasturelands of the Argentine Pampas and in Uruguay. Much of the Llanos of northern South America is given over to the grazing of Brahman (Zebu) crosses. The pastures of the Amazon basin, created in the latter part of the 20th century, consist of imported African tropical grasses, which support large herds of Brahman, Charollais, and other hybridized breeds as well as exotics such as Asian water buffalo. Stock raising also flourishes in eastern and southern Brazil and in the temperate zones of the Andes; it is pursued in nearly all environmentally suitable areas of every country.

In the higher regions of the Andes, generally above 10,000 feet, and in the colder or more arid lowland settings, cattle

give way to other grazing animals. Llamas and alpacas, along with sheep and goats, are found in the higher Andes from Ecuador through northern Argentina and Chile. Vicuñas are still found at very high elevations, usually above 14,000 feet, in Peru. Sheep predominate in Patagonia and Tierra del Fuego, while goats prevail in the arid Atacama Desert and in the drought polygon of northeastern Brazil. Pigs and smaller domestic animals like chickens are present in almost all rural areas of the continent. Within the former Inca settlement area of the Andes, extending from the far south of Colombia through northern Argentina, guinea pigs are still raised as a food source.

INDUSTRY

In most South American nations, the industrial sector has made only a limited contribution to the creation of new sources of employment. This fact, which is problematic especially in view of the rapid growth of the labour force, can be explained in part by the adoption of production techniques requiring a high ratio of capital to labour and in part by the sector's slow growth. In the 1990s about one-fourth of the continent's labour force was occupied in the industrial sector.

In the early 1990s the industrial sector generated more than one-third of the gross national product for South America as a whole. Of this total, about four-fifths represented manufacturing and the rest construction and public utilities. In the two most industrialized countries, Argentina and Brazil, the production of foodstuffs, beverages, and tobacco accounts for only about one-seventh of the total manufacturing output. The metallurgy and mechanical industries represent more than one-third of total output, while chemicals and petroleum refining contribute about one-fourth and textiles, footwear, and apparel about one-eighth. During the last quarter of the 20th century, South American industrial production made substantial gains, especially in the output of cement and steel (ingots, rolled, plates, and sheets), pig iron, automobiles, and household appliances. Brazil, with its manufacturing core centring on São Paulo, has emerged as the industrial giant of the continent, followed by Argentina, Venezuela, and Chile.

The construction industry in much of South America retains fairly traditional methods. Construction techniques are labour-intensive, quality is often low, and costs are relatively high. Yet the building of high-rise and mid-rise office towers, hotels, commercial structures, and condominiums during the last two decades has greatly altered the skylines of virtually every large city on the continent. Despite the existence of a huge housing shortage, residential construction has lagged significantly behind demand. This is due largely to reduced governmental ability to provide state-financed housing and to limited involvement of speculation capital in residential construction.

POWER AND IRRIGATION

The total annual generation of electricity in South America increased by 10 percent between 1987 and 1990, mainly through the construction of large-scale hydroelectric projects. Industry consumes almost two-fifths of the electric power generated in South America, while household consumption accounts for about another two-fifths. The rest goes to other uses or transmission losses.

Energy consumption

Private installed electrical capacity, which consists mainly of relatively high-cost thermoelectric plants, represents a low percentage of total installed capacity. The overwhelming trend has been toward increases in hydroelectric power owing to the growing importance of public power services and the corresponding decline of private power generation.

Argentina, Brazil, Paraguay, Uruguay, and Venezuela have initiated ambitious electrical installation programs that have taken advantage of some of the region's abundant hydroelectric resources. From the 1960s through the 1980s, a major thrust of international lending institutions, including the Inter-American Development Bank and the World Bank, was to support infrastructural improvements. As a result, by the late 20th century South America boasted several of the largest hydroelectric projects in the world, including the Itaipu Dam on the Paraguay-Brazil border and the Guri Dam in the Llanos of Venezuela. The regional nature of many major rivers has led to binational cooperation on many projects, including joint efforts between Argentina and Uruguay and between Brazil and Paraguay.

Some of the hydroelectric projects also have been designed for irrigation uses, but there are many instances in which the construction of distribution canals for irrigation has yet to be achieved. Only 8 percent of arable land and of land under permanent crops is irrigated. Brazil and Argentina have the largest amounts of irrigated acreages, whereas Suriname, Peru, Chile, and Guyana have the highest proportion of irrigation in relation to cultivable land. Because of the relative scarcity of farmland in those countries, large-scale irrigation is a basic necessity of the agricultural sector.

TRADE

In South America, most banks and financial institutions are large enterprises with branches in many cities and towns. In some countries a high proportion of these were government-owned until the late 1980s. Foreign-owned banks or joint-venture enterprises of local and foreign capitalization are common. Wholesale and particularly retail business enterprises, on the other hand, are mostly individual concerns and in many cases are family shops. Department stores or chain stores, uncommon in most South American countries until the early 1970s, have become an important part of the merchandising environment, especially in the larger cities. During the 1980s, modern managerial and marketing structures took hold in many countries—especially Brazil, Argentina, Chile, Uruguay, Colombia, and Venezuela—often giving a competitive edge in the marketplace to enterprises that adopted them.

Internal trade. Intraregional trade continues to be of relatively small importance in South America. Despite its rapid growth since World War II, intraregional trade in Latin America still accounts for only about one-tenth of total exports. A firm conviction prevails in South America that intensification of intraregional trade is a necessary condition for rapid economic growth because it would help to reduce the region's excessive dependence on foreign markets, diversify exports, and alleviate balance-of-payments problems.

South American trade with the rest of Latin America is concentrated in a few countries. Argentina, Brazil, and Venezuela account for more than half of the exports, and these same three countries also absorb about half of the imports from the rest of Latin America.

All the independent South American countries except Guyana and Suriname belong to the Latin American Integration Association (LAIA; formerly the Latin American Free Trade Association). Despite formidable obstacles, including unequal levels of development, inadequate infrastructural linkages, and enormous physical distances between countries, the LAIA has directed its efforts toward designing a common trade policy for member countries. It will gradually reduce import duties and other restrictions on imports from the rest of the world while arriving at agreements to compensate trade payments between member countries as well as making reciprocal credit arrangements between central banks. In addition, Bolivia, Colombia, Ecuador, Peru, and Venezuela formed the Andean Group for the purpose of reaching agreement on common trade problems, including external tariffs, reductions in tariffs applicable to subregional production, and coordination of policies toward foreign investment. Peru suspended its membership in 1992 but remained as an observer.

Latin American Integration Association

About three-fourths of the trade among LAIA members consists of basic commodities and about one-fifth of semimanufactured and manufactured goods. Among basic commodities the most important items are foodstuffs, beverages and tobacco, raw materials, and nonferrous metals. Among manufactured goods the main items of trade are chemicals, machinery, automobiles, and transport equipment.

All these efforts toward integration have been responsible in part for the rapid growth of the area's internal trade and for a large contribution toward a greater balance of

trade among these countries. An important component of this trade has been binational barter agreements. Trade surpluses and deficits between the nations have declined considerably.

External trade. External trade represents a key element in South America's economic growth. Essential imports, particularly capital and basic intermediate goods, are needed to accelerate the industrialization process. A major problem has been that exports and net external financing have not generated sufficient income to pay for those imports. Despite increases in trade, South America's share of world trade has remained small, primarily because the volume of trade between major industrialized countries has grown at an even faster rate.

Exports

South America's major exports, in terms of value, are mostly primary commodities, including foodstuffs and plant products, fuels, and raw materials. Within the first group the most important commodities are sugar, bananas, cocoa, coffee, tobacco, beef, corn, and wheat. Oil, natural gas, and petroleum products dominate the second group, while linseed oil, cotton, cattle hides, fish meal, wool, copper, tin, iron ore, lead, and zinc top the third group. South American manufactured goods are gaining access to world markets as well. Brazil has become a significant supplier of armaments worldwide as well as an exporter of, among other products, small aircraft and shoes. Several other nations, including Uruguay, Argentina, Colombia, and Chile, have also increased their nontraditional exports over the past 20 years. More than one-fourth of these exports are sent to the United States, another one-fifth to western Europe, and one-twentieth to South America. Since the 1970s the illicit movement of drugs—particularly cocaine—which is mainly conducted from Peru, Bolivia, and Colombia, has added enormously to the value of exports from the region.

Almost three-fourths of South America's imports consist of machinery, vehicles and parts, chemicals and pharmaceuticals, paper and paperboard, textile products, and other manufactures. About one-fourth of South America's total imports are from the United States, one-seventh come from western Europe, and another one-seventh originate in South America. In general, South America's foreign trade sector has been slow to diversify; it is heavily dependent on imports for domestic supplies of industrial goods and suffers from an imbalance in trade with the industrialized countries.

TRANSPORTATION

In an area the size of South America, an efficient system of transportation is necessary for the development of the hinterland, the expansion of national markets, and the integration of the different national economic systems. Unlike North America, South America still does not have an adequately integrated transportation network. Significant efforts have been made to improve both the connections within countries and the linkages between them.

Roads. South America has an extensive and rapidly expanding network of roads. In many countries, however, only a relatively small percentage of the roads are paved, and in the most remote areas they may be barely wide enough for two vehicles to pass easily. The remainder of the system consists of improved roads or simply of dirt roads.

Highway integration

In developing national segments of international highways, particular attention has been paid to road-integration projects. The Inter-American Development Bank and the World Bank were heavily engaged in some of these projects, as, for example, in the construction of the bridge links joining Paraguay and Argentina, Argentina and Uruguay, and Paraguay and Brazil (all these links were completed by the late 1970s). A road linking Venezuela and Brazil allows north-south movement through the Amazon basin. Brazil continues to have the largest network of roads belonging to the Pan-American Highway system, which extends throughout the Americas.

Because of the size of the continent and the immense variety of physical environments, an efficient road network is of utmost importance. Roads not only provide the primary passenger routes for the great majority of people but also offer the most cost-effective means of moving goods within countries. In all South American nations, truck transportation has taken an increasingly large share of the volume of goods carried by land. In addition to stimulating economic development, routes such as the Transamazonian Highway and the Marginal de la Selva Highway linking the countries on the east side of the Andes, constructed since the 1970s, also represent attempts to spur development. The results of this effort, however, have been mixed, because making land available for settlement has often caused considerable ecological damage to the tropical forests.

Railways. In most South American countries railways have lost their dominant position as the major mode of transportation, having been replaced by the integrated road networks that have developed rapidly since the 1960s. Moreover, rail transport is plagued by operational problems as well as by obsolete equipment. Almost all lines are single-tracked, which makes traffic slow and discourages passenger service. Many countries have two or more track gauges, which impedes the efficient integration of the rail system.

Until the 1980s, virtually all railways were owned by the state. Since then, governments, as part of their overall efforts to privatize their national economies, have divested themselves of a large percentage of publicly owned railroads. This has led to the elimination of a huge number of passenger routes as well as the reduction of much of the freight component.

Maritime transport. Sea transportation has long been a vital component of the transport systems of South American countries. The great majority of imports and exports to and from the continent moves by ship. South America has a number of outstanding natural harbours, such as Rio de Janeiro, Salvador, Montevideo, and Valparaíso, along with numerous improved ports and roadsteads, including Buenos Aires, Callao, and Barranquilla. Many of these port facilities had degenerated significantly by the 1960s, to the point that some of the region's largest ports were blacklisted by insurers and shipping companies. Since the early 1970s, many of these ports have undergone extensive renovation and modernization, including the installation of containerization facilities.

Ports

Several countries are making a determined effort to develop and enlarge their national merchant marines. This effort is meant partly to arrest earlier trends of having their trade carried by ships from outside the region and partly to promote regional integration and improve the national balance of payments.

Waterways. There are two inland waterway systems of international importance, the Paraguay-Uruguay basin (which includes territory in four countries) and the Amazon basin (six countries). Each has several thousand miles of navigable waterways. Furthermore, there are three other minor systems: the Magdalena in Colombia, the Orinoco in Venezuela, and the São Francisco in Brazil. The remaining rivers are unsuitable for navigation. There are drawbacks to using some inland waterways, including dry seasons, the direction of water flow, and difficult rapids. In general, the volume of traffic on the waterways of South America is relatively small, and the prospects for increasing it are limited.

Air transportation. Air transportation has developed rapidly since World War II, mainly because it avoids the forbidding geographic obstacles that hamper surface travel. The increase in air transportation is particularly significant with respect to passenger traffic but applies less to the handling of bulky freight.

Each country has its own system of internal air services, operated until the late 1980s chiefly by government-owned or by heavily subsidized private companies. While several governments still operate an international carrier, privatization in the airline industry has spread to internal carriers. All the South American capitals and most of the large cities are linked by direct air services to the major traffic centres of the United States and Europe. Domestic traffic links have expanded extensively since the late 1970s, when "short take-off" jets were introduced into service.

(E.C.G./H.F.A.)

SOUTH AMERICAN GEOGRAPHIC FEATURES OF SPECIAL INTEREST

Landforms

ANDES MOUNTAINS

The Andes mountain system consists of a vast series of extremely high plateaus surmounted by even higher peaks that form an unbroken rampart over a distance of some 5,500 miles (8,900 kilometres)—from the southern tip of South America to the continent's northernmost coast on the Caribbean. One of the Earth's great natural features, the Andes separate a narrow western coastal area from the rest of the continent, affecting deeply the conditions of life within the ranges themselves and in surrounding areas. The Andes contain the highest peaks in the Western Hemisphere. The highest of them is Mount Aconcagua (22,831 feet [6,959 metres]) on the border of Argentina and Chile.

The Andes are not a single line of formidable peaks but a succession of parallel and transverse mountain ranges, or cordilleras, and of intervening plateaus and depressions. Distinct eastern and western ranges—respectively named the Cordillera Oriental and the Cordillera Occidental—are characteristic of most of the system. The directional trend of both the cordilleras generally is north-south, but in several places the Cordillera Oriental bulges eastward to form either isolated peninsula-like ranges or such high intermontane plateau regions as the Altiplano (Spanish: "High Plateau"), occupying adjoining parts of Argentina, Chile, Bolivia, and Peru.

Some historians believe the name Andes comes from the Quechuan word *anti* ("east"); others suggest it is derived from the Quechuan *anta* ("copper"). It perhaps is more reasonable to ascribe it to the *anta* of the older Aymara language, which connotes copper colour generally.

Map coverage of the Andes Mountains can be found below in the following sections: for the southern ranges, see *Patagonia;* for the central ranges, see *Amazon River basin;* and for the northern ranges, see *Orinoco River basin.*

Physical features. There is no universal agreement about the major north-south subdivisions of the Andes system. For the purposes of this discussion, the system is divided into three broad categories. From south to north these are the Southern Andes, consisting of the Fuegian and Patagonian cordilleras; the Central Andes, including the Chilean and Peruvian cordilleras; and the Northern Andes, encompassing the Ecuadorian, Colombian, and Venezuelan (or Caribbean) cordilleras.

Three subdivisions

Geology. The Andean mountain system is the result of global plate-tectonic forces during the Cenozoic Era (the last 66.4 million years) that built upon earlier geologic activity. About 250 million years ago, the crustal plates constituting the Earth's landmass were joined together into the supercontinent Pangaea. The subsequent breakup of Pangaea and of its southern portion, Gondwana, dispersed these plates outward, where they began to take the form and position of the present-day continents. The collision (or convergence) of two of these plates—the continental South American Plate and the oceanic Nazca Plate—gave rise to the orogenic (mountain-building) activity that produced the Andes.

Many of the rocks comprising the present-day cordilleras are of great age. They began as sediments eroded from the Amazonia craton (or Brazilian shield)—the ancient granitic continental fragment that constitutes much of Brazil—and deposited between about 450 and 250 million years ago on the craton's western flank. The weight of these deposits forced a subsidence (downwarping) of the crust, and the resulting pressure and heat metamorphosed the deposits into more resistant rocks; thus, sandstone, siltstone, and limestone were transformed, respectively, into quartzite, shale, and marble.

Approximately 170 million years ago this complex geologic matrix began to be uplifted as the eastern edge of the Nazca Plate was forced under the western edge of the South American Plate (*i.e.,* the Nazca Plate was subducted), the result of the latter plate's westward movement in response to the opening of the Atlantic Ocean to the east. This subduction-uplift process was accompanied by the intrusion of considerable quantities of magma from the mantle, first in the form of a volcanic arc along the western edge of the South American Plate and later by the injection of hot solutions into surrounding continental rocks; the latter process created numerous dikes and veins containing concentrations of economically valuable minerals that later were to play a critical role in the human occupation of the Andes.

The intensity of this activity increased during the Cenozoic—notably between about 15 and 6 million years ago—and the present shape of the cordilleras emerged. The resultant mountain system exhibits an extraordinary vertical differential of more than 40,000 feet between the bottom of the Peru-Chile (Atacama) Trench off the Pacific coast of the continent and the peaks of the high mountains within a horizontal distance of less than 200 miles. The tectonic processes that created the Andes have continued to the present day. The system—part of the larger Circum-Pacific volcanic chain that often is called the Ring of Fire—remains volcanically active and is subject to devastating earthquakes.

Physiography of the Southern Andes. The Fuegian Andes begin on the mountainous Estados (Staten) Island, the easternmost point of the Tierra del Fuego archipelago, reaching an elevation of 3,700 feet. They run to the west through Grande Island, where the highest ridges—including Mounts Darwin, Valdivieso, and Sorondo—are all less than 7,900 feet high. The physiography of this southernmost subdivision of the Andes system is complicated by the presence of the independent Sierra de la Costa.

The Patagonian Andes

The Patagonian Andes rise north of the Strait of Magellan. Numerous transverse and longitudinal depressions and breaches cut this wild and rugged portion of the Andes, sometimes completely; many ranges are occupied by ice fields, glaciers, rivers, lakes, or fjords. The crests of the mountains exceed 10,000 feet (Mount Fitzroy reaching 11,073 feet) north to latitude 46° S but average only 6,500–8,400 feet from latitude 46° to 41° S, except for Mount Tronador (11,453 feet). North of Lake Aluminé (Argentina) the axis of the cordillera shifts to the east up to a zone of transition between latitude 37° and 35° S, where the geographic aspect and geomorphic structure change. This zone marks the most commonly accepted northern extent of the Patagonian Andes; there is some disagreement, however, about this limit, some placing it farther south, at the Gulf of Penas, (47° S) and others considering it to be to the north, around 30° S.

The line of permanent snow becomes higher in elevation with decreasing latitude in the Southern Andes: 2,300 feet in Tierra del Fuego, 5,000 feet at Osorno Volcano (41° S), and 12,000 feet at Domuyo Volcano (36°38′ S). A line of active volcanoes—including Yate, Corcovado, and Macá—occurs about 40° to 46° S; the southernmost of these, Mount Hudson of Chile, erupted in 1991. Enormous ice fields are located between Mount Fitzroy (called Mount Chaltel in Chile) and Lake Buenos Aires (Lake General Carrera in Chile) at both sides of Baker Fjord; the Viedma, Upsala, and other glaciers originate from these fields. Other notable features are the more than 50 lakes found south of 39° S. Those depressions that are free of water form fertile valleys called vegas, which are easily reached by low passes. Magnificent and impenetrable forests grow on both sides of these cordilleras, especially on the western slopes; these forests cover the mountains as high as the snow line, although at the higher altitudes toward the north and in Tierra del Fuego the vegetation is lower and less dense. Both Argentina and Chile have created national parks to preserve the area's natural beauty.

Physiography of the Central Andes. The Central Andes

The Patagonian Andes in the Torres del Paine National Park, near Puerto Natales, Chile.

begin at latitude 35° S, at a point where the cordillera undergoes a sharp change of character. Its width increases to about 50 miles, and it becomes arid and higher; the passes, too, are higher and more difficult to cross. Glaciers are rare and found only at high elevations. There is virtually no vegetation, lakes having disappeared north of 39° S and forests north of 37°. The main range serves as the boundary between Chile and Argentina and also is the drainage divide between rivers flowing to the Pacific and the Atlantic. The last of the southern series of volcanoes, Mount Tupungato (21,555 feet) is just east of Santiago, Chile. A line of lofty, snowcapped peaks rise between Tupungato and the mighty Mount Aconcagua. To the north of Aconcagua lies Mount Mercedario (22,211 feet), and between them are the high passes of Mount Espinacito (16,000 feet) and Mount Patos (12,825 feet). South of Anconcagua the passes include Pircas (16,960 feet), Bermejo (more than 10,000 feet), and Iglesia (13,400 feet). Farther north the passes are more numerous but higher. The peaks of Mounts Bonete, Ojos del Salado, and Pissis surpass 20,000 feet; the snow line also is much higher.

The peak of Tres Cruces (22,156 feet) at 27° S latitude marks the culmination of this part of the cordillera. To the north is found a transverse depression and the southern limit of the high plateau region called the Atacama Plateau in Argentina and Chile and the Altiplano in Bolivia and Peru. The cordillera grows wider as it advances into Bolivia and Peru, where the great plateau is bounded by two ranges: the Occidental and the Oriental.

The Altiplano

Northward, to latitude 18° S, the peaks of El Cóndor, Sierra Nevada, Llullaillaco, Galán, and Antofalla all exceed 19,000 feet. The two main ranges and several volcanic secondary chains enclose depressions called salars because of the deposits of salts they contain; in northwestern Argentina, the Sierra de Calalaste encompasses the large Antofalla Salt Flat. Volcanoes of this zone occur mostly on a northerly line along the Cordillera Occidental as far as Misti Volcano (latitude 16° S) in Peru.

The western slopes of the Cordillera Occidental descend gradually to the Atacama Desert along the coast. At about 18° S the trend of the Cordillera Occidental changes to a northwesterly direction. The Cordillera Oriental to the east, lower and built on a broad bed of lava, is cut and denuded by rivers with steep gradients, fed by heavy rainfall. It has two sections. The southern portion is 150 miles wide and—with the exception of Chorolque Peak in Bolivia (18,414 feet)—of relatively low elevation. The northern section in Bolivia, called Cordillera Real, is narrow, with higher peaks and glaciers; the most important peaks, at over 21,000 feet, are Mounts Illimani and Illampu.

At about latitude 22° S the Cordillera Oriental penetrates into Bolivia and describes a wide semicircle to the north and then to the northwest; to the west the Altiplano reaches its broadest extent. The Altiplano—500 miles long and 80 miles wide—is one of the largest interior basins of the world. Varying in elevation from 11,200 to 12,800 feet, it has no drainage outlet to the ocean. Roughly in the centre of the plateau is a great depression between the two cordilleras. Lake Titicaca, the highest navigable lake of the world (110 miles long), fills the northern part of the depression; the Desaguadero River flows south through the depression, draining Titicaca water into the smaller Lake Poopó.

As the Andes enter Peru, the Cordillera Occidental runs parallel to the coast, while the Cordillera Real from Bolivia ends in the rough mountain mass of the Vilcanota Knot at latitude 15° S. From this knot (*nudo*), two lofty and narrow chains emerge northward, the Cordilleras de Carabaya and Vilcanota, separated by a deep gorge; a third range, the Cordillera de Vilcabamba, appears to the west of these and northwest of the city of Cuzco. The three ranges are products of erosive action of rivers that have cut deep canyons between them. West of the Cordillera de Vilcabamba, the Apurímac River runs in one of the deepest canyons of the Western Hemisphere. The city of Cuzco lies in the valley west of the Cordillera de Vilcanota at an altitude of nearly 11,000 feet.

The Peruvian Andes traditionally have been described as three cordilleras, which come together at the Vilcanota, Pasco, and Loja (Ecuador) knots. The Pasco Knot is a large, high plateau. To the west it is bounded by the Cordillera Huarochirí, on the west slope of which the Rímac River rises in a cluster of lakes fed by glaciers and descends rapidly to the ocean (15,700 feet in 60 miles). Ticlio Pass, at an altitude of some 15,800 feet, is used by a railway. Many small lakes and ponds are found on the knots, with Lake Junín (about 20 miles long) being the largest.

The Pasco Knot

North of the Pasco Knot, three different ranges run along the plateau: the Cordilleras Occidental, Central, and Oriental. In the Cordillera Occidental, at latitude 10° S, the deep, narrow Huaylas Valley separates two ranges, Cordillera Blanca to the east and Cordillera Negra to the west; the Santa River runs between them and cuts Cordillera Negra to drain into the Pacific. Cordillera Blanca is a complex highland with permanently snowcapped peaks, some among the highest of the Andes (*e.g.*, Mount Huascarán, at 22,205 feet). The glaciers that rise there often are broken off by earthquakes and rush down the slopes, demolishing vegetation and settlements in their paths. Cordillera Negra, so named because it is not covered with snow, is lower.

The two ranges join together at latitude 9° S. The Marañón River, which runs northward between the Cordilleras Occidental and Central at about 6° S, changes its direction of flow to the northeast, penetrating into a region of nar-

row transverse water gaps (*pongos*) that cut the cordillera to reach the Amazon basin. These include Rentema (about one and one-fourth miles long and 200 feet wide), Mayo, Mayasito, and Huarcaya gaps and—the most important—Manseriche Gap, which is seven miles long.

Between the Cordilleras Central and Oriental, the Huallaga River runs in a deep gorge with few small valleys; it cuts the eastern cordillera at Aguirre Gap (latitude 6° S). The Cordillera Oriental ends in the Amazon basin at 5° S.

The permanent snow line reaches an altitude of 19,000 feet in Mount Chanchani (about latitude 16° S) and declines to about 15,000 feet in Cordillera Blanca and to 13,000 feet on Mount Huascarán. Permanent snow disappears north of 8° S, the puna grasslands end, and the so-called humid puna, or *jalca,* begins. Mountains become wider and smoother in appearance, while vegetation changes to heathland and trees. The altitude diminishes, and passes are much lower, as at Porculla Pass (7,000 feet) east of Piura.

Physiography of the Northern Andes. A rough and eroded high mass of mountains called the Loja Knot (4° S) in southern Ecuador marks the transition between the Peruvian cordilleras and the Ecuadorian Andes. The Ecuadorian system consists of a long, narrow plateau running from south to north bordered by two mountain chains containing numerous high volcanoes. To the west, in the geologically recent and relatively low Cordillera Occidental, stands a line of 19 volcanoes, 7 of them exceeding 15,000 feet in elevation. The eastern border is the higher and older Cordillera Central, capped by a line of 20 volcanoes; some of these, such as Chimborazu Volcano (20,702 feet), have permanent snowcaps.

The Ecuadorian Andes

The outpouring of lava from these volcanoes has divided the central plateau into 10 major basins that are strung in beadlike fashion between the two cordilleras. These basins and their adjacent slopes, which are intensively cultivated, contain roughly half of Ecuador's population.

A third cordillera has been identified in the eastern jungle of Ecuador and has been named the Cordillera Oriental. The range appears to be an ancient alluvial formation that has been divided by rivers and heavy rainfall into a number of mountain masses. Such masses as the cordilleras of Guacamayo, Galeras, and Lumbaquí are isolated or form irregular short chains and are covered by luxuriant forest. Altitudes do not exceed 7,900 feet, except at Cordilleras del Cóndor (13,000 feet) and Mount Pax (11,000 feet).

North of the boundary with Colombia is a group of high, snowcapped volcanoes (Azufral, Cumbal, Chiles) known as the Huaca Knot. Farther to the north is the great massif of the Pasto Mountains (latitude 1°–2° N), which is the most important Colombian physiographic complex and the source of many of the country's rivers.

Three distinct ranges, the Cordilleras Occidental, Central, and Oriental, run northward. The Cordillera Occidental, parallel to the coast and moderately high, reaches an elevation of nearly 13,000 feet at Mount Paramillo before descending in three smaller ranges into the lowlands of northern Colombia. The Cordillera Central is the highest (average altitude of almost 10,000 feet) but also the shortest range of Colombian Andes, stretching some 400 miles before its most northerly spurs disappear at about latitude 8° N. Most of the volcanoes of the zone are in this range, including Mounts Tolima (17,105 feet), Ruiz (17,717 feet), and Huila (18,865 feet). At about latitude 6° N, the range widens into a plateau on which Medellín is situated.

Between the Cordilleras Central and Occidental is a great depression, the Patía-Cauca valley, divided into three longitudinal plains. The southernmost is the narrow valley of the Patía River, the waters of which flow to the Pacific. The middle plain is the highest in elevation (8,200 feet) and constitutes the divide of the other two. The northern plain, the largest (15 miles wide and 125 miles long), is the valley of Cauca River, which drains northward to the Magdalena River.

The Cordillera Oriental trends slightly to the northeast and is the widest and the longest of the three. The average altitude is 7,900 to 8,900 feet. North of latitude 3° N the cordillera widens and after a small depression rises into the Sumapaz Uplands, which range in elevation from 10,000 to 13,000 feet. North of the Sumapaz Upland the range divides into two, enclosing a large plain 125 miles wide and 200 miles long, often interrupted by small transverse chains that form several upland basins called *sabanas* that contain about a third of Colombia's population. The city of Bogotá is on the largest and most populated of these *sabanas;* other important cities on *sabanas* are Chiquinquirá, Tunja, and Sogamoso. East of Honda (5° N) the cordillera divides into a series of abrupt parallel chains running to the north-northeast; among them the Sierra Nevada del Cocuy (18,022 feet) is high enough to have snowcapped peaks.

Farther north the central ranges of the Cordillera Central come to an end, but the flanking chains continue and diverge to the north and northeast. The westernmost of these chains is the Sierra de Ocaña, which on its northeastern side includes the Sierra de Perijá; the latter range forms a portion of the boundary between Colombia and Venezuela and extends as far north as latitude 11° N in La Guajira Peninsula. The eastern chain bends to the east and enters Venezuela as the Cordillera de Mérida. On the Caribbean coast just west of the Sierra de Perijá stands the isolated, triangular Santa Marta Massif, which rises abruptly from the coast to snowcapped peaks of 18,947 feet; geologically, however, the Santa Marta Massif is not part of the Andes.

The northern end of the Andes

The Venezuelan Andes are represented by the Cordillera de Mérida (280 miles long, 50 to 90 miles wide, and about 10,000 feet in elevation), which extends in a northeasterly direction to the city of Barquisimeto, where it ends. The cordillera is a great uplifted axis where erosion has uncovered granite and gneiss rocks but where the northwestern and southeastern flanks remain covered by sediments; it consists of numerous chains with snow-covered summits separated by longitudinal and transverse depressions—Sierras Tovar, Nevada, Santo Domingo, de la Culata, Trujillo, and others. The range forms the northwestern limit of the Orinoco River basin, beyond which water flows to the Caribbean. North of Barquisimeto, the Sierra Falcón and Cordillera del Litoral (called in Venezuela the Sistema Andino) do not belong to the Andes but rather to the Guiana system.

Soils. The complex interchange between climate, parent material, topography, and biology that determines soil types and their condition is deeply affected by altitude in the Andes. In general, Andean soils are relatively young and are subject to great erosion by water and winds because of the steep gradients of the land.

In the Fuegian and southern Patagonian Andes, the formation of soils is difficult; the actions of glaciers and of strong winds have left nearly bare rock in many places. Peat bogs, podzols, and meadow soils, all with thick horizons (layers) of humus, are found; drainage is poor. Volcanic soils that are rich in organic material and are well drained occur in the region of lakes. North of latitude 45° S, soils are formed directly on weathered rocks at higher elevations, and reddish brown soils with gravel and quartz are found in the lower zones; erosion is heavy.

North of 37° S the Atacama Desert is covered with heavily eroded desertic soils that are low in moisture and organic material and high in mineral salts. This soil type, with few differences, extends along the Cordillera Occidental to north of Peru.

From Bolivia to Colombia the soils of the plateau and the east side of the eastern cordilleras show characteristics closely related to altitude. In the Andean *páramo* embryonic soils black with organic material are found. At altitudes between 6,000 and 12,000 feet, red, brown, and chernozem soils occur on moderate slopes and on basin floors. In more poorly drained locations, soils with a permeable sandy horizon are relatively fertile; these soils are the most economically important in Bolivia, Peru, and Ecuador. The *sabana* soils of Colombia are gray-brown, with an impermeable claypan in certain levels.

At high elevations soils are thin and stony. On the east side of the eastern cordilleras, descending to the Amazon basin, thin, poorly developed humid soils are subject to considerable erosion. Intrazonal soils (those with weakly developed horizons) include humic clay and solonetz (dark

Intrazonal soils

alkaline soils) types found close to lakes and lagoons. Also included in this group are soils formed from volcanic ash in the Cordillera Occidental from Chile to Ecuador.

The azonal soils—alluvials (soils incompletely evolved and stratified without definite profile) and lithosols (shallow soils consisting of imperfectly weathered rock fragments)—occupy the major part of the Andean massif. In Colombia, sandy yellow-brown azonal soils on slopes and in gorges are the base of the large coffee plantations.

Climate. In general, temperature increases northward from Tierra del Fuego to the Equator, but such factors as altitude, proximity to the sea, the cold Peru (Humboldt) Current, rainfall, and topographic barriers to the wind contribute to a wide variety of climatic conditions. The hottest rain forests and deserts often are separated from tundralike puna by a few miles. There also is considerable climatic disparity between the external slopes (*i.e.*, those facing the Pacific or the Amazon basin) and the internal slopes of the cordilleras; the external slopes are under the influence of either the ocean or the Amazon basin. As mentioned above, the line of permanent snow varies greatly. It increases from 2,600 feet at the Strait of Magellan, to 20,000 feet at latitude 27° S, after which it begins descending again until it reaches 15,000 feet in the Colombian Andes.

Precipitation varies widely. South of latitude 38° S, annual precipitation exceeds 20 inches, whereas to the north it diminishes considerably and becomes markedly seasonal. Farther north—on the Altiplano of Bolivia, the Peruvian plateau, and in the valleys of Ecuador and the *sabanas* of Colombia—rainfall is moderate, though amounts are highly variable. It rains only in small amounts on the west side of the Peruvian Cordillera Occidental and somewhat more in Ecuador and Colombia. On the east (Amazonian) side of the Cordilleras Orientales, rainfall usually is seasonal and heavy.

Temperature varies greatly with altitude. In the Peruvian and Ecuadorian Andes, for example, the climate is tropical up to an altitude of 4,900 feet, becoming subtropical up to 8,200 feet; hot temperatures prevail during the day, and nights are mildly warm. Between 8,200 and 11,500 feet daytime temperatures are mild, but there are marked differences between night and day; this zone constitutes the most hospitable area of the Andes. From 11,500 to 14,800 feet it generally is cold—with great differences between day and night and between sunshine and shadow—and temperatures are below freezing at night. Between about 13,500 and 15,700 feet (the puna), the climate of the *páramo* is found, with constant subfreezing temperatures. Finally, above 15,700 feet, the climate of the peaks and high ridges is polar with extremely low temperatures and icy winds.

As in other mountainous areas of the world, a wide variety of microclimates (highly localized climatic conditions) exist because of the interplay of aspect, exposure to winds, latitude, length of day, and other factors. Peru, in particular, has one of the world's most complex arrays of habitats because of its numerous microclimates.

Dependence of life on altitude

Plant and animal life. The ability of plants and animals to live in the Andes depends largely on altitude, although the existence of plant communities also is determined by climate, availability of moisture, and soil and that of animal life by the abundance of food sources; the permanent snow line is the upper limit of habitation. Some plants and animals can live at any altitude, and others can live only at certain levels. Cats rarely live above 13,000 feet, whereas white-tailed mice usually do not stay lower than 13,000 feet and can live up to 17,000 feet. The camelids (llama, guanaco, alpaca, and vicuña) are animals primarily of the Altiplano (11,200 to 12,800 feet), although they can live well at lower altitudes. It is thought that the condor can fly up to 26,000 feet.

Probably the low barometric pressures of high altitudes are less important for vegetation, but altitude imposes a number of climatic variables—such as temperature, wind, radiation, and dryness—that determine what kinds of plants grow in different parts of the Andes. In general, the Andes can be divided into altitudinal bands, each with typical predominant vegetation and fauna; but latitude imposes differences between south and north, and proximity to the Pacific and to the Amazon basin is reflected in differences between the external and internal slopes of the Cordilleras Occidental and Oriental.

A zone at about latitude 35° S separates two different regions of the Andes. To the south, in the Patagonian Andes, the flora is austral (of southern aspect) instead of Andean. Magnificent mid-latitude rain forests of the conifer genus *Araucaria* and of oak, coigue (an evergreen used for thatching), chusquea, cypress, and larch occur.

Characteristics to the north are different. The Cordillera Occidental is extremely dry in the south, slightly humid (with moisture and scarce rainfall) in central and northern Peru, and humid with heavy or moderate rainfall in Ecuador and Colombia. Vegetation follows the climatic scheme: in the south it is poor and desertlike, though at higher altitudes steppe vegetation occurs. Animals include the guemul, puma, vizcacha, cuy (guinea pig), chinchilla, camelids, mice, and lizards; among the birds are the condor, partridge, parina, huallata, and coot. Agricultural potential is poor. The east side of the Cordilleras Orientales northward from Bolivia has lush vegetation, most of it tropical forest with a rich jungle fauna.

On the plateau (valleys, plains, ranges, and internal slopes of the cordilleras), life again is closely related to altitude. Tropical palms and eternal snows lie within a few miles of each other, where altitude may vary from 1,600 feet in deep gorges to more than 20,000 feet in peaks and ridges. Up to an elevation of 8,000 feet, vegetation reflects the dry tropical and subtropical climate, and agriculture is important: the great coffee industry of Colombia is located mainly in the warm valleys of this zone. Between 8,200 and 11,500 feet lies the most populated zone of the Andes; some of the major cities of the Andean countries are there, and the zone supports the main part of Andean agriculture. Temperatures vary from warm in the valleys to moderate low (down to 50° F [10° C]) on the plains, *sabanas,* and slopes, and there is seasonal rainfall and water from rivers. This zone also is suitable for livestock and poultry farming.

The *páramo*

Between 11,500 and 13,400 feet relief is usually rough and difficult for agriculture. In Colombia this zone is *páramo* and sub-*páramo,* with seasonal rainfall; in Ecuador rain is abundant; and in Peru and Bolivia the *páramo* has from moderate to scarce rainfall. From 13,400 to 15,700 feet (the puna), vegetation consists of plants that resist the cold temperature and nighttime freezing; above 16,000 feet, vegetation is almost absent.

The people. Human presence in the Andes is relatively recent; the oldest human remains to be found are only 10,000 to 12,000 years old, although habitation probably dates to much earlier times. The shortage of oxygen at high altitude, especially above 12,000 feet, is so physiologically demanding that it imposes deep adaptative changes even within the cells of the body. The highest altitude in the Andes at which people have resided permanently is 17,100 feet (shepherds in southern Peru) and, as temporary workers, 18,500 to 19,000 feet (Carrasco Mine, in the Atacama Desert, Chile).

From Patagonia to the southern limits of the Bolivian Altiplano, the Andes are sparsely populated; a few small groups of shepherds and farmers live on the lower slopes and vegas of the cordillera. Farther to the north, from Bolivia to Colombia, the largest population concentrations and most of the important cities of these countries are found in the Andes. In Peru and Bolivia, a significant proportion of the inhabitants live above 10,000 feet.

Roughly half the population of Bolivia are Aymara- and Quechua-speaking Indians; most of the remainder are Spanish-speaking mestizos (or mixed). In the Lake Titicaca district live remnants of the ancient Uru people. Population is distributed mainly between the high *páramos,* where, except for a seminomad population of shepherds, the principal occupation is mining, and the lower narrow valleys, where the people practice agriculture. In Peru, mining is the most important human activity above 11,500 feet, but the great majority of the Andean population is engaged in agriculture and raising sheep, goats, llamas, and alpacas; a growing proportion of people have become

Farmland in the Peruvian Andes near Cuzco, with the Cordillera de Vilcambamba in the background.

employed in industry and commerce. A group of Aymara-speaking Indians live in the south around Lake Titicaca, but the largest native population is Quechua-speaking; Quechua speakers constitute the great majority of the highland population.

The inhabitants of the Ecuadorian Andes are mainly Quechua speakers and mestizos; in the south there are small groups of Cañaris and, in the north, Salasacas. Agriculture is the main occupation; some Indian peoples engage in ceramics and weaving.

In Colombia the largest proportion of the population lives between 5,000 and 10,500 feet. Only a tiny fraction of the country's population is Indian, these groups living on the Altiplano of the Cordillera Oriental and in the Cordillera Central and the southern mountains. The zone of coffee plantations at about 3,000 to 6,500 feet is the most densely populated area.

The economy. *Agriculture and livestock.* Agriculture on the Andes is difficult, and crop yields are relatively poor. The water supply is inadequate, and a large part of the plateau region is dry or receives little and irregular seasonal rainfall. Temperatures of the high plains are too cold, and crops are subject to freezing. The terrain is rough, and soils are not well developed; and, where fertile valleys do occur, they are narrow and small.

Thus, a considerable amount of Andean agricultural production is for local consumption. Some products, however, have been grown in sufficient quantity to be exported, including coffee (especially from Colombia), tobacco, and cotton; in addition, large quantities of coca (the source of cocaine) have been exported from Colombia and Bolivia, despite efforts to curb production. The possibilities of increasing the amount of arable land area by irrigation are extremely limited.

Export crops

The natural pastures of the plateau regions are extensively used for cattle raising. Colombia exports cattle, and Peru has a large milk-canning and livestock industry. Sheep, goat, llama, and alpaca raising are widespread in Peru and Bolivia, with both countries exporting sheep and alpaca wool.

Mining. The mining industry of the Andes is one of the most important of the world. Mining is especially extensive in the south. The principal minerals are copper in Chile and Peru; tin in Bolivia; silver, lead, and zinc in Bolivia and Peru; gold in Peru, Ecuador, and Colombia; platinum and emeralds in Colombia; bismuth in Bolivia; vanadium in Peru; and coal and iron in Chile, Peru, and Colombia. Extensive deposits of petroleum are distributed along the entire eastern side of the Andes.

Transportation. The Andes always have been a formidable barrier for communication, with great effect on the economic and cultural development of the region. Production centres generally are far from seaports, and the mountainous character of the land makes the construction and maintenance of railways and roads difficult and expensive. A large network of pack trails are still in use between small communities and between farms and markets. Horses, donkeys, and mules are widely used; in Colombia the ox and in Peru and Bolivia the llama also are transport animals.

Most of the railways have been built to transport mining products, and the internal systems otherwise are little developed. There are two international railways between Chile and Argentina: the first connects Valparaíso and Buenos Aires, and the second, Antofagasta and Salta. La Paz, Bolivia, is connected with Buenos Aires, Antofagasta and Arica (Chile), and (via Lake Titicaca) Arequipa and Matarani (Peru). Peru has two important internal railways, one from Puno to Cuzco and the other from Lima to Cerro de Pasco and Huancavelica; the latter line is the highest in the world, crossing Ticlio Pass at an altitude of some 15,800 feet. The main rail line in Ecuador runs from Quito to Guayaquil, and in Colombia the main line connects Bogotá to the Caribbean coast.

Roads are more suitable for Andean agricultural regions, because the small and widely separated valleys make railway construction and operation too expensive. Since World War II, all countries along the Andean cordilleras have expanded their road networks both within and through the mountains, although only a small portion of these roads are paved. The Pan-American Highway winds through the mountains of Colombia and Ecuador, connecting the major cities; various routes in Peru, Bolivia, Argentina, and Chile also are included in the system.

Air transport has become particularly important in the Andes, where it has reduced the difficulties of overland communication. Air routes are especially well developed in Colombia and Peru.

Study and exploration. As mentioned above, the Andes have been populated for millennia. By the time of the Spanish conquest in the 1530s, the indigenous highland peoples had developed a thorough knowledge of the Andes and had built in them an extensive network of cities and connecting roads. Early Spanish exploration of the mountains consisted of plundering raids, although in the process most of the major modern Andean cities were founded.

The first systematic European study of the mountains came in the form of a series of surveys called the

Relaciones geográficas (1579–85), which in increasingly elaborate questionnaires recorded much geographic and economic information about Spain's overseas colonies. In 1735 an expedition led by the French naturalist Charles-Marie de La Condamine began to measure the arc of the meridian at the Equator in the Andes, and for several years this group surveyed the Ecuadorian ranges. An even more important series of investigations was conducted by the German naturalist and explorer Alexander von Humboldt, who arrived on the Venezuelan coast in 1799 and for five years made innumerable observations of Andean geology, climatology, and biology (particularly of altitude-based ecological zones).

Explorations of Humboldt

By the mid-19th century the now-independent Andean countries were conducting and sponsoring scientific exploration of the mountains. Among those active at that time were the British mountaineer Edward Whymper in Ecuador, the Peruvian Mariano Paz Soldan in Peru, and the Italian geographer Agostino Codazzi, who produced detailed maps of Colombia and Venezuela. Since the late 19th century much Andean research has been directed toward economic development, primarily mining operations and railway construction. (M.T.V./N.R.S.)

GRAN CHACO

The Gran Chaco is an immense lowland alluvial plain in interior south-central South America. The name is of Quechua origin, meaning "Hunting Land." Largely uninhabited, the Chaco is an arid subtropical region of low forests and savannas traversed by only two permanent rivers and practically unmarked by roads or rail lines. It is bounded on the west by the Andes mountain ranges and on the east by the Paraguay and Paraná rivers. The Chaco's northern and southern boundaries are not as precise: it generally is said to reach northward to the Izozog Swamps in eastern Bolivia and southward to about latitude 30° S, or roughly the Salado River in Argentina. Thus defined, the Gran Chaco extends some 450 miles (725 kilometres) from east to west and about 700 miles from north to south and covers about 280,000 square miles (725,000 square kilometres); of this total, slightly more than half lies within Argentina, a third in Paraguay, and the remainder in Bolivia. The two permanent rivers, the Pilcomayo and the Bermejo (Teuco) flow southeastward across the Chaco from their Andean headwaters to the Paraguay River and demarcate the three main regional divisions of the Chaco in Paraguay and Argentina: the Chaco Boreal north of the Pilcomayo, the Chaco Central between the two rivers, and the Chaco Austral south of the Bermejo; the portion of the Chaco in Bolivia commonly is called the Bolivian Chaco.

For map coverage of the Gran Chaco, see below *Río de la Plata system.*

Physical features. *Physiography.* The Gran Chaco is a vast geosynclinal basin formed by subsidence (or downwarping) of the area between the Andean cordilleras on the west and the Brazilian Highlands on the east as it filled with alluvial debris from these two features. Because of its alluvial character, the Gran Chaco is nearly stone-free and is composed of unconsolidated sandy and silty sediments that are up to 10,000 feet (3,050 metres) deep in some places. The only rock outcrops of consequence are a few isolated remnants in Paraguay along the Paraguay River and some sandstone mesas in northern Paraguay and southern Bolivia.

Drainage. All but the extreme northwestern sector of the Gran Chaco is drained by west-bank tributaries of the Paraguay and Paraná rivers. The Bermejo and the Pilcomayo, even though they manage to traverse the Chaco, remain typical of most Chaco streams. Their courses are marked by countless sloughs, oxbow lakes, braided channels, sandbars, and vast swamplands; and they sustain such high losses from flooding, seepage, and evaporation that only a meagre portion of their full flow ever reaches the parent stream. Most of the Chaco is so poorly drained that the shallow, irregular channels on the exceptionally level plain lead to rapid and extensive flooding during the rainy southern summers (October to March). At the peak of these floods, as much as 42,000 square miles, or about one-seventh, of the area of the Chaco may be inundated, although some of this is caused as much by improper drainage of the impermeable subsoils as by overflow of the streams. Saline water is common in both deep and shallow wells, and the location and maintenance of freshwater supplies generally is a matter of chance. The problem appears to be greatest in the Chaco Boreal, although it has been suggested that the situation is more like that of the remainder of the Chaco or like the Argentine Pampa, where groundwater problems are not now considered to be as severe as early settlers and explorers had postulated.

Summer flooding

Soils. Chaco soils range from sandy to heavy clay. Soils in the more humid east have more organic material and lateritic subsoils, whereas in the west the soils contain less surface organic material and have predominately calcareous subsoils. The local determining factor is drainage, whether a function of soil texture or of relative relief. Sometimes differences in elevation of less than three feet result in different soil types. Grasslands, or savannas, generally tend to be associated with sandier soils, bushlands with poorly drained clay soils, and the forestland with better-drained clay soils. In many cases, the high concentration of dissolved salts in the groundwater creates conditions in swampy sites that are intolerable to most plants, thus extending an arid appearance even into many areas where water is abundant.

Climate. With its considerable north-south extent, the Gran Chaco is subject to climates that vary from tropical in the north to warm-temperate in the south. Most of the region, however, is subtropical. Average temperatures vary from 60° to 85° F (16° to 29° C), with an average relative humidity between 50 and 75 percent. Great temperature contrasts exist, and the highest recorded temperatures for the continent occur in the Chaco. Average maximums are near 80° F (27° C), and absolute maximums may reach 116° F (47° C). The average minimum is about 57° F (14° C), although freezing winter temperatures can occur throughout the region.

The highest average annual rainfall—52 inches (1,320 millimetres)—is in the east, and precipitation gradually decreases to about 20 inches in the far west. Although the rainfall normally would be adequate for agriculture, roughly a third to half of the total comes in the hot summer. Evaporation losses sharply reduce the effective precipitation and give the Chaco an arid nature that is absent only in the permanent swamps and forests along the Paraguay River.

Although light breezes are common, outbreaks of cool polar air from the south, called pamperos in Argentina, bring thunderstorms and strong gusty winds that occasionally exceed 60 miles per hour. These air masses move northward into the Amazon basin (where they are called

Chip and Rosa Maria Peterson

Palm savanna in the Chaco Central, near Formosa, in Argentina.

friagems). The windiest season, however, is spring, during the transition from warm to hot weather. Dust storms may occur in the dry season.

Plant life. The vegetation of the Gran Chaco is intimately associated with the pattern of soils and reflects the same general east-west division. The eastern Chaco is noted for its parklike landscape of clustered trees and shrubs interspersed with tall, herbaceous savannas. To the west, a wide transition zone grades into the *espinal,* a dry forest of spiny, thorny shrubs and low trees. Chaco vegetation is adapted to grow under arid conditions and is highly varied and exceedingly complex. The climax vegetation is called *quebrachales,* and consists of vast, low hardwood forests where various species of quebracho tree are dominant and economically important as sources of tannin and lumber. These forests cover extensive areas away from the rivers; nearer the rivers they occupy the higher, better-drained sites, giving rise to a landscape in which the forests appear to be islands amid a sea of savanna grasses growing as high as a person on horseback. In the more arid western Chaco, thorn forests, the continuity of which is occasionally broken by palm groves, saline steppes, and savannas induced by fire or deforestation, are dominated by another quebracho tree that has a lower tannin content and is used most often for lumber. There is also a marked increase in the number and density of thorny species, among which the notorious vinal (*Prosopis ruscifolia*) was declared a national plague in Argentina because its thorns, up to a foot in length, created a livestock hazard in the agricultural lands it was invading.

Sources of tannin and lumber

Animal life. True to its name, the Gran Chaco has an abundance of wildlife. Among the larger animals are the jaguar, ocelot, puma, tapir, giant armadillo, spiny anteater, many foxes, numerous small wildcats, the agouti (a large rodent), the capybara (water hog), the maned wolf, the palustrian deer, the peccary, and the guanaco (a camelid related to the llama). The Chaco is one of the last major refuges for the rhea (or nandu), a large, flightless South American bird, and it has long been noted for its abundant and varied bird population. The streams are host to more than 400 fish species, among which are the salmonlike dorado and the flesh-eating piranha. Countless travelers' tales complain of the pestilent insects. Reptiles also are abundant, with numerous lizards and at least 60 known species of snakes, including many pit vipers and constrictors, while at least six species of poisonous tree toads have been identified.

The people and economy. *Early settlement.* The indigenous peoples of the Chaco were numerous. Because of their subsistence as hunters, gatherers, and fishermen, tribal units were not much larger than extended families. Nevertheless, from among the diverse dialects, anthropologists have described a few major linguistic associations: the Guaycurú, Lengua, Mataco, Zamuco, and Tupí-Guaraní. Most of these people lived under extremely primitive conditions; settlement depended on the availability of fresh water, making stream courses the most coveted sites. Implements were fashioned largely from wood and bones because of the absence of stones, while the spiny leaves of the pineapple-like groundcover *carraguatas* served as a universal source of fibre. The Chaco forest, despite its harshness, contained more plant sources of human sustenance—*e.g.,* edible pods, fruits, berries, and tubers—than surrounding areas, and this factor was well exploited by the native peoples. Game was gathered by trapping, netting, clubbing, and spearing, often in conjunction with large group drives. For those Indian groups still living outside the limits of European settlement, conditions are only slightly modified today, although these people now have domesticated animals and metal tools. Most tribes, however, exist as sort of a peasant pioneer fringe and practice some form of shifting subsistence agriculture.

European colonization and economic activity. Aside from the scattered (although successful) agricultural communes (*reducciones*) of the Jesuits and the settlement of Asunción, Paraguay, on its eastern fringe, the Chaco defied effective European occupancy until well into the 19th century. Hostile Indian groups, in concert with the forbidding nature of the Chaco itself, limited European influence in the colonial period to a situation much like a state of siege.

The limited early colonization in the Argentine and Bolivian Chaco was based on exploitation of the longhorn criollo (or Creole) cattle that roamed half wild throughout the region. The western Chaco Austral, near Salta, also was exploited as a source of heavy timbers for the mines in the highlands of Bolivia and Peru. In the late 19th century, the Chaco in Argentina and southern Paraguay became a land of great ranches (*estancias*) raising criollo cattle, and numerous, small, independent camps (*obrajes*) of woodcutters exploited the abundant hardwoods of the Chaco forests for lumber and firewood. Cattle grazing has continued to be the most extensive use of the land, with few substantial changes from pioneer days. One of the key problems in improving the cattle industry has been the apparent endemic nature of many serious cattle diseases and pests against which criollo cattle have developed some immunity, whereas purebred cattle have remained fully susceptible.

Cattle raising and logging

In the eastern Chaco, vast, highly capitalized industrial ventures established large plants to process the great quantities of tannin found in the various quebracho species. Unlike the *obrajes* of the woodcutters, these operations were large, centralized mills adjacent to rivers or rail lines, from which the selective cutting of quebracho has proceeded at a systematic pace. The slow growth habits of the quebracho trees, however, pose a threat to the tannin industry, as the pace of the harvest easily can exceed reforestation efforts. The relatively untouched Bolivian Chaco contains stands of quebracho timber, but most of these are in remote areas and have not been exploited while production has continued in the more accessible areas. Quebracho tannin has remained one of the economic mainstays of the Chaco, but it has faced competition from other sources of tannin, both natural and synthetic. Other forest products include lumber and heavy timbers from a variety of other species, firewood, and palo santo oil from the wood of *Bulnesia sarmientii,* a tree found in the more arid portions of the Chaco.

Modern developments. Cotton has become another principal crop of the Chaco. Wild cotton has been known in much of the region since pre-Columbian times, but it never was grown as anything more than an agricultural curiosity until the 20th century. During World War I, with cotton prices at a peak, large areas in Argentina's Chaco province were converted to cotton cultivation. Production was enhanced considerably by the use of irrigation and the development of drought-resistant stocks. The crop area subsequently has been expanded in Argentina, and cotton has become important in Paraguay; it also is grown in lesser quantities in Bolivia. These increases have occurred despite bad markets, insect plagues, and often poor weather in many years and more recent problems with soil erosion. Both fibre and cottonseed oil are produced, mainly for domestic consumption. Other crops include linseed, sunflowers, sorghum, and corn (maize).

The discovery of oil in the Bolivian piedmont in the 1920s led within a decade to the disastrous Chaco War between Bolivia and Paraguay, each country hoping to find more oil in the neighbouring Chaco Boreal. Paraguayan claims eventually were honoured, but they did not include any part of the oil-rich piedmont; subsequent explorations in Paraguay have been disappointing. Oil has been discovered across the border in Argentina, however, and large quantities of natural gas have been recovered on the northern fringe of the Bolivian Chaco near Santa Cruz.

Since World War II, efforts have been made by the respective governments to spur settlement of the Chaco. Argentine interest has been concentrated along the railways out of Resistencia and Formosa, with pioneer settlements composed mainly of eastern European immigrants and based on cotton production. In the central Paraguayan Chaco, which has been accessible by road only since 1965, Mennonite immigrants from Canada had settled in the 1920s and were joined by coreligionists from the Soviet Union in the 1930s. These settlers established self-sufficient colonies and were joined by another large contingent of refugees from the Soviet Union after World War II.

The Mennonite colonies

The Southern and Central Andes and Patagonia.

The primary land use in the Bolivian Chaco is still open cattle range. The nearby supplies of oil and natural gas and the hydroelectric and water storage capacity of such fast-flowing piedmont streams as the Pilcomayo, however, offer great development potential.

(G.E.Ma./M.D.H.M./K.E.W.)

PATAGONIA

The region of Patagonia covers nearly all of the southern portion of mainland Argentina. With an area of about 260,000 square miles (673,000 square kilometres), it constitutes a vast area of steppe and desert that extends from latitude 37° to 51° S. It is bounded, approximately, by the Patagonian Andes to the west, the Colorado River to the north (except where the region extends north of the river into the Andean borderlands), the Atlantic Ocean to the east, and the Strait of Magellan to the south; the region south of the strait—Tierra del Fuego, which is divided between Argentina and Chile—also is often included in Patagonia.

The name Patagonia is said to be derived from Patagones, as the Tehuelche Indians, the region's original inhabitants, were called by 16th-century Spanish explorers. According to one account, Ferdinand Magellan, the Portuguese navigator who led the first European expedition into the area, coined that name because the appearance of the Tehuelche reminded him of Patagon, a dog-headed monster in the 16th-century Spanish romance *Amadís of Gaul.*

Physical features. *Physiography.* Desert and semidesert cover the Patagonian tableland that extends from the Andes to the Atlantic Ocean. The general aspect of this tableland is one of vast steppelike (*i.e.,* virtually treeless) plains, rising in terrace fashion from high coastal cliffs to the foot of the Andes; but the true aspect of the plains is by no means as simple as such a general description would imply. The land along the Negro River rises in a series of fairly level terraces from about 300 feet (90 metres) at the coast to about 1,300 feet at the junction of the Limay and Neuquén rivers and 3,000 feet at the base of the Andes. The tableland region rises to an altitude of 5,000 feet.

South of the Negro River, the plains are much more irregular. Volcanic eruptions occurred in this area until fairly recent times, and basaltic sheets covered the tableland east of Lakes Buenos Aires and Pueyrredón. Near the Chico and Santa Cruz rivers, the plains have spread to within about 50 miles (80 kilometres) of the coast and reach almost to the coast south of the Coig and Gallegos rivers. In places, basaltic massifs (mountain masses) are the salient features of the landscape.

The coast

The coast consists largely of high cliffs separated from the sea by a narrow coastal plain. Thus, the plateaus are formed of horizontal strata, some of sedimentary rocks and others of lava flows. Areas of hilly land, composed of resistant crystalline rocks, stand above the plateaus.

Drainage and soils. The deep, wide valleys bordered by high cliffs that cut the tablelands from west to east are all beds of former rivers that flowed from the Andes to the Atlantic; only a few now carry permanent streams of Andean origin (the Colorado, Negro, Chubut, Senguerr, Chico, and Santa Cruz rivers). Most of the valleys either have intermittent streams—such as the Shehuen, Coig, and Gallegos rivers, which have their sources east of the Andes—or contain streams like the Deseado River, which completely dry up along all or part of their courses and are so altered by the combined effect of wind and sand as to afford little surface evidence of the rivers that once flowed in them. Still other streams, such as the Perdido, terminate in basins containing salt flats or salt ponds. The canyon bottoms consist mostly of deep beds of coarse alluvial sands and gravels, which act as groundwater reservoirs to supplement the scanty surface water.

The line of contact between the Patagonian tableland and the Patagonian Andes is marked by a chain of lakes found in glacier troughs or cirques that are dammed downslope by moraines and other glacial landforms consisting of unconsolidated and unsorted till. From Lake Nahuel Huapí northward, the lakes—except for Lake Lácar—drain to the Atlantic. South of Lake Nahuel Huapí, however, all the lakes except Viedma and Argentino drain to the Pacific through deep canyons that have been cut from west to east across the cordillera by headward erosion.

The best soils in Patagonia are found north of the Negro River, especially where they are formed from volcanic rock. Proceeding south, the soils become increasingly arid and stony, and broad expanses of stream-rounded pebbles, called *grava patagónica,* often are found on level ground.

Climate. Patagonia is influenced by the South Pacific westerly air current, which brings humid winds from the ocean to the continent. These winds, however, lose their humidity (through cooling and condensation) as they blow over the west coast of South America and over the Andes, and they are dry when they reach Patagonia. Patagonia can be divided into two main climatic zones—northern and southern—by a line drawn from the Andes at about latitude 39° S to a point just south of the Valdés Peninsula, at about 43° S.

The two climatic zones

The northern zone is semiarid, with annual mean temperatures between about 54° and 68° F (12° and 20° C); recorded maximum temperatures vary from about 106° to 113° F (41° to 45° C), and minimum temperatures from 12° to 23° F (−11° to −5° C). Sunshine, minimal along the coast, is most plentiful inland to the northwest. Annual rainfall amounts vary from about 3.5 to 17 inches (90 to 430 millimetres). The prevailing winds, from the southwest, are dry, cold, and strong.

The climate of the southern zone is sharply distinct from the humid conditions of the Andean cordillera to the west. In the northern part of the zone, Atlantic influences are practically nonexistent—probably because of the relatively high elevations of the coastal region, which reach 900 to 1,800 feet around San Jorge Gulf—although cold Pacific winds from the west and the cold Falkland Current off the Atlantic coast do have some effect. In the southern part, which becomes increasingly peninsular with higher latitude, the Atlantic exerts some influence. The zone has a cold, dry climate, with temperatures that are higher along the coast than they are inland and with strong west winds. Mean annual temperatures range from 40° to 55° F (4° to 13° C), with the maximum temperature reaching about 93° F (34° C) and minimum temperatures between 16° and −27° F (−9° and −33° C). Heavy snows fall in winter, and frosts can occur throughout the year; spring and autumn provide only short transitions between summer and winter. Average annual precipitation (rain and snow) ranges between about 5 and 8 inches, though as much as 19 inches has been recorded. Less precipitation falls in the arid central areas, which also receive more sunshine than the coast or the Andean cordillera.

Plant life. The long, narrow strip of Patagonia's western border supports vegetation like that found in the adjacent cordillera, primarily deciduous and coniferous forests. The vast tableland region is divided into northern and southern zones, each of which has its own characteristic vegetation.

The larger northern steppe zone extends south to about latitude 46° S. In the north is found *monte* vegetation—xerophytic (drought-tolerant) scrub forests—which gives way farther south to open bushland of widely spaced thickets between about 3 and 7 feet high. Grasses flourish in the sandy areas, while halophytic (salt-tolerant) grasses and shrubs predominate in the salt flats. The southern, more arid, zone extends south of 46° S. The vegetation is low and considerably more sparse and needs almost no water.

Animal life. Among the Patagonian birds are herons and other waders; predators such as the shielded eagle, the sparrow hawk, and the chimango (or beetle eater); and the almost extinct rhea (nandu). The typical marsupial of the region is the *comadreja* (a member of the weasel family). Species of bats include a long-eared variety. Armadillos, pichis (small armadillos), foxes, ferrets, skunks, mountain cats, and pumas are to be found, as are the Patagonian cavy (or mara) and different kinds of burrowing rodents, such as the vizcacha and the tuco-tuco. Of the larger mammals, the most noteworthy is the guanaco, a kind of llama, which has been hunted almost to extinction.

Patagonia has a number of species of poisonous snakes, as well as tortoises and a variety of lizards. Among the arthropods and arachnids are vinchucas (winged bugs), bloodsucker insects (transmitters of American trypanoso-

Herd of guanacos in eastern Patagonia, Valdés Peninsula, Argentina.

miasis, or Chagas' disease), scorpions, and several kinds of spiders, including one endemic genus called *Mecysmanchenius*. The rivers and lakes are naturally poor in fish, but some have been stocked with salmon and trout. Marine fish, however, as well as crustaceans and mollusks are plentiful off the coast.

Oil and natural gas

The economy. *Resource exploitation.* The oil fields around Comodoro Rivadavia and near Neuquén contain most of Argentina's reserves, and natural gas also has been found in these two areas; these are Patagonia's most valuable mineral assets. In addition, deposits of iron ore are worked at Sierra Grande, and some coal is mined in the south near Río Turbino. Other mineral deposits include manganese, tungsten (wolframite), fluorite (calcium fluoride), lead, heavy spar (barite, the principal ore of barium), copper and gold, vanadium, zinc-lead ore, and uranium. There also are deposits of kaolin and gypsum.

Dams have been constructed on the Neuquén and Limay rivers in order to exploit the hydroelectric potential of the western portion of Patagonia. The projects also have created large reservoirs that have made extensive irrigated agriculture possible in the Negro River region. Among the major crops grown are peaches, plums, almonds, apples, pears, olives, grapes, hops, dates, vegetables, aromatic plants, and alfalfa.

Tourism has become important since the end of World War II, as wildlife reserves and the national parks located along the Patagonian Andes have brought in growing numbers of those seeking recreation. There also has been an increase in scientific study (*e.g.*, glacier research) and in detailed mapping and surveying for mineral exploitation.

Transportation. Comodoro Rivadavia is connected to Buenos Aires by a road that runs more than 1,860 miles through the Patagonian coastal region. The roads farther inland, however, are few and of poor quality. Several railroads traverse the region from east to west; two that reach the foothills of the Andes are connected to Buenos Aires. Air services are focused chiefly on the towns of the coastal region. The chief ports are Rawson, Deseado, and Río Gallegos; San Antonio Oeste and Puerto Madryn, both on protected bays and developed for international traffic; and Comodoro Rivadavia, an outlet for petroleum products.

History. The original inhabitants of Patagonia consisted mostly of Tehuelche Indians, who are thought to have come from Tierra del Fuego. The most ancient artifacts, such as harpoons, found in the caves along the Strait of Magellan suggest that these people were moving up the mainland coast about 5,100 years ago. The robust and tall Tehuelche were divided into northern and southern groups, each with its own dialect. Spanish explorers found the Tehuelche living as nomadic hunters of guanaco and rhea. The surviving descendants of these people are few in number, nearly all of them having been assimilated into Spanish culture.

Early European settlement

Toward the end of the 16th century, the Spaniards attempted to colonize the Patagonian coastal region to clear it of English pirates, but a Jesuit settlement on San Matías Gulf came to nothing. In 1778 the English tried to settle on the same bay, and the Spaniards reacted by founding Patagonia's first two towns, San José and Viedma (originally named Nuestra Señora del Carmen). A Spanish settlement at Puerto Deseado lasted from 1780 to 1807, but three years later this region again was devoid of European settlement.

After Argentina became independent, Patagonia largely was left alone, until it was cleared of Indian occupation in the Conquest of the Desert campaigns of the 1870s. An attempt was then made to settle the region and to make it part of the national state. Immigration, however, was not massive, though people came for various reasons: some to exploit the economic resources and others (*e.g.*, the Welsh) to enjoy religious or political liberties. The mineral wealth of the region in particular attracted immigrants from Chile, and Chileans seeking temporary work rather than a fixed domicile now constitute the largest proportion of the population. Apart from major concentrations at Comodoro Rivadavia and in the towns strung out along the upper valley of the Negro River, Patagonia's sparse population is mostly rural. (E.F.G.D./K.E.W.)

Drainage systems

AMAZON RIVER BASIN

The Amazon (Portuguese and Spanish: Amazonas) is the greatest river of South America and the largest drainage system in the world in terms of the volume of the river's flow and the area of its basin. The total length of this great river—measured from the headwaters of the Ucayali-Apurímac river system in Peru—is about 4,000 miles (6,400 kilometres), which is slightly shorter than the Nile River but still the equivalent of the distance from New York City to Rome. Its westernmost source is high in the Andes Mountains, within 100 miles of the Pacific Ocean, and its mouth is in the Atlantic Ocean.

Extent of the basin

The vast Amazon basin (Amazonia), the largest lowland in Latin America, has an area of about 2.3 million square miles (6 million square kilometres) and is nearly twice as large as that of the Congo River, the Earth's other great equatorial drainage system. Stretching some 1,725 miles from north to south at its widest point, the basin includes the greater part of Brazil and Peru, significant parts of Colombia, Ecuador, and Bolivia, and a small area of Venezuela; roughly two-thirds of the Amazon's main stream and by far the largest portion of its basin are within Brazil. The Tocantins-Araguaia catchment area in Pará state covers another 300,000 square miles. Although considered a part of Amazonia by the Brazilian government and in popular usage, it is technically a separate system. It is estimated that about one-fifth of all the water that runs off the Earth's surface is carried by the Amazon. The flood-stage discharge at the river's mouth is about 6,180,000 cubic feet (175,000 cubic metres) per second, which is four times that of the Congo and more than 10 times the amount carried by the Mississippi River. This immense volume of fresh water dilutes the ocean's saltiness for more than 100 miles from shore.

The Central and Northern Andes and the Amazon River basin and its drainage network.

The extensive lowland areas bordering the main river and its tributaries, called *várzeas*, are subject to annual flooding, with consequent soil enrichment; however, most of the vast basin consists of upland, well above the inundations and known as *terra firme*. More than two-thirds of the basin is covered by an immense rain forest, which grades into dry forest and savanna on the higher northern and southern margins and into montane forest in the Andes to the west. The Amazon Rain Forest, which represents about half of the Earth's remaining rain forest, also constitutes its largest reserve of biological resources.

The first European to explore the Amazon, in 1541, was the Spanish soldier Francisco de Orellana, who is said to have given the river its name after reporting pitched battles with tribes of female warriors, whom he likened to the Amazons of Greek mythology. Although the name Amazon is conventionally employed for the entire river, in Peruvian and Brazilian nomenclature it properly is applied only to sections of it. In Peru the upper main stream (fed by numerous tributaries flowing from sources in the Andes) down to Iquitos (Peru) is called Marañón (Portuguese: Maranhão), and from there to the Atlantic it is called Amazonas. In Brazil the name Solimões is used from Iquitos to the mouth of the Negro River and Amazonas only from the Negro to the sea.

Physical features. *Landforms and drainage patterns.* The Amazon basin is a great structural depression, a subsidence trough that has been filling with immense quantities of sediment of Cenozoic age (*i.e.*, from the past 66.4 million years). This depression, which flares out to its greatest dimension in the Amazon's upper reaches, lies between two old and relatively low crystalline plateaus, the rugged Guiana Highlands to the north and the lower Brazilian Highlands (lying somewhat farther from the main river) to the south. The Amazon basin was occupied by a great freshwater sea during the Pliocene Epoch (5.3 to 1.6 million years ago). Sometime during the Pleistocene Epoch (1,600,000 to 10,000 years ago) an outlet to the Atlantic was established, and the great river and its tributaries became deeply entrenched into the former Pliocene seafloor.

The modern Amazon and its tributaries occupy a vast system of drowned valleys that have been filled with alluvium. With the rise in sea level that followed the melting of the Pleistocene glaciers, the steep-sided canyons that had been eroded into the Pliocene surface during the period of lower sea levels were gradually flooded. In the upper part of the valley—in eastern Colombia, Ecuador, Peru, and Bolivia—more recent outwash from the Andes has covered many of the older surfaces.

Physiography of the river course. The Amazon River has its main outlet north of Marajó Island, a lowland somewhat larger in size than Denmark, through a cluster of half-submerged islets and shallow sandbanks. Here the mouth of the river is 40 miles (64 kilometres) wide. The port city of Belém is on the deep water of the Pará River, an estuary marking the south side of Marajó, which is fed chiefly by the Tocantins River entering it southwest of Belém. The port city's link with the main Amazon channel is either north along the ocean frontage of Marajó or following the deep but narrow *furos* (channels) of Breves that bound the island on the southwest and link the Pará River with the Amazon. There are more than 1,000 tributaries of the Amazon that flow into it from the Guiana Highlands and from the Brazilian Highlands, as well as from the Andes. Seven of these tributaries—the Japurá (Caquetá in Colombia), Juruá, Madeira, Negro, Purus, Tocantins, and Xingu rivers—are more than 1,000 miles long; and one, the Madeira River, exceeds 2,000 miles from source to mouth. The largest oceangoing ships can ascend the river 1,000 miles to the city of Manaus, while lesser freight and passenger vessels reach Iquitos, Peru, 1,300 miles farther upstream, at any time of year.

Major tributaries

The sedimentary axis of the Amazon basin comprises two distinct groups of landforms: the *várzea*, or floodplain of alluvium of Holocene age (*i.e.*, up to 10,000 years old), and the *terra firme*, or upland surfaces of Pliocene and Pleistocene materials (those from 10,000 to 5,300,000 years old) that lie well above the highest flood level. The floodplain of the main river is characteristically 12 to 30 miles wide. It is bounded irregularly by low bluffs 20 to 60 feet high, beyond which the older, undulating upland extends both north and south to the horizon. Occasionally these bluffs are undercut by the river as it swings to and fro across the alluvium, producing the *terra caída*, or "fallen land," so often described by Amazon travelers. At the city of Óbidos, where the river narrows to a width of 1.25 miles, a low range of relatively hard rock interrupts the otherwise continuous floodplain.

The streams that rise in the ancient crystalline highlands—the Jari, Trombetas, and Negro to the north and the Tocantins-Araguaia, Xingu, and Tapajós to the south—are so-called "blackwater" streams; they are acidic and rich in humus. Because these streams originate in nutrient-poor, often sandy uplands, they carry little or no silt or dissolved solids. Where such blackwater tributaries enter the main river, they are sometimes blocked off to form funnel-shaped, freshwater lakes or estuaries, as at the mouth of the Tapajós.

Blackwater rivers

In contrast, the Madeira River, which joins the Amazon some 50 miles downstream from Manaus and its principal affluents—the Purus, Juruá, Ucayali, and Huallaga on the right or southern bank and the Japurá (Caquetá), Içá (Putumayo), and Napo from the northwest—have their source in the youthful and tectonically active Andes. There they pick up the heavy sediment loads that account for their "whitewater" designation. Where the silt-laden waters of the Amazon (Solimões in Brazil), derived from these streams, meet those of the Negro at Manaus, the darker and hence warmer and sediment-free waters of the latter tend to be overrun by those of the Amazon, creating a striking colour boundary which is erased by turbulence downstream.

The mother river, the Marañón above Iquitos, rises in the central Peruvian Andes at an elevation of 15,870 feet in a small lake in the Cordillera Huayhuash above Cerro de Pasco. The Huallaga and Ucayali, major right-bank affluents of the Marañón, originate considerably farther south. The headwaters of the deeply entrenched Apurímac and Urubamba, tributaries in turn of the Ucayali, reach to within 100 miles of Lake Titicaca (elevation 12,500 feet) on the Peru-Bolivia border, the farthest of any stream in the system from the great river's mouth.

The Negro River, the largest of all the Amazon tributaries, accounts for about one-fifth of the total discharge of the Amazon and 40 percent of its aggregate volume measured just below the confluence at Manaus. Its drainage area of 292,000 square miles includes that of the Branco, its major left-bank tributary, with its source in the Guiana Highlands. Another of the Negro's affluents, the Casiquiare, is a product of the bifurcation of the Orinoco River; it forms a link between the Amazon and the Orinoco's drainage system. The Branco watershed, approximately coincident with the state of Roraima, includes extensive tracts of sandy, leached soils that support a grassy and stunted arboreal cover (*campos*). Other tributaries of the Negro, such as the Vaupés and Guainía, drain eastward from the Colombian Oriente. The river traverses some of the least populous and least disturbed parts of the Amazon basin, including several national parks, national forests, or indigenous reserves. In its lower reaches it becomes broad and island-filled, in places reaching widths of 20 miles.

The Negro River and its affluents

The Madeira River, second largest affluent of the Amazon, has a discharge of perhaps two-thirds that of the Negro. Silt from its turbid waters has choked its lower valley with sediments; where it joins the Amazon below Manaus, it has contributed to the formation of the 200-mile-long island of Tupinambarana. Beyond its first cataract 600 miles up the river, its three major affluents—the Madre de Dios, the Beni, and the Mamoré—gave easy access to the rubber-rich forests of the Bolivian Oriente, while the Mamoré's tributary, the Guaporé, opened the way to the goldfields of Mato Grosso. Even more important to the rubber tappers were the meandering Purus and Juruá rivers that flank the Madeira on the west.

Hydrology. Most of the estimated 1.3 million tons of sediment that the Amazon pours daily into the sea is transported northward by coastal currents to be deposited along the coasts of northern Brazil and Guiana. As a

consequence, the river is not building a delta. Normally, the effect of the tide is felt as far upstream as Óbidos, 600 miles from the river's mouth. A tidal bore called the *pororoca* occurs at times in the estuary prior to spring tides. With an increasing roar it advances upstream at 10 to 15 miles per hour, forming a breaking wall of water from 5 to 12 feet high.

At the Óbidos narrows, the flow of the river has been measured at 216,000 cubic metres per second; its width is constricted to little more than a mile. Here the average depth of the channel below the mean watermark is more than 200 feet, well below sea level; in most of the Brazilian part of the river its depth exceeds 150 feet. Its gradient is extraordinarily slight. At the Peruvian border, some 2,000 miles from the Atlantic, the elevation above sea level is less than 300 feet. The maximum free width (without islands) of the river's permanent bed is 8.5 miles, upstream from the mouth of the Xingu. During great floods, however, when the river completely fills the floodplain, it spreads out in a band 35 miles wide or more. The average velocity of the Amazon is about 1.5 miles per hour, a speed that increases considerably at flood time.

The Amazon floods

The rise and fall of the water is controlled by events external to the floodplain. The floods of the Amazon are not disasters but rather distinctive, anticipated events that define the calendar and the rhythm of life much as seasons do elsewhere. Their marked regularity and the gradualness of the change in water level are due to the enormous size of the basin, the gentle gradient, and the great temporary storage capacity of both the floodplain and the estuaries of the river's tributaries. The upper course of the Amazon has two annual floods, and the river is subject to the alternate influence of the tributaries that descend from the Peruvian Andes (where rains fall from October to January) and from the Ecuadorian Andes (where rains fall from March to July). This pattern of alternation disappears farther downstream, the two seasons of high flow gradually merging into a single one. Thus, the rise of the river progresses slowly downstream in a gigantic wave from November to June, and then the waters recede until the end of October. The flood levels are, in places, from 40 to 50 feet above low river.

Climate. The climate of Amazonia is warm, rainy, and humid. The length of day and night is equal on the Equator (which runs only slightly north of the river), and the usually clear nights favour relatively rapid radiation of the heat received from the sun during the 12-hour day. There is a greater difference between daytime and midnight temperatures than between the warmest and coolest months. Hence, night is the winter of the Amazon. At Manaus, the average daily temperature is 89° F (32° C) in September and 75° F (24° C) in April, but the humidity is consistently high and often oppressive. During the winter months of the Southern Hemisphere, a powerful south-polar air mass occasionally pours northward into the Amazon region, causing a sharp drop in temperature, known locally as a *friagem,* when the mercury may register as low as 57° F (14° C). At any time of the year, several days of heavy rain can be succeeded by clear, sunny days and fresh, cool nights with relatively low humidity. In the lower reaches of the river basin, cooling trade winds blow most of the year.

The main influx of atmospheric water vapour into the basin comes from the east. About half of the precipitation that falls originates from the Atlantic Ocean; the other half comes from evapotranspiration from the tropical forest and associated convectional storms. Rainfall in the lowlands typically ranges from 60 to 120 inches (1,500 to 3,000 millimetres) annually in the central Amazon basin (*e.g.,* Manaus). On the eastern and western margins of the

Rainfall

basin, rainfall occurs throughout the year, whereas in the central part there is a definite drier period, usually from June to November. Manaus has experienced as many as 60 consecutive days without rain, but such droughty periods are uncommon. The dry season is not sufficiently intense to arrest plant growth, but it may facilitate the onset and spread of fires, whether arsonous or natural. To the west the Andes form a natural barrier that prevents most of the water vapour from leaving the basin.

Along the southern margin of the Amazon basin the climate grades into that of west-central Brazil, with a distinct dry season during the Southern Hemispheric winter. As elevations increase in the Andes, temperatures fall significantly.

Soils. The vast Amazonian forest vegetation appears extremely lush, leading to the erroneous conclusion that the underlying soil must be extremely fertile. In fact, the nutrients in the system are locked up in the vegetation, including roots and surface litter, and are continuously recycled through leaf fall and decay. Generally, the soils above flood level are well-drained, porous, and of variable structure. Often they are sandy and of low natural fertility because of their lack of phosphate, nitrogen, and potash and their high acidity. Small areas are underlain with basaltic and diabasic rocks, with reddish soils (*terra roxa*) of considerable natural fertility. The *terra preta dos Indios* ("black earth of the Indians") is another localized and superior soil type.

The agricultural potential of the annually flooded *várzea* areas is great. Their soils do not lack nutrients, since they are rejuvenated each year by the deposit of fertile silt left as the waters recede, but use for agricultural purposes is limited by the periodic inundations. It is estimated that these valuable soils occupy some 25,000 square miles.

The rain forest

Plant life. The overwhelmingly dominant feature of the Amazon basin is the tropical rain forest, or selva. From the air the Amazon forest appears to stretch unbroken to the horizon like a tufted green carpet. Closer inspection reveals its bewildering complexity and prodigious variety of trees; as many as 100 arboreal species have been counted on a single acre of forest with hardly any one of them occurring more than once.

The Amazon forest has a strikingly layered structure. The sun-loving giants of the uppermost story, the canopy, soar to as much as 120 feet above the ground; occasional individual trees, known as emergents, rise beyond the canopy, frequently attaining heights of 200 feet. Their straight, whitish trunks are splotched with lichens and fungus. A characteristic of these giant trees is the buttresses, or basal enlargements of their trunks, which presumably help stabilize the top-heavy trees during infrequent heavy winds. Further characteristics of the canopy trees are their narrow, downward-pointing "drip-tip" leaves that easily shed water and their cauliflory (the production of flowers directly from the trunks rather than from the branches). Flowers are inconspicuous. Among the canopy species, which capture most of the sunlight and conduct most of the photosynthesis, prominent members include the rubber tree (*Hevea brasiliensis*), the silk-cotton (*Ceiba pentandra*), the Brazil nut (*Bertholletia excelsa*), the sapucaia (*Lecythis*), and the sucupira (*Bowdichia*). Many creatures, including monkeys and sloths, spend their entire lives in this sunlit canopy. Below it are found two or three levels of shade-tolerant trees, including many species of palms, such as *Mauritia, Orbignya,* and *Euterpe.* Myrtles, laurels, bignonias, figs, Spanish cedars, mahogany, and rosewoods are also common. They support a myriad of epiphytes (plants living on other plants)—such as orchids, bromeliads, and cacti—as well as ferns and mosses. The entire system is laced together by a bewildering network of woody ropelike vines known as lianas.

In addition to the rain forests of the *terra firme,* there are two types of inundated rain forests, *várzea* and *igapó,* which constitute about 3 percent of the total Amazonian rain forest. *Várzea* forests can be found in the silt- and nutrient-rich floodplains of whitewater rivers such as the Madeira and the Amazon, with their ever-changing mosaic of lakes, marshes, sandbars, abandoned channels, and natural levees. They are generally not as high, diverse, or old as those of the *terra firme,* being subject to periodic destruction by floods and human manipulation. (The *várzea* and its flood-free margins are the principal rainforest habitat of human beings.) Wild cane (*Gynerium*) and aquatic herbs and grasses, as well as fast-growing pioneer tree species such as *Cecropia, Ficus,* and *Erythrina,* are conspicuous.

Igapó forests grow along the sandy floodplains of blackwater rivers such as the Negro, the Tapajós, and the Trom-

betas. Because human settlement is limited in these plains, there may be undisturbed, seasonally flooded forests that stand in water for up to half the year, the water reaching heights of up to 40 feet. A canoe can often be paddled between the trunks of trees adapted to such an aquatic environment.

The lowland rain forest on the Andean fringe grades into a discontinuous, tangled montane or cloud forest of misshapen trees cloaked with mosses, lichens, and bromeliads. Here one encounters the cinchona or fever-bark tree, once exploited for its antimalarial agent quinine. At still higher elevations is found the grass and shrub growth of the cold *puna* and *páramo* regions.

Along the drier, southern margin of the Amazon basin, high forest gives way to the *cerrado* (savanna and scrub) and *caatinga* (heath forest). The latter is characteristic of parts of the Mato Grosso Plateau, where taller forest is restricted to the stream courses and swales (marshy depressions) that dissect the upland surface. On the sandy soils of the lower Negro and the Branco drainage areas and locally in Amapá, grassy savannas dotted with stunted trees replace the high forest.

Animal life. To give a succinct overview of the complete fauna of the Amazon is as impossible as it is to adequately describe the great diversity of its flora; in part this is because many of the region's species have yet to be identified. The rivers and streams of the basin teem with life, and the forest canopy resonates with the cries of birds and monkeys and the whine of insects. There is a notable paucity of large terrestrial mammal species; indeed, many of the mammals are arboreal.

More than 8,000 species of insects alone have been collected and classified. Myriads of mosquitoes plague travelers and may transmit such diseases as malaria and yellow fever. Leaf-cutting ants (*Atta* and *Acromyrmex*) and other pests may torment the traveler. The most troublesome insects of all are the ubiquitous, small, black flies, called *piums*, whose bite can itch for days.

The Amazon and its tributaries, together with the bordering *várzea* lakes and flooded forests, constitute a vast sea of fresh water, much of it slowly flowing, which teems with fish life. About 1,500 fish species have been found within the Amazon system, but many more remain unidentified. Most fish are migratory, moving in great schools at spawning time. Fish represent a critical source of protein in the often meat-poor diet of the peasant (*caboclo*) population (the term *caboclo* is used for the peasant population of mixed Indian-European blood). Among the more important commercial species are the pirarucu (*Arapaima gigas*), one of the world's largest freshwater fish, and various giant catfish. The well-known, small, flesh-eating piranha generally feeds on other fish but may attack any animal, including humans, that enters the water; its razor-sharp teeth cut out chunks of flesh, stripping a carcass of its meat in a few minutes. The traffic in frozen and dried fish to urban markets has increased to such a degree that some stocks are locally threatened. With the rapid means of transport afforded by jet airplanes, a worldwide market has developed for tropical aquarium fish distinctive to the Amazon. Iquitos, Manaus, and the Colombian port of Leticia are centres of this trade.

Fish

Crocodiles are hunted for their skins; river turtles and their eggs are considered a delicacy; the giant sea cow, or manatee, is sought for its flesh and for oil. All are threatened by overhunting, and the manatee has been listed as an endangered species. Aquatic animals also include freshwater dolphins (*Inia geoffrensis*); the capybara, the largest rodent in the world (weighing up to 170 pounds); and the nutria, or coypu, valued especially for its pelt. Other common rodents are the paca, agouti, porcupine, and local species of squirrels, rats, and mice.

The tapir, the white-lipped peccary, and several species of deer are native to the Amazon basin and much sought for their meat. Water buffalo, introduced from Southeast Asia as work and dairy cattle, have run wild in the remote, swampy parts of Marajó Island.

Especially characteristic of the Amazon forest are several species of monkeys. Of note are the howler monkeys, which make the selva resound with their morning and evening choruses. The small, agile squirrel monkey, the most ubiquitous of Amazonia's monkeys, is used in laboratories, as is the larger spider monkey. Among a host of other primate species are woolly monkeys, capuchin monkeys, titis, sakis, and marmosets. All species are used for food and frequently are seen for sale in local markets. As the human population increases and the shotgun replaces the blowgun, pressure on the wild fauna is mounting.

Large cats, such as the jaguar and ocelot, are rare, although pumas may be found in larger numbers in the Andean fringe of the basin. Smaller carnivores include coati, grisons, and weasels. Countless bats inhabit the Amazonian night, including the blood-drinking vampire bat.

Large cats

The Amazon basin is exceedingly rich in birdlife. Morning and evening, the parrots and macaws fly to and from their feeding grounds, their brilliant plumage flashing in the sunlight and their raucous voices calling out their presence. Through the day the caciques quarrel in trees where their hanging nests swing by the dozens. Hoatzins screech in noisy flocks from streamside brush, while solitary hawks and eagles scream from tree stumps. Everywhere is heard the twittering of small birds, the sound of woodpeckers, and the gutteral noises of such waterbirds as herons, cormorants, roseate spoonbills, and scarlet ibises. Parakeets, more common than sparrows in the United States, fly around in great flocks. At dusk, toucans cry a discordant plaint from the treetops and are joined by ground-dwelling tinamous and quail. The night air is filled with the cries of various species of nightjar.

The people. *Early settlement patterns.* At the time of the European conquest, the bottomlands and fringing upland surfaces of the Amazon River and its major tributaries supported relatively dense, sedentary populations of indigenous peoples who practiced intensive root-crop farming, supplemented by fishing and by hunting aquatic mammals and reptiles. The higher areas away from the rivers and their floodplains, were—and still are in some of the more remote sectors—inhabited by small, widely dispersed, seminomadic tribes of Indians. These groups traditionally have relied predominantly on hunting large and small animals and on gathering wild fruits, berries, and nuts, while practicing some small-patch agriculture of low yield. In the early 1990s the Indian population of the Amazon basin numbered about 600,000, of whom perhaps close to one-third live in Brazil and the rest in the Oriente of the four Andean countries.

Indians

The Amazonian Indians early devised means of making the poisonous bitter cassava (manioc) edible; the end product, called *farinha*, became a food staple widely used today in much of tropical America. Amazonian Indians perfected the use of quinine as a specific against malaria, extracted cocaine from the leaves of the coca tree, and collected the sap of the Brazilian rubber tree (*Hevea brasiliensis*). They were skilled navigators in their dugout canoes and sailing rafts (*jagandas*), and they invented the blowgun and the hammock. One of their ancient arrow poisons, curare (*Chondrodendron tomentosum*), has been used in modern times in the therapy of a host of paralyses and spastic disorders, such as multiple sclerosis.

The early European explorers of the Amazon provisioned themselves from the food supplies of the Indians they met and commandeered their canoes. Large numbers of Indians were taken into slavery, especially during the organized raids (*bandeiras*) of the 16th to 18th century; many others succumbed to such European diseases as influenza, measles, and smallpox. The result was a complete breakdown of native life and a precipitous decrease in the Indian population; survivors fled into increasingly inaccessible sections of the Amazon basin. As late as 1906 there were reports of the wholesale capture of Indians who were enslaved in order to tap rubber, which was plentiful and commanded a high price on the world market but which was difficult to exploit because rubber trees were sparsely scattered over a huge area.

Decline of Indian culture

Settlement by Europeans and mestizos (those of mixed Indian and European ancestry) did not occur to any appreciable degree until the 1870s and '80s, when victims of severe droughts in northeastern Brazil began to move into Amazonia to profit from the rubber boom. Another wave

of immigration began at the end of World War II, spurred by the rapid economic development of the region.

Modern settlement patterns. Its vast area notwithstanding, the Amazon basin, in the late 20th century, has a predominantly urban population. Almost one-third of the estimated nine million Brazilians living in the 1.9 million-square-mile area officially designated as Legal Amazonia are concentrated in Belém and Manaus, cities with more than one million inhabitants, and in Santarém. These cities, which are logistic bases of operations for cattle ranching, mining, timber, and agroforestry projects, are still growing rapidly, with modern residential towers and shantytowns standing side by side. Even frontier trading centres in the interior such as Marabá, Pôrto Velho, and Rio Branco have 100,000 or more inhabitants. In the upper reaches of the drainage area, places such as Florencia in Colombia, Iquitos and Pucallpa in Peru, and Santa Cruz in Bolivia have become significant urban centres with most of the amenities of modern life. Air service effectively connects them with Andean and coastal metropolises and even with the more isolated settlements and mission stations of the Oriente.

The economy. *Development of the Amazon basin.* Since World War II the economic development of the Amazon basin has been high on the agenda of every country of which it is a part. From the mid-1940s onward, a number of "penetration roads" have been built from the populous highlands of Colombia, Ecuador, Peru, and Bolivia into the Oriente, which have funneled untold numbers of landless peasants into the lowlands. They also have served to facilitate development of major oil discoveries and timber resources. Tropical hardwoods, river fish, and, since the 1980s, clandestinely produced cocaine have been objects of commercial exploitation, along with Brahman-type livestock raised on pastures newly carved from the selva. Such activities have led to widespread displacement of indigenous groups, who were either forced onto new reserves or left to survive as best they could.

The opening of the Amazon basin has been pursued most aggressively in Brazil. In the mid-1950s the decision was made to refocus the country toward its interior by constructing a new inland capital, Brasília. One consequence of this decision was the initiation of a massive road-building program that aimed at integrating the North (consisting of the states of Amazonas, Acre, and Pará and the territories of Rondônia, Roraima, and Amapá) with the rest of Brazil while establishing an escape valve for the crowded and drought-stricken Northeast. A 1,100-mile-long highway linking Brasília with Belém, the trade centre at the mouth of the Amazon, was completed in 1964. Along with the even more ambitious 3,400-mile all-weather Transamazonian Highway from the Atlantic port of Recife to Cruzeiro do Sul on the Peruvian border—with extensions north to Santarém and Manaus (later to the Venezuelan border) and southward to Cuiabá (Mato Grosso) and Pôrto Velho (Rondônia)—it was to provide the frame for a network of nearly 20,000 miles of highways and feeder routes that was to supersede the traditional fluvial transport system.

Brazilian road-building program

The government had planned to settle about 100,000 families along the Transamazonian Highway, but this goal was not reached. Indeed, the majority of families who did come abandoned the *agrovilas* within a few years because of declining crop yields on the poor soils, weed invasions, plant diseases, lack of credit, and the distance to markets. Disillusioned by the Transamazonian experience, the government shifted its emphasis to encouraging large-scale, capitalist enterprises. Cheap credit and tax breaks were offered to promote the creation of big cattle ranches within Legal Amazonia.

The completion of the Cuiabá–Pôrto Velho highway about 1970 facilitated movement between Mato Grosso and the Rondônia area along the Bolivian border with its more fertile *terra roxa* soils. It brought an unanticipated flood of immigrants from South Brazil, who had become displaced by the shift to large-scale commercial production of export crops (soybeans, citrus, cotton, and wheat). Between 1970 and 1990 the population of Rondônia increased from roughly 116,000 to more than 1,000,000, and that of Acre to the west reached 400,000 by 1990.

Agriculture and forestry. Upland rice, manioc (cassava), and, to a lesser extent, corn (maize) form the mainstay of smallholder agriculture, providing the carbohydrates for the *caboclo* diet. Jute, heart of palm (from *Euterpe oleracea*), and guarana (*Paullinia cupana,* for a favourite Brazilian soft drink) are all minor commercial crops. Black pepper, introduced from Southeast Asia, has become a specialty crop of Japanese colonists.

Cattle pasture by far dominates land use on the cleared parts of the Amazon basin, both in areas of large ranches, such as southern Pará and Mato Grosso, and in areas initially cut over by smallholders for annual crops, as along the Transamazonian Highway. Pasture is even dominant in areas such as Rondônia, where government programs have promoted the cultivation of cacao, coffee, Brazil nuts, and other perennial crops for which a ready cash market exists.

Cattle pasture

Excellent timber is furnished by the mahogany (*Swietenia macrophylla* and *Swietenia humilis*), the Amazonian cedar (*Cedrela odorata*), the Brazilian rosewood (*Dalbergia nigra*), and many other species. Some types, however, are threatened by intensive exploitation. Other trees, such as the coumarou, or tonka bean (*Dipteryx odorata*), yield perfumes, flavourings, and pharmaceutical ingredients. The economic kings of trees, however, are the rubber tree and the Brazil nut. The rubber tree has been one of the most important objectives in the penetration and exploitation of the forest. It gave rise to a period of great but temporary prosperity, especially for the city of Manaus. The rubber gathered from both wild trees and those grown in small plantations continues to make a contribution to the Amazonian economy.

In Brazil areas within the remaining undisturbed forest have been designated for the use of rubber tappers and nut collectors. Yet the establishment of such "extractive reserve" lands has come into conflict with the claims of both squatters and speculators. The latter often have obtained titles by devious means, and their activities require close monitoring.

Corporate farming and agroforestry operations such as Fordlandia, Belterra, and Jari in eastern Brazil and Tournavista in Peru have had little success; the Jari enterprise, for example, was taken over by a consortium of Brazilian investors and the government in 1982. Transnational corporations investing in livestock operations, especially in southern Pará and Mato Grosso, included Volkswagen AG, Swift-Eckrich, Inc., King Ranch, Inc., and Liquigas Italiana. All have terminated their activities.

Mining and energy. The exploitation of the enormously rich mineral complex of the Serra dos Carajás area west of the boom town of Marabá (population 153,000 in 1991) on the Tocantins River has been highly profitable, but it has also had harmful effects on the environment. The site of one of the world's largest and richest iron ore deposits, the district also produces gold, copper, nickel, manganese, tin, and bauxite. The million-acre concession is run by the Companhia Vale do Rio Doce (CVRD), a partnership between private capital and the federal government. Plans for the local smelting of the iron ore could require the clearing of 490,000 acres (200,000 hectares) of forest annually to provide charcoal for producing pig iron. A rail line connects the Carajás development with the Atlantic coast.

Gold mining reached a feverish pitch in the 1980s, stimulated by high world prices of gold. At the height of the Amazon "gold rush," as many as a half million transient miners (*garimpeireos*) came equipped with picks, shovels, and sluice boxes to search for the mineral in the alluvial deposits of the Tocantins valley at Serra Pelada. Brazil's annual production peaked in 1987 at nearly 90 tons, declining thereafter. The mercury used in extracting the gold polluted waterways, causing the fish that are so important in the local diet to become inedible. On the Madeira River, teams operating from rafts pump up from the riverbed auriferous sediments, which have to be subjected to a similar treatment. Bauxite mining, both at Carajás and on the Trombetas River north of the Amazon, requires the use of large settling ponds to trap effluents.

Gold mining

The energy requirements of both the Carajás development and the city of Belém are met by the giant Tucuruí hydroelectric plant on the Tocantins (with a planned power capacity of 7,260 megawatts), the fifth-largest hydroelectric power station in the world. A more modest hydroelectric facility on a small river north of Manaus supplies that city with power. A growing sensitivity to the harmful consequences for both human beings and the environment of the construction of large dams has caused several ambitious projects to be placed on hold.

The principal oil developments within Amazonia have taken place in the Cordillera Oriental of the Andean countries. Oil pipelines lead from producing districts in both Colombia (the upper Putumayo) and Ecuador (Lago Agrio), as well as northeastern Peru, to export terminals on the Pacific coast. Within the Brazilian and Bolivian portions of the basin, developments have been of minimal consequence.

Ecological concerns. International concern about the ecological consequences of continuing deforestation has been growing and was underscored by the United Nations Conference on the Environment and Development ("Earth Summit") held in Rio de Janeiro in 1992. International calls for conservation are based on the view that the Amazon basin is a global resource, one that serves as a control mechanism for the world's climate and as a genetic repository for the future. The nations of the region, however, tend to look upon such calls as a challenge to "national sovereignty."

The extent and rate of deforestation have been subject to continuing controversy. The difficulty of distinguishing via satellite imagery between regenerating secondary vegetation and undisturbed forest as well as the persistence of cloud cover and sometimes smoke have frustrated investigators. The employment of radar has made investigations more precise. It has been suggested that by 1990 some 10 percent of the Amazon selva may have been cleared for pasture, crops, lumber, and firewood. In Brazil deforestation was initiated in Mato Grosso and southern Pará in the 1960s and became widespread over the next two decades in Rondônia and Acre. Already in 1988 Rondônia was estimated to have been deforested by 17 percent, and the process is continuing. In Colombia the upper Putumayo and Caquetá river areas, in Ecuador the province of Napo, and in Peru the Tingo Maria–Pucallpa district have been among the more notable foci of clearing. The cultivation of coca for illicit production of cocaine continues to stimulate such activities.

The consequences of continuing deforestation have been much discussed. Although the forest is an efficient absorber of carbon dioxide, scientists believe that the volume of gas released when substantial parts of the forest are cleared and burned may contribute to global warming through the greenhouse effect. (For further details, see the article HYDROSPHERE, THE: *Impact of human activities on the hydrosphere: Buildup of greenhouse gases.*) Continued conversion of tropical forest to cropland, pasture, or second-growth forest (*capoeira*) may reduce the region's evapotranspiration, thereby interrupting the hydrologic cycle and the recycling of soil nutrients; a likely consequence is an increase in the amount of water running off the surface and greater extremes in water levels.

The unique gene pool of the Amazon Rain Forest, with perhaps two-thirds of the known organisms of the world, is threatened by continuing deforestation. Particular emphasis has been placed on the threat to biodiversity and the possible loss of as yet unknown and unexploited pharmaceuticals contained in the forest.

Finally, at stake is also the survival of many indigenous peoples who, through long residence, have become integrated into the ecosystem of the rain forest and have learned some of its many secrets.

Study and exploration. At the outset of the 19th century, the German explorer Alexander von Humboldt mapped the connection between the Amazon and Orinoco systems through the Casiquiare River. The English naturalist H.W. Bates spent the years from 1848 to 1859 along the Amazon, collecting thousands of species of animals and recording his notes of animals, local peoples, and natural phenomena in a charmingly objective manner. His book, *The Naturalist on the River Amazons,* originally published in two volumes in 1863, is still regarded as one of the great classics on the Amazon River. An official expedition was sent from the United States to Amazonia in the mid-19th century; in 1854 in Washington, D.C., William Lewis Herndon published as a public document the report that he and Lardner Gibbon—both lieutenants in the U.S. Navy—had made to Congress under the title of *Exploration of the Valley of the Amazon.*

The 20th century. The period since 1900 has been one of numerous exploratory and scientific expeditions. In 1913–14, the former U.S. president Theodore Roosevelt and Brazilian Colonel Cândido Rondon headed an expedition that explored a tributary of the Madeira and made natural history collections and observations. A party sponsored by Harvard University's Institute of Geographical Exploration did important scientific work in the years 1910–24. The American Geographical Society compiled data for and published detailed maps of this vast region.

Since World War II, the international scientific community has been increasingly attracted to Amazonia. British, French, German, Japanese, and North American groups have carried out detailed biophysical and cultural surveys; a large number of international workshops, conferences, and symposia on Amazonian problems have been held. Brazilian scientists have also contributed significant research on issues concerning the area. Particularly important has been the work of the National Institute of

ORINOCO RIVER BASIN

The Orinoco River (Spanish: Río Orinoco) and its tributaries constitute the northernmost of South America's four major river systems. Bordered by the Andes Mountains to the west and the north, the Guiana Highlands to the east, and the Amazon watershed to the south, the river basin covers an area of about 366,000 square miles (948,000 square kilometres). It encompasses approximately four-fifths of Venezuela and one-fourth of Colombia. The Orinoco River itself flows in a giant arc for some 1,700 miles (2,740 kilometres) from its source in the Guiana Highlands to its mouth on the Atlantic Ocean. Throughout most of its course it flows through Venezuela, except for a section where it forms part of the frontier between Venezuela and Colombia. The name Orinoco is derived from Guarauno words meaning "a place to paddle"—*i.e.*, a navigable place.

For most of its length, the Orinoco flows through impenetrable rain forest or through the vast grassland (savanna) region of the Llanos (Spanish: "Plains"), which occupies three-fifths of the Orinoco basin north of the Guaviare River and west of the lower Orinoco River and the Guiana Highlands. The savanna was given its name by the Spaniards in the 16th century and long has been used as a vast cattle range. Since the 1930s this region has been developing into one of the most industrialized areas of South America.

Physical features. *Physiography of the Orinoco.* The western slopes of the Sierra Parima, which form part of the boundary between Venezuela and Brazil, are drained by spring-fed streams that give rise to the Orinoco River. The source is placed in Venezuela at the southern end of the Sierra Parima, near Mount Delgado Chalbaud at an elevation of some 3,300 feet (1,000 metres). From its headwaters the river flows west-northwest, leaving the mountains to meander through the level plains of the Llanos. The volume of the river increases as it receives numerous mountain tributaries, including the Mavaca River on the left bank and the Manaviche, Ocamo, Padamo, and Cunucunuma rivers on the right.

The Casiquiare River

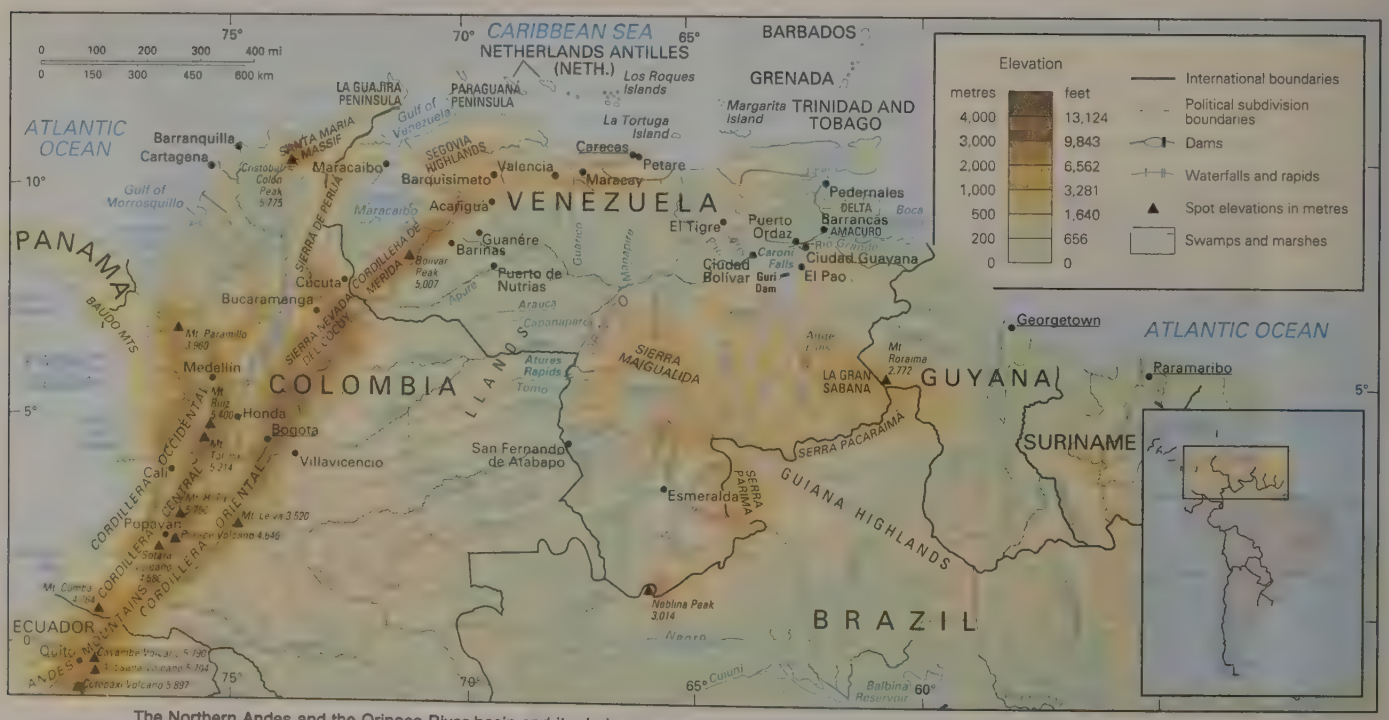
Below the town of Esmeralda, some of the waters of the Orinoco flow south into the Casiquiare River (Brazo Casiquiare; sometimes called the Casiquiare Channel). This channel, a feature peculiar to the Orinoco River system, is a natural passage that flows generally south until it combines with the Guainía River to form the Negro River, thus linking the Orinoco and Amazon river systems.

After its bifurcation in the Casiquiare, the Orinoco bends to the northwest and flows in great meandering curves to its confluence with the Ventuari River. There the river turns to the west to run between high alluvial banks, its course marked by extensive sandbars. Near San Fernando de Atabapo, the Atabapo and Guaviare rivers join the Orinoco, marking the end of the upper Orinoco.

Downstream from San Fernando de Atabapo, the river flows northward and forms part of the border between Venezuela and Colombia. It passes through a transitional zone, the Region of the Rapids (Región de los Raudales), where the Orinoco forces its way through a series of narrow passages among enormous granite boulders. The waters fall in a succession of rapids, ending with the Atures Rapids. In this region, the main tributaries are the Vichada and Tomo rivers from the Colombian Llanos, and the Guayapo, Sipapo, Autana, and Cuao rivers from the Guiana Highlands.

The Atures Rapids mark the beginning of the lower Orinoco basin, in which the river makes its great bend to the east. In this section, the river flows slowly through the lowest level of the plains and increases to about five miles in width. Along the bend, it receives the largest number of tributaries of its entire course, including the Meta, Arauca, and Capanaparo rivers. The Apure River contributes waters from numerous Andean streams, which form a swampy maze in their lower courses.

From its junction with the Apure, the Orinoco meanders eastward over gently sloping plains. Shoals and alluvial islands are abundant; some of the islands are large enough to divide the channel into narrow passages. Tributaries include the Guárico, Manapire, Suatá (Zuata), Pao, and Caris rivers, which enter on the left bank, and the Cuchivero and Caura rivers, which join the main stream on the right. So much sediment is carried by these rivers that they often form islands at their mouths. The Caroní River, one of the Orinoco's largest tributaries, joins the river on its right bank after passing through the Guri Reservoir formed by Guri (Raúl Leoni) Dam, above Ciudad Guayana (also called Santo Tomé de Guayana); farther upstream, on the Churún River (a tributary of the Caroní), are the Angel Falls, the highest waterfall in the world (3,212 feet). Many lagoons, including the Mamo, Amana, and Colorada, are located on the banks of the



The Northern Andes and the Orinoco River basin and its drainage network.

Orinoco River near Ciudad Guayana, in Venezuela.

Orinoco west of its confluence with the Caroní and east of Ciudad Bolívar.

The delta region

About 30 miles downstream of Ciudad Guayana, at the town of Barrancas, the Orinoco begins to form its great delta. The delta extends for about 275 miles along the Atlantic coast, from Pedernales on the Gulf of Paria in the northwest to Barima Point in the southeast on the Boca Grande (literally, the "Great Mouth"). Scores of islands are connected by innumerable canals (*caños*), which form an intricate network. The main channel of the Orinoco, known in the delta as the Río Grande, flows eastward from Barrancas to discharge into the Boca Grande.

Physiography of the Llanos. The Llanos encompasses nearly all of the western lower Orinoco basin, occupying some 220,000 square miles; most of the land is less than 1,000 feet above sea level. The High Plains (Llanos Altos) are most conspicuous near the Andes, where they form extensive platforms between rivers and are some 100 to 200 feet above the valley floors. Away from the mountains they are increasingly fragmented, as in the dissected tableland of the central and eastern Venezuelan Llanos (the Sabana de Mesas) and the hill country (*serranía*) south of the Meta River in Colombia. The Low Plains (Llanos Bajos) are defined by two rivers, the Apure in the north and the Meta in the south. The lowest portion of the Llanos is an area that lies to the west of the lower Orinoco valley; this area is converted annually into an inland lake by flooding.

In addition to the Apure and the Meta, the principal streams draining the Llanos include the Guaviare and Arauca rivers. Seasonal changes between saturation and dehydration have led to advanced laterization of the soil, the process in which the base minerals have been leached away or incorporated into insoluble iron and aluminum silicates. Fine-grained soils form hardpans (cemented layers of soils), and in gravel regions, iron-cemented quartz conglomerates underlie the surface. Excessive acidity and the lack of nutrient bases, organic matter, and nitrogen make virtually all mature soils infertile.

Climate. The climate of the Orinoco basin is tropical, with the seasons marked by differences in rainfall rather than in temperature. The year is divided into two seasons—rainy and dry (locally known as winter and summer)—the former extending from April to October or November and the latter most marked from November through March or April. The wet and dry seasons result from the annual migration of the intertropical convergence zone, a low-pressure trough between the hemispheric easterlies, or trade winds; the passage of the zone northward from its summertime position south of the Equator brings the rainy winter period.

Rainfall varies considerably throughout the drainage basin. The northeast trade winds blow across the coastal districts without losing much of their moisture, in some places leaving less than 20 inches (510 millimetres) of precipitation per year. Areas lying behind topographic barriers also get little rain, while windward slopes generally are well watered. In some regions enough rain falls to support a lush jungle growth, and in others there is enough for a true rain forest (selva). The Llanos experience severe drought from about January to April and then undergo extensive flooding from June to October. Monthly precipitation is seldom less than 10 inches in the Colombian Llanos between April and November. The rains peak about midyear in the Venezuelan north, with monthly totals of roughly 10 inches. Annual precipitation is highest near the Andes, where Villavicencio, Colom., receives 180 inches; and there is a pronounced decrease toward the central plains, where Puerto de Nutrias, Venez., receives 45 inches.

Temperatures

In contrast to precipitation, temperature differences in the basin are slight throughout the year; and no month averages more than 69° F (21° C) or less than 64° F (18° C). Whatever the average temperature, there is little difference from month to month. The only marked variation is from day to night, being greater than that from month to month. On the Llanos, daily maximum temperatures rise above 95° F (35° C) in the dry period; the dry winds and nocturnal cooling bring relief with normal minimum temperatures between 65° and 75° F (18° and 24° C).

Hydrology. The river basin, as a geomorphological feature, dates from the Quaternary Period (*i.e.,* the past 1.6 million years). The enormous quantities of material produced by the highland regions are carried down by torrential rains to the rivers. The rivers, unable to hold the excessive material, overflow or break their banks, producing periodic floods that submerge the lowlands. Under these conditions, drainage presents an unstable and indefinite pattern, marked by the shifting of rivers, lagoons, and swamps over the lower lands. The Orinoco delta is rapidly extending into the ocean, but the tremendous amounts of sediments that accumulate are accelerating the subsidence (sinking) that also is occurring in the delta region.

Wide fluctuations in the river's flow reflect the seasonal rainfall pattern. During the dry season, or "low-water" period, from October to March, the average depth of the Orinoco is about 49 feet in the lower basin near Ciudad Bolívar. The rise of the river begins with manifest regularity in April at the beginning of the rainy season. The "high-water" period from April to October reaches its maximum in July. The depth of the river at this period is about 165 feet at Ciudad Bolívar. From June to August the lowlands of the basin are flooded and in some places are 65 feet under water. At the end of August the waters gradually recede until they again reach their lowest point in October.

Plant life. Most of the Llanos consists of treeless savanna. In the low-lying areas, swamp grasses and sedges are to be found, as is bunchgrass (*Trachypogon*). Long-stemmed grass dominates the dry savanna and is mixed with carpet grass (*Axonopus affinis*), the only natural grass to provide green forage during the dry season.

The most conspicuous trees in the Llanos occur in the gallery forests that occur in the alluvial soils deposited along the rivers and in the narrower files of trees known as *morichales,* named for the dominant moriche, or miriti, palm (*Mauritia flexuosa*), that follow minor water courses. Broad-leaved evergreens originally occupied the high-rainfall zone in the Andean piedmont. There also is a handful of xerophytic trees (*i.e.,* those adapted to arid conditions), including the *chaparro* (scrub oak) and the dwarf palm, scattered on the open savanna. Much of this natural tree

cover, however, has been reduced by deforestation. The Guiana Highlands are covered with high, dense forest that is interrupted by small patches of savanna. The tropical rain forest of the upper Orinoco valley contains hundreds of species of trees. Mangrove swamps cover much of the delta region.

Birds

Animal life. More than 1,000 species of birds frequent the Orinoco region; among the more spectacular are the scarlet ibis, the bellbird, the umbrella bird, and numerous parrots. The great variety of fish include the carnivorous piranha, the electric eel, and the *laulao*, a catfish that often attains a weight of more than 200 pounds. The Orinoco crocodile is the longest of its kind in the world, reaching a length of more than 20 feet; among other inhabitants of the rivers are caimans (a crocodile-like amphibian) and snakes, including the boa constrictor. The arrau, or side-necked turtle, the shell of which grows to a length of about 30 inches, nests on the sandy islands of the river. Insects include butterflies, beetles, ants, and mound-building termites.

The Llanos have few indigenous animals. Most mammals nest in the gallery forests along the streams and feed on the grassland. The only true savanna dwellers in the region are a few burrowing rodents and about two dozen species of birds (among them the white and scarlet ibis, the *morichal* oriole, and the burrowing owl). Several species of deer and rabbit, the anteater and armadillo, the tapir, the jaguar, and the largest living rodent, the capybara, also can be found.

The people. *Indigenous peoples of the basin.* Except for the Guajiros of Lake Maracaibo, most of the Venezuelan aboriginal population lives within the Orinoco River basin. The most important indigenous groups include the Guaica (Waica), also known as the Guaharibo, and the Maquiritare (Makiritare) of the southern uplands, the Warrau (Warao) of the delta region, and the Guahibo and the Yaruro of the western Llanos. These peoples live in intimate relationship with the rivers of the basin, using them as a source of food as well as for purposes of communication.

Settlement. Until the mid-1900s, settlement was limited to widely scattered ranches known as *hatos* ("cow herds"), a few villages, and missionary stations along the lower courses of the region's rivers. Oil strikes in the eastern and central Venezuelan Llanos at El Tigre (1937) and Barinas (1948) initiated industrial and urban development in a region that had been sparsely populated until that time. Several of the "boom towns" of that period, such as El Tigre, have grown into sizable cities. An expansion of intensive agriculture occurred with the settlement, which began in the 1950s, of pioneer farmers in the Andean piedmont and along the river valleys. Major concentrations of these small farms are located in the vicinity of Barinas, Guanare, and Acarigua in Venezuela and in the Ariari region in Colombia.

As a result of this settlement, a high degree of urbanization has occurred in the Venezuelan Llanos, with more than half of the people living in cities of 10,000 or more inhabitants. The important towns, with the exception of Ciudad Bolívar, are built on high ground to avoid recurrent flooding. Town plans reflect Spanish influence: streets are arranged in a gridiron pattern with a central plaza. By contrast, population increase has been modest in the Colombian areas of the Llanos and—with the exception of the region around Ciudad Guayana—in the Guiana Highlands.

The economy. *Resource exploitation.* The Guiana Highlands are rich in mineral deposits. Iron ore, containing high concentrations of iron, is mined at Cerro Bolívar and El Pao. Other minerals include deposits of manganese, nickel, vanadium (a metallic element used to form alloys), bauxite, and chrome. There also are deposits of gold and diamonds. Petroleum and natural gas are exploited in the Venezuelan Llanos and the Orinoco delta.

The Venezuelan Llanos long have been one of South America's major livestock-raising areas, with cattle being predominant. In addition, sugarcane, cotton, and rice are grown on a commercial scale on the plains; and coffee has become important on the northwestern and northern highland fringes of the river basin. Land-reclamation and flood-control projects in the delta region have been planned in order to open vast agricultural lands.

Although agriculture and cattle raising have continued as mainstays of the basin's economy, the base has been widened by the exploitation of petroleum and other minerals and by the establishment of certain industries. Industrial development of the river basin is concentrated around Ciudad Guayana and includes the production of steel, aluminum, and paper. The industrial growth of Ciudad Guayana has been made possible by the construction of the Macagua and Guri dams, which have harnessed much of the immense hydroelectric potential of the Caroní River. The power supplied by this vast project is supplemented by natural gas piped from the oil fields north of the Orinoco River.

The Ciudad Guayana complex

Transportation. The Orinoco and its tributaries long have served as vast waterways for the indigenous inhabitants of the Venezuelan interior. Especially during the floods of the rainy season, boats with outboard motors are the only means of communication throughout large areas of the river basin. Large river steamers travel upriver for about 700 miles from the delta to the Atures Rapids. Dredging has allowed large oceangoing vessels to navigate the Orinoco from its mouth to its confluence with the

Horses being watered on the Llanos, in eastern Colombia.

Caroní River—a distance of about 225 miles—in order to tap the iron ore deposits of the Guiana Highlands.

Considerable road construction has been undertaken in the Venezuelan Llanos since World War II. The Llanos and the Guiana region were connected in 1967 with the completion of a mile-long bridge across the Orinoco at Ciudad Bolívar. Earlier, in 1961, the mouth of the Caroní was bridged to connect the new industrial town of Puerto Ordaz with the old Orinoco port of San Félix, thereby creating the urban unit of Ciudad Guayana; Ciudad Guyana subsequently was connected to Caracas by a major highway.

Study and exploration. European exploration of the Orinoco River basin began in the 16th century. A series of expeditions sponsored by the German banking house of Welser of Augsburg penetrated the Llanos southward across the Apure and Meta rivers. From the east, several Spanish expeditions ascended the river from its mouth without much success. In 1531 the Spanish explorer Diego de Ordaz voyaged up the river, and that same year another Spanish explorer, Antonio de Berrio, descended the Casanare and Meta rivers and then descended the Orinoco to its mouth.

In 1744 Jesuit missionaries reached the Casiquiare River. Alexander von Humboldt, the German naturalist, traveled more than 1,700 miles through the Orinoco basin in 1800. By 1860 steamships were navigating the Orinoco. The source of the river remained in dispute, however, until a Venezuelan expedition finally identified it in 1951.

(Me.F.G./Di.B./Ed.)

RÍO DE LA PLATA SYSTEM

The Río de la Plata (literally, "River of Silver"; in English often called the River Plate) is a tapering intrusion of the Atlantic Ocean occurring on the east coast of South America between Uruguay to the north and Argentina to the south. While some geographers regard it as a gulf or as a marginal sea of the Atlantic, and others consider it to be a river, the majority regard it as the estuary of the Paraná and Uruguay rivers (as well as of the Paraguay River, which drains into the Paraná). The Río de la Plata receives waters draining from the basin of these rivers, which covers much of south-central South America; the total area drained is about 1,600,000 square miles (4,144,000 square kilometres), or about one-fourth of the surface of the continent. Montevideo, the capital of Uruguay, is located on the northern shore of the estuary, and Buenos Aires, the capital of Argentina, is on the southwestern shore.

Rivers of the system

The delta of the Paraná and the mouth of the Uruguay meet at the head of the Río de la Plata. The breadth of the estuary increases from the head seaward, a distance of about 180 miles (290 kilometres): it is 31 miles from the city of Punta Lara on the southern (Argentine) shore to the port of Colonia del Sacramento on the northern (Uruguayan) shore, and 136 miles from shore to shore at the Atlantic extremity of the estuary. To those who regard the Río de la Plata as a river, it is the widest in the world, with a total area of about 13,500 square miles.

Physical features. The Paraná River (Spanish: Río Paraná; Portuguese: Rio Paraná), together with its tributaries, forms the larger of the two river systems that drain into the Río de la Plata. The Paraná—meaning "Father of the Waters" in the Guaraní language—is 3,032 miles (4,880 kilometres) long and extends from the confluence of the Grande and Paranaíba rivers in southern Brazil, running generally southwestward for most of its course, before turning southeastward to drain into the Río de la Plata. The Paraná customarily is divided into two segments: the Alto (Upper) Paraná above the confluence with the Paraguay River and the Paraná proper (or lower Paraná) below the confluence.

Physiography of the Alto Paraná basin. The Grande River rises in the Serra da Mantiqueira, part of the mountainous hinterland of Rio de Janeiro, and flows westward for approximately 680 miles; but its numerous waterfalls—such as the Marimbondo Falls, with a height of 72 feet (22 metres)—makes it of little use for navigation. The Paranaíba, which also has numerous waterfalls, is formed by many affluents, the northernmost headstream being the São Bartolomeu River, which rises just to the east of Brasília.

From its origin in the Grande-Paranaíba confluence to its junction, some 750 miles downstream, with the Paraguay, the Alto Paraná receives many tributaries from both the right and the left. The three most important tributaries—the Tietê, Paranapanema, and Iguaçu rivers—all join the Alto Paraná on its left bank and have their sources within a few miles of the Atlantic coast of Brazil.

The Alto Paraná first flows in a southwesterly direction down a deep cleavage in the southern slope of the ancient Brazilian Highlands, the configuration of which determines its course. Just before it begins to run along the frontier between Brazil to the east and Paraguay to the west, the river has to cut through the Serra de Maracaju (Mbaracuyú), which in the past had the effect of a dam, until the Itaipu hydroelectric dam project was completed there in 1982; the river once expanded its bed into a lake 2.5 miles wide and 4.5 miles long, with Guaíra, Braz., standing on the southern shore. The river's passage through the mountains was, until 1982, marked by the Guairá Falls (Salto das Sete Quedas), which had eight times the water volume of the Niagara River of North America. Since the completion of the Itaipu project's first stage, the falls and lake have been submerged, and a reservoir now extends upstream for some 120 miles and covers more than 700 square miles.

The Iguaçu River

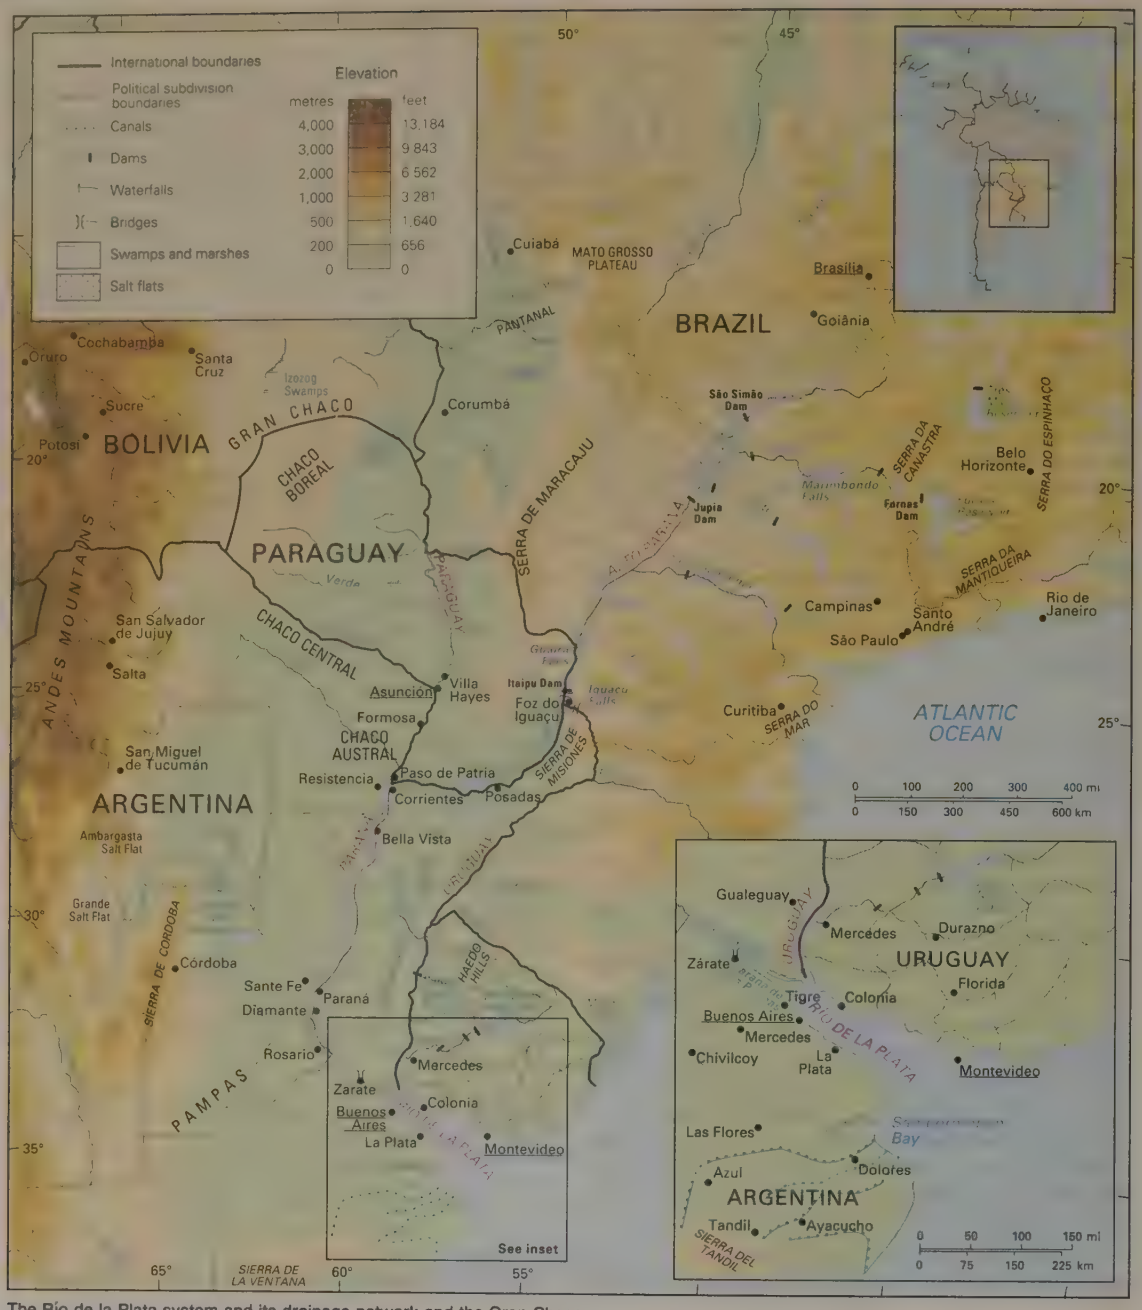
The Iguaçu River (Iguaçu meaning "Great Water" in the Guaraní language) joins the Alto Paraná at the point where Brazil, Paraguay, and Argentina converge. Rising in the Serra do Mar near the Brazilian city of Curitiba (for which reason it is sometimes called the Rio Grande de Curitiba), the Iguaçu flows about 380 miles from east to west, during which some 70 waterfalls reduce the river's elevation by a total of about 2,650 feet. While the Ñacunday Falls are 131 feet high, the spectacular Iguaçu Falls, on the frontier between Brazil and Argentina, 14 miles upstream from the Iguaçu–Alto Paraná confluence, have a height of about 270 feet—almost 100 feet higher than Niagara Falls. As the river approaches the falls, it widens before plunging over the crescent-shaped edge, producing horseshoe-shaped cataracts more than two miles wide. Below the falls, the river passes for several miles through a gorge (Garganta del Diablo; literally, "Devil's Throat") that is only 164 feet wide between heights varying from 65 to 328 feet.

From the Iguaçu confluence to its junction with the Paraguay River, the Alto Paraná continues as the frontier between Paraguay and Argentina. So long as it is flanked on the left (Argentine) bank by the steep edge of the Sierra de Misiones, the river proceeds in a generally southwesterly direction, but it twists repeatedly to and fro over a rocky bed studded with outcrops of porphyritic basalt. At Posadas, Arg., however, where it is about 1.5 miles wide, the river turns abruptly westward and begins a more meandering course, embracing islands of considerable size and punctuated so frequently by rapids and by outcrops of basalt that navigation is difficult. At the Apipé Rapids the river is only about 4 to 6 feet deep.

Physiography of the Paraguay basin. At Paso de Patria, on the right (Paraguayan) bank, the Paraná receives its greatest tributary, the Paraguay River. The fifth largest river in South America, the Paraguay (Spanish: Río Paraguay; Portuguese: Rio Paraguai) is 1,584 miles (2,550 kilometres) long. The name Paraguay, also taken from the Guaraní language, could be translated "river of *paraguas* (coloured, plumed birds)" or "river of cockades," an allusion, perhaps, to the plumed headdresses once worn by the riverine peoples.

The Paraguay also rises in southern Brazil, in the central plateaus of Mato Grosso state, at an altitude of 980 feet above sea level. Where it becomes navigable for small craft—about 150 miles downstream, near Cáceres, Braz., after its confluence with the Sepotuba River—it is 275 feet wide and 20 feet deep. Another 20 miles downstream, where the Jauru River joins it at an elevation of 400 feet, the Paraguay enters the Pantanal, a vast seasonal swamp that covers much of southern Mato Grosso and northwestern Mato Grosso do Sul state. During the dry season

The Pantanal



The Río de la Plata system and its drainage network and the Gran Chaco.

(May to October) the swamps in the Pantanal shrink to small patches of marshy land. With the onset of the rains in November, the slow-flowing rivers are quickly filled to capacity, and a large, shallow lake is formed. Spanish missionaries mistook this for a permanent lake, and it appeared as "Lago Xarays" on early maps of the region.

The Paraguay's main channel skirts the Pantanal's western edge over a sandy bed, flowing around the many islands in its course. During its passage through the Pantanal, the river receives such important tributaries as the Cuiabá, Taquari, and Miranda rivers. About 470 miles downstream, it flows north-south to form the boundary between Brazil and Paraguay before being joined by a tributary, the Apa River, that flows in from the east and demarcates part of the Brazilian-Paraguayan frontier. The river then enters Paraguay, having traveled about 640 miles from its source. After flowing for more than 200 miles across Paraguay, it is joined by the Pilcomayo River at the Argentinian border, near Asunción. It then flows south-southwest along the Argentine-Paraguayan frontier for about 140 miles, until it is joined on its west bank by the Bermejo River. Continuing along the border for another 40 miles, it then empties into the Paraná River at a short distance from the Argentine city of Corrientes.

From its confluence with the Apa for the 630 miles to its mouth, the Paraguay runs on a shallow, broad bed, with an average width of about 2,000 feet. South of Asunción, the river's right (Argentine) bank gradually lowers, whereas its left (Paraguayan) bank becomes elevated, forming cliffs. Along this stretch, floods develop principally on the western bank, spreading over the Argentine plain for distances of from three to six miles. These lands form part of the Gran Chaco.

Physiography of the lower Paraná basin. After its juncture with the Paraguay, the combined stream of the Paraná turns southward as it passes Corrientes. It now becomes a typical "plains" river, banked by its own alluvial deposits and having an extensive floodplain on its right bank, with tracts up to 24 miles wide subject to inundation. Its permanent bed, about 2.5 miles wide at Corrientes, narrows to about 8,000 feet at Bella Vista, to about 7,000 feet at Santa Fe, and to about 6,000 feet at Rosario, and it is strewn throughout with chains of islands. Santa Fe, on the right bank opposite the port of Paraná, stands where the

Paraná receives its last major tributary, the Salado River. Between Santa Fe and Rosario, however, the right bank begins to rise as the river skirts the edge of the undulating plain, which flanks it down to the delta, and reaches altitudes ranging from about 30 to 65 feet. The left bank, meanwhile, is always higher than the right but has to sustain the erosive action of the water, which becomes increasingly turbid as great masses of soil are constantly falling into it; in the delta the main branch of the river runs along a break in the terrain, with its left bank consisting of a cliff about 75 feet high.

The Paraná delta

The delta of the Paraná has its apex as far north as Diamante, upstream from Rosario, where branches of the river begin to turn southeastward. About 11 miles wide at its upper end, the width of the delta grows to roughly 40 miles at the river mouth, where the separated branches of the Paraná flow into the Río de la Plata, about 200 miles from Diamante. With an area of 5,500 square miles, the delta is advancing steadily, as an estimated 165 million tons of alluvial deposits are added annually. Within the delta the river divides again and again into distributary branches, the most important being the two last great channels, the Paraná Guazú and the Paraná de las Palmas. The islands of the delta, alluvial in origin, are low-lying and of varying size. Their shores and the outer fringes of the river have protective embankments covered with trees but nevertheless may be submerged in times of flooding, when they present the appearance of flooded forests.

Physiography of the Uruguay basin. The Uruguay River (Spanish: Río Uruguay; Portuguese: Rio Uruguai) is the other major system, 990 miles (1,593 kilometres) in length, that flows into the Río de la Plata. Like the Alto Paraná and the Paraguay, the Uruguay originates in southern Brazil, formed by several small streams that rise on the western slopes of the Serra do Mar. From the south it is joined by the Pelotas River, which divides the states of Rio Grande do Sul and Santa Catarina. After flowing west, the Uruguay turns southwest at its juncture with the Peperi Guaçu River, the first sizable tributary to join it from the north. For most of its course, the fast-flowing Peperi Guaçu marks the boundary between the Argentine province of Misiones and Brazil; and after its confluence with the Uruguay, the latter river divides Brazil and Argentina. A few miles beyond the juncture with the Peperi Guaçu, the river is constricted between rocky walls in the Grande Falls, a two-mile stretch of rapids with a total descent of 26 feet in 8 miles. At the cataracts, the river narrows suddenly from 1,500 feet to an extreme of 100 feet.

Several small rivers join the Uruguay from the west and are navigable in their lower reaches by canoes and small boats. The principal ones, from north to south, are the Aguapey, Miriñay, Mocoretá (which divides Entre Ríos and Corrientes), and Gualeguaychú. The important tributaries of the Uruguay, however, come from the east. The Ijuí, Ibicuí, and the Cuareim are short rivers but of considerable volume; the last forms part of the boundary between Brazil and Uruguay. At the mouth of the Cuareim, the Uruguay becomes the boundary line between Argentina and Uruguay, and the river flows almost directly south. A dam above the falls at Salto, Uruguay, impounds Lake Salto Grande some 40 miles upstream. The Negro River, approximately 500 miles long and the Uruguay's largest tributary, joins the latter only 60 miles from the Río de la Plata. The Negro rises on the Brazilian border in Rio Grande do Sul state and flows westward through central Uruguay. Like the Alto Paraná, the Uruguay generally is clear and carries little silt, except in the seasonal floods. After its juncture with the Negro, the Uruguay broadens sharply to a width of 4 to 6 miles and becomes a virtual extension of the Río de la Plata estuary.

Physiography of the Río de la Plata. The two contributory river systems bring down an immense quantity of silt each year. The muddiness of the water in the Río de la Plata itself is increased by the tides and winds that hinder the deposition of silt on the bed. When sediments do settle, the mineral and organic matter form great shoals, banks, or bars: the Playa Honda Shoal is just off the Paraná delta, the Ortiz and Chico shoals are farther downstream, and the Rouen, Inglés, Alemán, and Arquímedes shoals are still farther out. The depth of the water—varying from 6 feet above the shoals to 65 feet in the intervening channels—is reduced along the southern coast by an offshore shoal.

Silt and shoals

The Argentine coast of the estuary is low-lying; its banks are of marine debris and coarse sand, and the coast is subject to flooding in places. The entrances to Argentine ports (including that of Buenos Aires) require constant dredging. The Uruguayan coast stands considerably higher and consists largely of rocks and dunes. Off the Uruguayan coast are several small islands, such as Hornos, San Gabriel, López, Lobos, Farallón, and—opposite the mouths of the Uruguay and Paraná Guazú rivers—Martín García.

Hydrology of the system. The velocity of the Paraná's current changes frequently during the river's long course. For the Alto Paraná, the rate becomes slower wherever the bed widens (especially when a real lake is formed, as at Itaipu Dam) and much faster wherever the bed narrows (as in the canyon downstream from Itaipu). Farther downstream, it slackens on its way to Posadas but accelerates thereafter over a series of rapids and races. It becomes slower again downstream from Corrientes, stabilizing its flow at a mean rate of 2.5 miles per hour on the way to the Río de la Plata.

Throughout the basin of the Paraguay River, which covers more than 380,000 square miles, elevations rarely exceed 650 feet above sea level. Thus, over a long distance, the gradient of the river varies only slightly from about 0.75 to 1 inch per mile (1.2 to 1.6 centimetres per kilometre). The various streams of the basin have low banks or natural levees, built up when silt is deposited along the slower-flowing portions of the river channel during flood stage. When the river recedes, its banks thus remain elevated above the level of the neighbouring plains. During floods a continuous water table, often as much as 15 miles wide, underlies the inundated plains, and about 38,600 square miles of surface area are flooded. The Paraguay has varying rates of flow between its source and its confluence with the Paraná. Above Corumbá, in Brazil, it has a typically tropical regime—at its highest in February and at its lowest from July to August. Below Corumbá, the high point occurs in July and the low point from December to January.

The volume of flow

The volume of the lower Paraná is, for practical purposes, correlated to the amount it receives from the Paraguay, which supplies about 25 percent of the total. High periods occur normally between November and February and low periods in August and September. The river's mean overall volume at the Río de la Plata is about 610,700 cubic feet (17,293 cubic metres) per second, with the highest recorded volume being 2,295,000 cubic feet per second (1905) and the lowest 86,400 (1945).

An important factor in the hydrologic regime of the lower Paraná is that the Alto Paraná and the Paraguay reach their maximum flow at different times. Whereas the mountainous basin of the Alto Paraná is drained so rapidly that water begins to rise at Corrientes in November, reaching its maximum height there in February, the Pantanal swamps of the upper basin of the Paraguay retain precipitation so much longer that the Paraguay's high water does not reach Corrientes until May, reaching its maximum in June. Thus, levels on the lower Paraná begin to sink in March, rise from May, and sink again from July to September. Whenever both the Alto Paraná and the Paraguay reach their highest levels at the same time, the lower Paraná has to carry an exceptionally heavy volume of water—as it did in 1905, when the delta experienced heavy flooding.

The volume of water discharged by the Río de la Plata into the Atlantic is estimated at about 776,900 cubic feet per second. Although the water of the tributary rivers is so widely distributed over the length and breadth of the estuary that variations in their volume do not affect the level of the water, the estuary's level is considerably affected by variations of the tides and, especially, of the winds reaching it. The ocean tides are relatively weak, but they flow 120 miles up the Paraná and the Uruguay rivers from their mouths on the estuary. The average tidal range is 0.5 foot at Montevideo and 2.5 feet at Buenos Aires. The pampero

Lush vegetation of the Pantanal, Mato Grosso do Sul state, in Brazil.

(a wind from the south to southwest) and southeasterly winds called *sudestados* both exert a great influence on the Río de la Plata: the pampero, when it is most powerful, drives the water onto the Uruguayan coast, so that the water level drops on the Argentine side; the southeasterly wind has the effect of flooding the Paraná delta and causing the level to drop on the Uruguayan coast.

Climate. The basins of the Alto Paraná and Paraguay have a hot and humid climate throughout the year. The winters (April to September) are dry, and the summers (October to March) are rainy. Annual mean temperatures in the upper basin are above 68° F (20° C), the absolute maximum temperature being from 104° to 107° F (40° to 42° C) and the absolute minimum temperature being about 37° F (3° C). January frequently is the warmest month. More than four-fifths of the annual precipitation occurs in the summer months, with the least amount of rain falling in July and August. Annual rainfall varies from 80 inches (2,000 millimetres) in the mountains to the east to 40 inches in the west. Rainfall takes the form of drenching downpours often accompanied by hailstorms.

The climate of the middle and lower basins progresses from subtropical in the north to temperate in the south. The mean annual temperature along the Río de la Plata is 55° F (13° C), and monthly averages are always over 50° F (10° C). Frosts are frequent in the winter months in the south but can occur as far north as Asunción and Paraná state in Brazil. Humidity in the lower basin is notably high—averaging 70 percent annually along the Río de la Plata—and sometimes is quite stifling in summer; the moist vapours become still thicker when the Paraná brings down the torrential waters of the tropical basin. Rainfall in the southern basin is somewhat less plentiful than in the north, but it occurs at all seasons. The mean annual precipitation along the Río de la Plata is 44 inches.

Plant life. The Brazilian section of the Alto Paraná forms the boundary between two zones: that of the forest to the east and of the savanna to the west. Forests include stands of Paraná pine (*Araucaria angustifolia*), an evergreen conifer valued for its softwood timber. The treeless savanna, with grasses and bushes, is used for cattle raising.

The Pantanal complex

In the upper Paraguay River basin, some of the Pantanal's vegetation, called the "Pantanal complex," is typical of the Mato Grosso Plateau, while the remainder of the basin is typical of lowlands. Plants that thrive in water and in moist soils, as well as those that flourish at moderate temperatures or are adapted to dry regions, are found within the complex. The water plants, found on the permanently flooded lands, are typified by the water hyacinth and by the Amazon, or royal, water lily (*Victoria amazonica*). Moisture-loving species, such as the trumpetwood and the guama, flourish over most of the floodplain. On the savanna, after the floods, various grasses such as paspalum and knotroot bristle grass reappear. Vegetation of a more evolved type, which thrives at moderate temperatures, occupies the unflooded highland. It is represented by nut-bearing palms and by various types of laurels. Dense, evergreen forest galleries grow along stream banks. In the forests of the region, the carandá (a tropical palm that yields a wax similar to carnauba wax), the paratudo, the muriti palm (a large fan palm), and various types of quebracho trees (South American hardwoods that are a source of tannin) predominate.

Farther south, thick, subtropical, semi-deciduous forests extend westward from the Misiones region of Argentina along the Paraná and cover much of eastern Paraguay. These forests provide such decorative hardwoods as lapacho and also contain *Ilex paraguariensis,* a member of the holly family whose roasted leaves are used to prepare the brewed beverage maté. Some forest trees, outside the forest zone proper, still occur in areas of woodland downstream to the Paraná delta. In the Gran Chaco region along the west bank of the river, and in other sections where drought is more pronounced, a thorn forest of xerophytic (drought-tolerant) plants occurs. In the lowlands of eastern Paraguay, forest cover and savanna grasslands alternate.

Animal life. The river system has a rich and varied animal life throughout its length. Among its many edible fish are the dorado (a gold-coloured river fish that resembles a salmon), the *surubí* (a fish with a long rounded body, flattened at the nose), the *patí* (a large, scaleless river fish that frequents deep and muddy waters), the pacu (a large river fish with a flat body, almost as high as it is long), the pejerrey (a marine fish, silver in colour, with two darker bands on each side), and the corbina (white sea bass); the stretch of the Paraná upstream from Corrientes is popular for its dorado sport fishing. Also of note is the meat-eating piranha, a fish resembling the bluegill that travels in large schools and inhabits the tropical parts of the system.

Reptiles include the iguana lizard, two species of caiman (a crocodilian), the water boa, the rattlesnake, the cross viper, and the *yarará* (the most prevalent South American representative of the viper family). Frogs and toads are plentiful, as are freshwater crabs. There are innumerable species of insects and spiders, and the islands are plagued by mosquitos. Herons, cormorants, storks, and game birds also are plentiful.

The people. Before the arrival of the Spanish in the 16th century, the aboriginal population of interior south-central South America was culturally diverse and highly fragmented. The northern basins of the Alto Paraná and Paraguay rivers were inhabited primarily by Guayacurú- and Bororo-speaking peoples. Nomadic hunter-gatherers roamed Mato Grosso and the Pantanal, where the sea-

The original inhabitants

sonally abundant fish were of particular importance. To the south, along the Paraguay and Alto Paraná rivers, the Guaraní occupied semipermanent villages and cleared patches of surrounding forest for the cultivation of corn (maize), cassava (manioc), and other crops. West of the Paraguay River, the Gran Chaco supported sparse populations of nomadic foragers, such as the Lengua and Abipón, as did the Argentine Pampa on the southern shore of the Río de la Plata.

In what is now Paraguay, the Spaniards and Portuguese interbred freely with the indigenous peoples. Consequently, the present riverine population of the country largely is mestizo, or mixed, and Guaraní as well as Spanish is the common language. In Brazil, however, miscegenation was less general, and some groups of indigenous peoples have remained relatively intact, forming isolated nuclei. Others, like the Bororo, Tereno, and Bacairi, constitute minorities who have adopted some aspects of Christianity and Brazilian culture but who also have retained separate tribal identities and live on the fringe of the region. A significant element in the population of the Alto Paraná region of Brazil consists of descendents of mainly German and Japanese immigrants.

The shores of the Río de la Plata now contain the highest population concentrations of the river system and are the most densely populated areas of both Argentina and Uruguay. In contrast to most of the upper basin, this region is populated mainly by people of European descent. Buenos Aires, on the Argentinian shore, is the centre of one of the world's largest urban agglomerations and contains about a third of Argentina's population; Montevideo, on the Uruguayan side, is considerably smaller but still is one of South America's major cities.

The economy. *Resource exploitation.* The economic usefulness of these river systems is not commensurate with the area that they drain. Economic uses to which these rivers might lend themselves, such as irrigation or hydroelectric power, are difficult to achieve. The swamps of the Pantanal and the Chaco long made agriculture a virtual impossibility in these areas. The gradual use of the potential electric power represented by sites such as Itaipu or Foz do Areia, however, has begun to stimulate the development of industry and agriculture.

The economic development of the upper basin has been hindered by limited natural resources. Paraguay and adjacent parts of Brazil and Argentina are virtually devoid of mineral deposits. Industry, therefore, is limited to processing agricultural products, mainly hides and starch from cassava, or gathering such forest products as petitgrain oil from naturally growing citrus trees. Decorative hardwoods from eastern Paraguay and softwood timber (*Araucaria*) have declined in importance as stocks have been depleted. Cattle grazing long has dominated the Chaco, Mato Grosso, and the grasslands of eastern Paraguay, but the difficulty of transporting beef to distant markets has restricted most production to local consumption. Small-scale farming of food crops occupies most of the rural population. Along the Alto Paraná, successful plantations have been established that produce maté, tung oil, and tea. Agriculture

The lower basin also has been a traditional region of livestock production. Corrientes province and the Pampa region near Río de la Plata in Argentina and the prairies of Uruguay long have supported ranches raising high-quality cattle and sheep; livestock products still dominate the exports of both countries. Crops of cotton, flax, and corn are important along the Argentine shore of the Paraná. Uruguay has attempted to diversify its agriculture, but nearly all of the land area is still used for grazing.

Transportation. A major impediment to economic development in the upper part is poor navigation. A large portion of the upper basin cannot be used at all or is limited to vessels with shallow drafts. Elsewhere, navigation can be maintained in many areas only by constant dredging and renovation of port facilities. The value of these river systems as commercial arteries, therefore, is concentrated on the lower reaches.

The current, narrowness, curves, and presence of exposed rock sills on the Alto Paraná restrict considerably the size of vessels, and several rapids can be passed only with the use of winches to pull the vessels. The river's narrowness, whirlpools, and the increased speed of the current make navigation more dangerous as the mouth of the Iguaçu is approached. A railroad to the town of Guaíra circumvents the Itaipu hydroelectric site and opens up another 400 miles of navigable river farther upstream; in addition, a nearby bridge across the river between Brazil and Paraguay and another across the Iguaçu between Brazil and Argentina are vital links in the regional road system. On the Paraguay River, navigation is complicated by the large seasonal fluctuations in the water level. Small oceangoing ships can reach Asunción but risk being stranded during the dry season. Shallow-draft vessels are able to reach Corumbá, Braz., at all seasons, and smaller craft can reach Cáceres.

By contrast, large oceangoing vessels can travel up the lower Paraná as far as Santa Fe or Paraná. Ocean trade also can reach Concepción del Uruguay directly by the Uruguay River. Long fleets of barges carry the bulk of the river freight. For the people living along its shores, the Río de la Plata always has been useful as a waterway. As a thoroughfare for trade, the estuary is important not only to the people of the coasts but also to the inhabitants of the most remote areas of the drainage basin. Buenos Aires is one of the principal seaports of the world and is the main

Bridge over the Alto Paraná River between Ciudad del Este, Paraguay, and Foz do Iguaçu, Braz.

port of Argentina. Both Buenos Aires and Montevideo are concerned primarily with meat and grain exports from the hinterland; the refrigerators, flour mills, and shipyards required for this trade are located in the coastal zone, as are factories for vegetable oils, textile industries, metallurgical plants, and petroleum refineries.

History. *Early European exploration and settlement.* The Río de la Plata was first explored by Europeans in 1516, when an expedition led by Juan Díaz de Solís, chief navigator of Spain, traversed the estuary as part of its effort to find a route to the Pacific; the estuary was temporarily named in memory of Díaz de Solís after his death on its shores at the hands of unfriendly Charrua Indians. The Portuguese navigator Ferdinand Magellan reached the estuary in 1520 and explored it briefly before his expedition continued on its circumnavigation of the globe. Between 1526 and 1529 the Italian explorer Sebastian Cabot made a detailed study of the estuary and explored the Uruguay and Paraná rivers. Cabot ascended the Paraná as far as the present city of Asunción, Paraguay, and also traveled some distance up the Paraguay River; at Asunción he obtained silver trinkets in barter with the Guaraní Indians, and his interest in these objects gave rise to the estuary's permanent name, Río de la Plata, in the hope that it might indeed become a river of silver.

Survey of Sebastian Cabot

Several failed attempts at establishing settlements on the south shore of the estuary (notably near the present location of Buenos Aires) eventually led to explorations upriver and to the founding of Asunción in 1537; Buenos Aires was not refounded until 1580. By about 1610 Jesuit priests had established the first of more than 30 mission settlements that, until the expulsion of the Jesuits in 1767, were the heart of what became known as the "Jesuit Empire." Remarkable ruins of mission churches in Argentina's Misiones province and in eastern Paraguay are all that remain of this extraordinary enterprise. Throughout the Spanish colonial era the Río de la Plata remained a backwash of the empire. The estuary was virtually closed to legal commerce, and Spain ignored the region until Portuguese and English ambitions threatened to expand into the estuary in the 1760s.

Mapping of the basin. The Spaniard Sebastián del Cano, who accompanied the Magellan expedition, was able to include relatively accurate markings of the Paraná, Paraguay, and Uruguay rivers in the map of the estuary that he drew up in 1523. Further cartographic work by agents of the Spanish crown was supplemented considerably by that of Jesuit missionaries, who first covered the entire basin of the Paraná (including the Paraguay River) in an extensive series of maps produced in the 17th century. In the second half of the 18th century, commissioners demarcating the frontiers between Spanish and Portuguese possessions produced a new series of maps. Of later cartographers, the Spanish naturalist and geographer Félix de Azara and the French physician and naturalist Martin de Moussy are the most important.

The region since 1800. Navigation of the river system became a problem when the independent states of Argentina, Uruguay, Brazil, and Bolivia emerged on its courses. Territorial conflicts and restrictions on navigation caused several wars, culminating in the Paraguayan War, or War of the Triple Alliance (1864/65–70), in which Francisco Solano López led Paraguay in a disastrous struggle against Brazil, Uruguay, and Argentina. In the 20th century, similar conflicts, sharpened by rumoured oil wealth, resulted in the Chaco War (1932–35) between Paraguay and Bolivia.

The development of agricultural wealth, particularly in Argentina, resulted in greater appreciation of the commercial value of these river systems after the mid-19th century. Beginning in the 1850s, thousands of German, French, and Italian colonists settled along the lower Paraná River in Santa Fe province. In the 1890s, German pioneers began to carve agricultural settlements from the forests along the Alto Paraná in Paraguay and Argentina. These people later were followed by other Europeans and by a significant number of Japanese.

Wheat, beef, wool, cotton, and hides entered the river and world trade in increasing quantities from Argentina and Uruguay, while from Brazil and Paraguay came forest and tropical products and maté. Port construction and dredging made Buenos Aires more valuable as a seaport, and by 1902 similar improvements had been completed at Rosario. Channel marking, soundings, dredging, and other aids to navigation became a responsibility of all the riparian states. (W.F.O./D.O./N.R.S.)

SÃO FRANCISCO RIVER

One of the great rivers in South America, the São Francisco, 1,811 miles (2,914 kilometres) long, is the fourth largest river system of the continent and the largest river wholly within Brazil. It has been called the "river of national unity" because it long has served as a line of communication between Brazil's maritime and western regions and between the northeast and the south. The river is named for the 16th-century Jesuit leader St. Francis Borgia (São Francisco de Borja). It is an important source of hydroelectric power and irrigation for eastern and northeastern Brazil. The São Francisco basin occupies some 243,700 square miles (631,200 square kilometres).

Physical features. *Physiography.* The São Francisco River rises at about 2,400 feet (730 metres) above sea level on the eastern slope of the Serra da Canastra in southwestern Minas Gerais state, about 150 miles northwest of the city of Belo Horizonte. The river flows for more than 1,000 miles northward across the states of Minas Gerais and Bahia, through the extensive Sobradinho Reservoir, to the twin cities of Juàzeiro and Petrolina. In this stretch the river receives its main left-bank tributaries—the Para-

The upper course

The São Francisco River and its drainage network.

catu, Urucuia, Corrente, and Grande rivers—and its main right-bank tributaries—the Verde Grande, Paramirim, and Jacaré.

About 100 miles below Petrolina, the São Francisco begins a great curve to the northeast and enters a stretch of rapids and falls 300 miles long. In this section the river forms the border between the states of Bahia to the south and Pernambuco to the north. The upper rapids are navigable during periods of high water, but below Petrolina the river is impassable. The broken course—during which the São Francisco receives the São Pedro, Ipueira, and Pajeú rivers—culminates in the great Paulo Afonso Falls. At the top of the falls, the river divides suddenly and violently and cuts three successive falls through the granite rocks for a total drop of about 275 feet. Below the falls the river flows about 190 miles to its relatively narrow mouth on the Atlantic Ocean, about 60 miles northeast of Aracaju. In its lower section the São Francisco is joined by the Moxotó River and forms the border between the states of Sergipe to the south and Alagoas to the north.

Climate and hydrology. The river basin is largely a tropical desert, and the climate generally is hot and dry. The average maximum temperature for the region is 92° F (33° C) and the average minimum 66° F (19° C). The highest temperature recorded is 107° F (42° C). The prevailing winds are from the southeast, east, and northeast. Rainfall is deficient over most of the area, and drought is frequent. Average annual precipitation measures 20 to 40 inches (510 to 1,020 millimetres) in most of the middle basin and 40 to 80 inches in the headwaters region and below the Paulo Afonso Falls; most of the falls zone receives less than 20 inches annually, and a small portion receives less than 10 inches. Precipitation occurs during the summer months (December to March), while the rest of the year—the winter season—is dry.

Because the São Francisco River flows through the driest region of Brazil, it is subject to seasonal changes in water level of up to 30 feet. All its tributaries run dry during the dry season. Until the river was dammed at Juàzeiro, the riverbed upstream from there would vary from a narrow channel during drought periods to a much wider channel during the rainy season; the Sobradinho Reservoir now holds water throughout the year, although its level can vary considerably.

Plant life. The upper (southern), relatively wet part of the basin is covered with savanna (grassland with patches of trees), called *cerrados,* and with forests of mixed evergreen and deciduous trees. Hardwoods include the jacaranda, Brazilian cedar (*cedro*), and vinhatico; cochineal cactus, aloes, and vanilla plants also grow there. Characteristic of the middle river basin is caatinga vegetation (from the Tupí-Guaraní word meaning "white forest"), an area of stunted, often thorny forest. Among the dominant tree species are the leguminous *catingueiras* and *juremas,* members of the euphorbia (spurge) family, and the barriguda tree (a palmlike tree of the Bombacaceae family); bromeliads (plants with basal, often spiny leaves) and a wide variety of cacti constitute the undergrowth. Economically useful species include the caroa, used for its fibres; the castor oil plant; oil, carnauba, and date palms; and cashew and rubber trees.

Caatinga vegetation

The falls zone lies in the dry Brazilian interior, known as the *sertão.* The small amount of rainfall in the area permits the growth of only xerophytic (drought-resistant) brush and grasses. The dry forests of the hilly uplands support carnauba and babassu palms and such plants as the cactus, the rock rose, and the rhododendron. One unusual plant of the *sertão* region is the evergreen *aveloz,* which can grow to heights of 15 to 20 feet and is used as a hedgerow to mark field boundaries. Underground water in the region often is too saline for irrigation or drinking.

The lower São Francisco flows through a floodplain of fine silt soils, and vegetation thrives there. Most of the original tropical semi-deciduous forest that grew along the river, however, has been cleared for agriculture.

Animal life. Animals are not abundant in the São Francisco basin. Among the mammals are various marsupials, rodents (including the large capybara), and skunks; a small wild cat called the *gato de mata;* the titi monkey, which lives in the more wooded areas; and the armadillo, which is ideally suited to the harsh *sertão* environment.

Birds include the partridgelike tinamous, notably the red-winged tinamou (*Rhynchotus rufescens*), as well as doves, parrots, the yellow finch, and the ubiquitous vulture. The drier areas of the basin have some smaller birds, such as hummingbirds and the sabia, a songbird of the thrush family. The birds of the São Francisco basin are greatly prized in Brazil as pets. Their numbers have been reduced, however, by the clearing of habitat for crops and pastures and by hunting.

The river's fish are an important food source. Among the major food species are robalo (a kind of snook), sardines, *pocomó,* and *sarapó.* In addition, the river mouth contains manatees (sea cows) and various species of sharks.

The people and economy. The São Francisco basin in general is inhabited by people of mixed Portuguese, Indian, and African descent. Most people in the coastal region, however, are of predominantly African ancestry, since that region was the main destination of the slave trade to Brazil.

Cassava cultivation along the São Francisco River downstream of Pirapora, Minas Gerais state, in Brazil.

The upper-middle basin is an agricultural region in which cotton, beans, rice, and corn (maize) are grown. The region also produces pineapples, potatoes, maté (tea), melons, sugarcane, coffee, castor and cottonseed oils, and rum. Its major urban centre is Pirapora, Minas Gerais.

Vazante agriculture

The dry *sertão* is used largely for livestock grazing, mainly cattle, goats, sheep, and donkeys. Along the riverbanks *vazante* agriculture is practiced: during the rainy season, shallow waterbeds (*vassantes*) are enclosed by bars of river sediment and support the cultivation of cassava (manioc), corn, beans, and melons. Truck crops are grown on the riverbanks, and carnauba wax, caroa fibre, and rubber are collected. The major city is the market centre of Salvador, the capital of Bahia state. Most of the lower river valley is dry and suitable only for grazing. On the coastal lowlands, rice and sugarcane are grown.

The São Francisco basin contains deposits of agate, gold, iron, diamonds, opals, antimony, galena (the principal ore of lead), mercury, copper, arsenic, manganese, cobalt, and pyrites. There also are deposits of salt, sulfur, alum, marble, limestone, and clay. The river's hydroelectric potential, however, is its most important resource. The main centres of power generation for northeastern Brazil are at the Paulo Afonso Falls and the dam impounding the Três Marias Reservoir. In addition, hydroelectric plants at dams on the upper and lower stretches of the river supply power to the coastal cities of Salvador, Aracaju, and Recife.

The river basin also is important as a source of irrigation water. The largest storage dam, near Petrolina and Juàzeiro, impounds the vast Sobradinho Reservoir. In addition to the Três Marias Reservoir, there is a large reservoir at Pedra d'Água, and there are plans for a reservoir on the Jaguaribe and a 300-mile-long irrigation canal to join the São Francisco at Petrolina to branches in eastern Pernambuco, Paraíba, and eastern Ceará states.

The river is navigable for small steamers for more than 1,000 miles from Pirapora, Minas Gerais, to Petrolina and Juàzeiro. Sandbars at the river's mouth prevent the entry of deep-draft ocean vessels. There is a railway bridge across the river at Pirapora, and another bridge connects the cities of Petrolina and Juàzeiro. Although river transport is slow and difficult, the São Francisco is an important link between the mining districts of Minas Gerais and roads that radiate north and east from Juàzeiro.

Study and exploration. The earliest European forays beyond the coast and into the São Francisco basin consisted of slave raids on the Indian population. Other than some scattered settlement for cattle ranching, little attention was given to the interior until the 19th century. Considerable scientific study was carried out in northeastern Brazil following the malaria epidemic of 1938, and the disease was eradicated from the region by 1940. Modern research has included groundwater inventories, aerial photographic and radar surveys of the basin, and exploration for economically exploitable minerals. In addition, early Indian settlements have been the focus of archaeological excavations, and the region's plants have been studied for their possible pharmaceutical value. (C.E.Ca./K.E.W.)

BIBLIOGRAPHY

General works. Broad geographic surveys of the region and of individual countries include PRESTON E. JAMES and C.W. MINKEL, *Latin America*, 5th ed. (1986); GILBERT J. BUTLAND, *Latin America*, 3rd ed. (1972); HAROLD BLAKEMORE and CLIFFORD T. SMITH, *Latin America*, 2nd ed. (1983); and ARTHUR MORRIS, *South America*, 3rd ed. (1987). JAN KNIPPERS BLACK (ed.), *Latin America: Its Problems and Its Promise*, 2nd ed. (1991), is a collection of authoritative studies in physical, economic, and political geography. Useful annual publications include the *South American Handbook*, a travel guide; and *South America, Central America, and the Caribbean* (irregular), published by Europa Publications. (C.W.M.)

Physical and human geography. *Geology:* CARLOS SCHOBBENHAUS *et al.* (eds.), *Geologia do Brasil* (1984), is a thorough account (in Portuguese) of the geology of the continent's largest country. English-language discussions of the continent's geology are found mostly in periodical literature, such as A. FORERO SUAREZ, "The Basement of the Eastern Cordillera, Colombia: An Allochthonous Terrane in Northwestern South America," *Journal of South American Earth Sciences*, 3(2–3):141–151 (1990); VICTOR A. RAMOS, "The Birth of Southern South America," *American Scientist*, 77(5):444–450 (1989), and "The Tectonics of the Central Andes," in SYDNEY P. CLARK, JR., B. CLARK BURCHFIEL, and JOHN SUPPE (eds.), *Processes in Continental Lithospheric Deformation* (1988), pp. 31–54; and JORGE JULIAN RESTREPO and JEAN FRANCOIS TOUSSAINT, "Terranes and Continental Accretion in the Colombian Andes," *Episodes*, 11(3):189–193 (1988). (V.A.R.)

The land: Descriptions of the physical geography of South America are provided in the general works cited above and in E.J. FITTKAU *et al.* (eds.), *Biogeography and Ecology in South America* (1969); A.C.S. WRIGHT and J. BENNEMA, *The Soil Resources of South America* (1965); JOSÉ A.J. HOFFMAN (compiler), *Atlas climático de America del Sur* (1975), with text in Spanish and English; and such classic accounts as CHARLES-MARIE DE LA CONDAMINE, *A Succinct Abridgement of a Voyage Made Within the Inland Parts of South America*, trans. from French (1747); and ALEXANDER VON HUMBOLDT, *Personal Narrative of Travels to the Equinoctial Regions of the New Continent, During the Years 1799–1804*, trans. from French, 7 vol. (1814–29), available also in later editions. (C.W.M.)

Works on South America's plant and animal life include ADRIAN FORSYTH and KENNETH MIYATA, *Tropical Nature* (1984), an introduction to a number of Neotropical organisms in their forest setting, by two well-traveled naturalists; JEAN DORST, *South America and Central America* (1967), a well-illustrated natural history; JOHN C. KRICHER, *A Neotropical Companion* (1989), an exploration of the tropical rain forest, tropical savannas, and coastal ecosystems; GEORGE GAYLORD SIMPSON, *Splendid Isolation: The Curious History of South American Mammals* (1980), an authoritative introduction to the evolution of South American mammalian fauna that was later complemented by the so-called "Great American Biotic Interchange," in which North American species migrated southward; MICHAEL A. MARES and DAVID J. SCHMIDLY (eds.), *Latin American Mammalogy: History, Biodiversity, and Conservation* (1991), a collection of articles; ROBERT S. RIDGELY and GUY TUDOR, *The Birds of South America*, vol. 1, *The Oscine Passerines* (1989), a discussion of identification, habitat, behaviour, and range of the species of the group; GHILLEAN T. PRANCE (ed.), *Biological Diversification in the Tropics* (1982), a collection of technical papers on the biotic refuges in northern South America that were caused by climatic change; and FRANÇOIS VUILLEUMIER and MAXIMINA MONASTERIO (eds.), *High Altitude Tropical Biogeography* (1986), a series of specialist scientific papers focusing on the adaptive evolution of specific groups of plants, animals, and insects, principally in the Andes. (D.W.Ga.)

The people: A general survey of ethnic origins, geographic distribution of the various groups, and racial relations is found in MAGNUS MORNER, *Race Mixture in the History of Latin America* (1967); and in MARVIN HARRIS, *Patterns of Race in the Americas* (1964, reprinted 1980). NICOLÁS SÁNCHES-ALBORNOZ, *The Population of Latin America* (1974; originally published in Spanish, 1973); and WILLIAM M. DENEVAN (ed.), *The Native Population of the Americas in 1492*, 2nd ed. (1992), are historical summaries. DARCY RIBEIRO, *The Americas and Civilization* (1971; originally published in Portuguese, 1970), studies the cultural complexes of the Americas. RICHARD GRAHAM (ed.), *The Idea of Race in Latin America, 1870–1940* (1990), is a history of the concept and of governmental politics in connection with it. A useful reference source on the subject is ROBERT M. LEVINE, *Race and Ethnic Relations in Latin America and the Caribbean* (1980). The most comprehensive and convenient work on all aspects of information about the South American Indians remains the monumental JULIAN H. STEWARD (ed.), *Handbook of South American Indians*, 7 vol. (1946–59). On indigenous languages, in addition to specific chapters in the previously mentioned works, see ČESTMÍR LOUKOTKA, *Classification of South American Indian Languages*, ed. by JOHANNES WILBERT (1968). JOSEPH H. GREENBERG, *Language in the Americas* (1987), offers a controversial classification that minimizes the number of Indian language families in the Americas. A useful overview is presented in HARRIET E. MANELIS KLEIN and LOUISA R. STARK (eds.), *South American Indian Languages* (1985). Demographic dynamics are studied in WALTER WILLCOX (ed.), *International Migrations*, 2 vol. (1929–31, reprinted 1961), in which the most complete statistics on mass European immigration before 1930 are interpreted; W.D. BORRIE, *The Cultural Integration of Immigrants* (1959); RICHARD W. WILKIE, *Latin American Population and Urbanization Analysis: Maps and Statistics, 1950–1982* (1984); ECONOMIC COMMISSION FOR LATIN AMERICA, *Dynamics and Structure of the Human Settlement Process in Latin America and the Caribbean* (1984), a United Nations study; and DEBRA A. SCHUMANN and WILLIAM L. PARTRIDGE (eds.), *The Human Ecology of Tropical Land Settlement in Latin America* (1989). (Gr.W.K.)

The economy: General surveys of economic conditions, government policies, foreign economic relations, and social devel-

opments include ELIANA CARDOSO and ANN HELWEGE, *Latin America's Economy: Diversity, Trends, and Conflicts* (1992); JOHN SHEAHAN, *Patterns of Development in Latin America: Poverty, Repression, and Economic Strategy* (1987); JAMES DINSMOOR, *Brazil—Responses to the Debt Crisis* (1990); ROBERT N. GWYNNE, *New Horizons? Third World Industrialization in an International Framework* (1990); PEDRO-PABLO KUCZYNSKI, *Latin American Debt* (1988); and RHYS JENKINS, *Transnational Corporations and Uneven Development: The Internationalization of Capital and the Third World* (1987). Two annuals, *Economic and Social Progress in Latin America*, prepared by the Inter-American Development Bank; and *Economic Panorama of Latin America*, prepared by the United Nations' Economic Commission for Latin America and the Caribbean, offer current information. The roles of natural resources, the environment, and agriculture in the economic development of the continent are examined in DAVID GOODMAN and MICHAEL REDCLIFT (eds.), *Environment and Development in Latin America: The Politics of Sustainability* (1991); JOSEPH S. TULCHIN and ANDREW I. RUDMAN (eds.), *Economic Development and Environmental Protection in Latin America* (1991); MICHAEL J. TWOMEY and ANN HELWEGE (eds.), *Modernization and Stagnation: Latin American Agriculture into the 1990s* (1991); JOHN O. BROWDER (ed.), *Fragile Lands of Latin America: Strategies for Sustainable Development* (1989); DENNIS J. MAHAR, *Government Policies and Deforestation in Brazil's Amazon Region* (1989), a brief treatment; and MERILEE S. GRINDLE, *State and Countryside: Development Policy and Agrarian Politics in Latin America* (1986). Special studies of other aspects of continental economy include FELIPE LARRAÍN and MARCELO SELOWSKY (eds.), *The Public Sector and the Latin American Crisis* (1991); ROSEMARY THORP, *Economic Management and Economic Development in Peru and Colombia* (1991); GARY GEREFFI and DONALD L. WYMAN, *Manufacturing Miracles: Paths of Industrialization in Latin America and East Asia* (1990); and LAWRENCE S. GRAHAM and ROBERT H. WILSON, *The Political Economy of Brazil: Public Policies in an Era of Transition* (1990). (E.C.G.)

Geographic features of special interest. *Landforms:* On the Andes, classic works on the geography and geology include ALAN G. OGILVIE, *Geography of the Central Andes* (1922); and ISAIAH BOWMAN, *The Andes of Southern Peru* (1916). The role of plate tectonics in the formation of the Andes is discussed in R.W.R. RUTLAND, "Andean Orogeny and Ocean Floor Spreading," *Nature*, 233(5317):252–255 (1971); and DAVID E. JAMES, "The Evolution of the Andes," *Scientific American*, 229(2):60–69 (August 1973). HAROLD OSBORNE, *Indians of the Andes: Aymaras and Quechuas* (1952, reissued 1973), is still a useful discussion of the indigenous peoples. More recent works are SHOZO MASUDA, IZUMI SHIMADA, and CRAIG MORRIS (eds.), *Andean Ecology and Civilization* (1985), a collection of conference papers; *Lost Crops of the Incas: Little-Known Plants of the Andes with Promise for Worldwide Cultivation* (1989), a report prepared by a panel of the National Research Council; BENJAMIN S. ORLOVE and GLYNN CUSTRED (eds.), *Land and Power in Latin America: Agrarian Economies and Social Processes in the Andes* (1980); and WILLIAM P. MITCHELL, *Peasants on the Edge: Crop, Cult, and Crisis in the Andes* (1991). The classic of Andean exploration by EDWARD WHYMPER, *Travels Amongst the Great Andes of the Equator* (1892), is available in later editions. (N.R.S.)

Literature in English for the Gran Chaco and Patagonia is scarce. Early descriptions of the Gran Chaco include LUIS JORGE FONTANA, *El Gran Chaco* (1881, reprinted 1977), the diary (in Spanish) of an 18th-century explorer; and JOHN GRAHAM KERR, *A Naturalist in the Gran Chaco* (1950, reprinted 1968), an account of the author's expeditions in 1889–97. More recent discussions of the two regions can be found in the relevant sections of HERBERT WILHELMY and WILHELM ROHMEDER, *Die La Plata Länder: Argentinien, Paraguay, Uruguay* (1963); and PRESTON E. JAMES, *Latin America*, 4th ed. (1969); and in PHILIP CARAMAN, *The Lost Paradise: An Account of the Jesuits in Paraguay, 1607–1768* (1975); BRUCE CHATWIN, *In Patagonia* (1977, reprinted 1988); and JOHN RENSHAW, "Property, Resources and Equality Among the Indians of the Paraguyan Chaco," *Man*, 23(2):334–352 (June 1988). (K.E.W.)

Drainage systems: Introductory overviews of the Amazon River basin include HELEN SCHREIDER and FRANK SCHREIDER, *Exploring the Amazon* (1970), a well-illustrated descriptive book; the treatment of the basin in N. MARK COLLINS (ed.), *The Last Rain Forests* (1990), pp. 110–129; CATHERINE CAUFIELD, *In the Rainforest* (1985); and HILGARD O'REILLY STERNBERG, *The Amazon River of Brazil* (1975). The issue of tropical forest conversion and its ecologic impact came to public attention with the appearance of R.J.A. GOODLAND and H.S. IRWIN, *Amazon Jungle: Green Hell to Red Desert?* (1975). Collections of essays on the basin, often elaborating on this theme, include HAROLD SIOLI (ed.), *The Amazon: Limnology and Landscape Ecology of a Mighty Tropical River and Its Basin* (1984); ROBERT E. DICKINSON (ed.), *The Geophysiology of Amazonia* (1987); MARIANNE SCHMINK and CHARLES H. WOOD (eds.), *Frontier Expansion in Amazonia* (1984); and JOHN HEMMING (ed.), *Change in the Amazon Basin*, 2 vol. (1985). SUSANNA HECHT and ALEXANDER COCKBURN, *The Fate of the Forest: Developers, Destroyers, and Defenders of the Amazon* (1989), is an overarching historical survey, richly documented, with a critical examination of the political, social, and economic background of the escalating degradation of the Amazon environment. Other studies of people and society, mostly with emphasis on Brazil, include MARIANNE SCHMINK and CHARLES H. WOOD, *Contested Frontiers in Amazonia* (1992); JULIE SLOAN DENSLOW and CHRISTINE PADOCH, *People of the Tropical Rain Forest* (1988); EUGENE PHILIP PARKER (ed.), *The Amazon Caboclo* (1985); JOHN HEMMING, *Amazon Frontier: The Defeat of the Brazilian Indians* (1987); and, for recent archaeological discoveries, ANNA C. ROOSEVELT, "Secrets of the Forest," *The Sciences*, 32:22–28 (November/December 1992). Works on resources and ecology include ENEAS SALATI *et al.*, "Amazonia," in B.L. TURNER II *et al.*, *The Earth as Transformed by Human Action* (1990), pp. 479–493; DAVID CLEARY, *The Brazilian Rainforest: Politics, Finance, Mining, and the Environment* (1991); KENT H. REDFORD and CHRISTINE PADOCH (eds.), *Conservation of Neotropical Forests* (1992); HILGARD O'REILLY STERNBERG, "Manifest Destiny and the Brazilian Amazon," in CONFERENCE OF LATIN AMERICANIST GEOGRAPHERS, *Yearbook*, vol. 13 (1987), pp. 25–35; MICHAEL GOULDING, *Amazon: The Flooded Forest* (1989); WILLIAM M. DENEVAN and CHRISTINE PADOCH (eds.), *Swidden-Fallow Agroforestry in the Peruvian Amazon* (1988); PHILIP M. FEARNSIDE, *Human Carrying Capacity of the Brazilian Rainforest* (1986); D.A. POSEY and W. BALÉE (eds.), *Resource Management in Amazonia* (1989); and, on dwindling wildlife, NIGEL J.H. SMITH, *Man, Fishes, and the Amazon* (1981); and KENT H. REDFORD, "The Empty Forest," *BioScience*, 42(6):412–422 (June 1992). Broader surveys of the economic development of the basin include *Minimum Conflict: Guidelines for Planning the Use of American Humid Tropic Environments* (1987), prepared by the United Nations Environment Programme in cooperation with the government of Peru; and STEPHEN G. BUNKER, *Underdeveloping the Amazon* (1985), with an overview of economic history. HENRY WALTER BATES, *The Naturalist on the River Amazons*, 2 vol. (1863, reissued 1989); ALFRED RUSSEL WALLACE, *A Narrative of Travels on the Amazon and Rio Negro*, 2nd ed. (1889, reprinted 1972); and RICHARD SPRUCE, *Notes of a Botanist on the Amazon & Andes*, 2 vol. (1908, reissued 1970), are classics of natural history exploration. WM. LEWIS HERNDON and LARDNER GIBBON, *Exploration of the Valley of the Amazon*, 2 vol. (1853–54), is also informative. (Ja.J.P.)

Detailed studies in Spanish of the physical and human geography of the Orinoco River basin include RAFAEL GÓMEZ PICÓN, *Orinoco, río de libertad*, 2nd rev. ed. (1978); and FRANCISCO TAMAYO, *Los Llanos de Venezuela*, 2nd ed. (1987). The most useful English-language description of the basin still is found in the essays by Alexander von Humboldt in his work cited above in the section on the land. Specialized studies include CARL F. NORDIN, JR., and DAVID PEREZ-HERNANDEZ, *Sand Waves, Bars, and Wind-Blown Sands of the Río Orinoco, Venezuela and Colombia* (1989); and EDWIN D. MCKEE, *Sedimentary Structures and Textures of the Río Orinoco Channel Sands, Venezuela and Colombia* (1989). Among the works on the people of the basin are JOHANNES WILBERT and MIGUEL LAYRISSE (eds.), *Demographic and Biological Studies of the Warao Indians* (1980); and JOHANNES WILBERT, "Geography and Telluric Lore of the Orinoco Delta," *Journal of Latin American Lore*, 5(1):129–150 (Summer 1979), also on the Warao Indians. The settlement of the Llanos is described in JANE M. RAUSCH, *A Tropical Plains Frontier: The Llanos of Colombia, 1531–1831* (1984), and *The Llanos Frontier in Colombian History, 1830–1930* (1993). (Ed.)

English-language sources on the other major river basins are scarce. For the Paraná-Paraguay-Rio de la Plata basin, see M.M. South Asian Arts

South Asia, consisting of the huge subcontinent of India, includes Pakistan, Bangladesh, Sri Lanka (formerly Ceylon), as well as the nation of India itself. In spite of differences in physical appearance, complexion, stature, and other ethnological features, the people of the entire region of South Asia are unified by a common cultural and ethical outlook; a wealth of ancient textual literature in Sanskrit, Prākrit, and regional languages is a major unifying factor. Music and dance, ritual customs, modes of worship, and literary ideals are similar throughout the subcontinent, even though the region has been divided into kaleidoscopic political patterns through the centuries.

The close interrelationship of the various peoples of South Asia may be traced in their epics, as in the *Rāmāyaṇa* and the *Mahābhārata*. Kinship between the gods and heroes of regions far distant from each other is evident, and the place-names themselves often evoke common sources. Moreover, there have been continual attempts to impose a political unity over the region. In the 3rd century BC, for example, the emperor Aśoka had almost all of this region under his sway; in the 11th century AD, Rājendra I Cōḷa conquered almost the whole of India and a good portion of Southeast Asia; and the great Mughal Akbar again achieved this in the 16th century. Though the expansion and attenuation of boundary lines, the bringing together or pulling apart politically of whole regions, have characterized all of South Asian history, the culture has remained essentially one.

The geography of the region encouraged a common adoration of mountains and rivers. The great Himalayas, which form the northern boundary, are the loftiest of mountains and are conceived to be the embodiment of nobility, the abode of immaculate snow, and the symbol of a cultural ideal. Similarly, the great rivers such as the Brahmaputra and the Indus are regarded as the mothers of their respective regions, assuring prosperity through their perennial supply of water.

The association of lakes and springs with water sprites and sylvan fairies, called *nāga*s and *yakṣa*s, is common throughout the region. Karkoṭa, the name of an early dynasty, itself signifies *nāga* worship in Kashmir. Sculptures of *nāga*s and *yakṣa*s found in widespread sites suggest a common spirit of adoration, as do sculptures, paintings, temples, and religious texts that for centuries were preserved within an oral tradition without losing their immaculate intonation. The same classical dance is seen in sculpture in Gandhāra in Pakistan, in Bhārhut in the north, and in Amarāvatī in the south.

The relation of the various arts to each other is very close in South Asia, where proficiency in several arts is necessary for specialization in any one. Thus, it is believed that without a good knowledge of dance there can be no proficiency in sculpture, for dance, like painting or sculpture, is a depiction of all the world. For its rhythmic movements and exposition of emotion, dance also requires musical accompaniments; hence, knowledge of musical rhythm is essential. For the stirring of emotion either in music or in dance, knowledge of literature and rhetoric is believed to be necessary; the flavour (*rasa*) to be expressed in music, dance, sculpture, or painting requires a literary background. Thus all the arts are closely linked together.

The arts were cultivated in South Asia not only as a noble pastime but also in a spirit of dedication, as an offering to the Almighty. Passages in literature refer to princes studying works of art for possible defects. One inscription that mentions the name of the *sūtra-dhāra* ("architect") of the 8th-century Mallikārjuna temple at Pattadakal epitomizes the accomplishments and ideals, in both theory and practice, of the artist.

Artists traditionally have enjoyed a high position in South Asian societies. Poets, musicians, and dancers held honoured seats in the royal court. An inscription mentions the appreciation bestowed by Rājendra Cōḷa on a talented dancer, and the architect of the temple at Tiruvoṟṟiyūr, who was also patronized by Rājendra, was eulogized for his encyclopaedic knowledge of architecture and art. Nonetheless, the folk arts were closely linked with the elite arts. Tribal group dances, for example, shared common elements with classical art, dance, and music. Among the artistic traditions of the Indian subcontinent, sculpture in the round (*citra*) is considered the highest artistic expression of form, and sculpture in relief (*ardhacitra*) is next in importance. Painting (*citrābhāsa*, literally "the semblance of sculpture") ranks third. Feeling for volume was so great that the effect of chiaroscuro (*i.e.*, use of light and shade to indicate modelling) was considered very important in painting; a passage from a drama of the 5th-century poet Kālidāsa describes how the eye tumbles over the heights and depths suggested in the modelling of a painting. A classical text on art, *Citrasūtra* enumerates noteworthy factors in paintings: the line sketch, firmly and gracefully drawn, is considered the highest element by the masters; shading and depiction of modelling are valued by others; the decorative element appeals to feminine taste; and the splendour of colour appeals to common taste. The use of a minimum of drawing to produce the maximum effect in suggesting form is considered most admirable.

Portraits play an important role in the visual arts of South Asia, and there are many literary references to the effective depiction of portraits both in painting and in sculpture. A 6th-century text, the *Viṣṇudharmottara*, classifies portraiture into natural, lyrical, sophisticated, and mixed, and men and women are classified into types by varieties of hair—long and fine, curling to right, wavy, straight and flowing, curled and abundant; similarly, eyes may be bow-shaped, of the hue of the blue lotus, fishlike, lotus-petal-like, or globular. Artistic stances are enumerated, and principles of foreshortening are explained. Paintings or sculptures were believed to take after their creators, even as a poem reflects the poet.

Although South Asia has continually been subjected to strong outside influences, it has always incorporated them into native forms, resulting not in imitation but in a new synthesis. This may be seen even in the art of the Gandhāra region of Pakistan, which in the 4th century BC was immersed in Greco-Roman tradition. In the sculpture of this period Indian themes and modes have softened the Western style. Foreign influence is evident after the invasion of the Kushāns in the 1st century AD, but the native element predominated and overwhelmed the foreign influence. During the Mughal period, from the 16th century, when Muslims from Central Asia reigned in South Asia, the blend of Iranian and Indian elements produced a predominantly Indian school that spread throughout the region, making it a unified cultural area under imperial rule. The influence of Islāmic art was enhanced by the second Mughal emperor, Humāyūn, who imported painters from the court of the Shāh of Persia and began a tradition that blended Indian and Persian elements to produce an efflorescence of painting and architecture.

Art in all these regions reflects a system of government, a set of moral and ethical attitudes, and social patterns. The desire of kings to serve the people and to take care of them almost as offspring is evident as early as the 3rd century BC. The ideal of the king as the unrivalled bowman, the unifier, the tall and stately noble spirit, the sacrificer for the welfare of the subjects, and the hero of his people (who conceive of him on a stately elephant) is comprehensively illustrated in a magnificent series of coins from the Gupta Empire of North India of the 4th–6th centuries. The concepts of righteous conquest and righteous warfare

are illustrated in sculpture. The long series of sculptures illustrating the history of the South Indian Pallava dynasty of the 4th–9th centuries gives an excellent picture of the various activities of government—such as war and conquests, symbolic horse sacrifices, the king's council, diplomatic receptions, peace negotiations, the building of temples, appreciation of the fine arts (including dance and music), and the coronation of kings—all clearly demonstrating what an orderly government meant to the people. Similarly, moral attitudes are illustrated in sculptures that lay stress on *dharma*—customs or laws governing duty. The doctrine of *ahiṃsā*, or noninjury to others, is often conceived symbolically as a deer, and the ideal of a holy place is represented as a place where the deer roams freely. The joy in giving and renunciation is clearly indicated in art. Sculptures illustrate simple and effective stories, as from the *Pañca-tantra*, one of the oldest books of fables in the world. The spirit of devotion, faith, and respect for moral standards that has throughout the centuries pervaded the subcontinent's social structure is continuously represented in South Asian painting and sculpture.

Bibliography 708

Literature

The peoples of South Asia have had a continuous literature from the first appearance in the Punjab of a branch of the Indo-European-speaking peoples who also settled all of Europe and Iran. In India this branch of Indo-Aryans, as they are usually called, met earlier inhabitants with different languages and no doubt a different culture—possibly a culture akin to that of the Indus Valley civilization, which had a script, and perhaps a literature of its own, of which nothing is known. Certain to have been settled in India were peoples who spoke languages of Dravidian origin, as well as other languages, called Munda, now preserved only by aboriginal tribes, which show affinities with the languages of Southeast Asia.

The earliest literature is of a sacred character and dates from about 1400 BC in the form of the Rigveda. This work stands at the beginning of the literature of the Veda, or canonical Hindu sacred writings, which as a whole is roughly contemporary with the settlement of the Indo-Aryan peoples in the Punjab and farther east, in the mesopotamia of the Ganges and Yamunā rivers. The language of the Rigveda, which is a compilation of hymns to the high gods of the Aryan religion, is complex and archaic. It was simplified and codified in the course of the centuries from 1000 to 500 BC, which saw the development of prose commentaries called the *Brāhmaṇas*, *Āraṇyakas*, and *Upaniṣads*. While there must have been a long tradition of grammarians, the final codification of the language is ascribed to Pāṇini (5th or 6th century BC), whose grammar has remained normative for the correct language ever since. This language is called Sanskrit (Tongue Perfected). Sanskrit has had a scarcely interrupted literature from about 600 BC until today, but its greatest efflorescence was in the classical period, from the 1st to 7th centuries AD. Because it was identified with the Brahminical religion of the Vedas, reform movements such as Buddhism and Jainism disdained the use of Sanskrit and adopted literary languages—amalgams of different dialects of the parent language—of their own, Pāli in Buddhism and Ardhamāgadhī in Jainism. These languages, usually called Prākrits—that is, derivative as well as more "natural" languages—produced a vast and, again, mostly sacred literature. In a further development of these dialects, the early beginnings can be seen of modern Indo-Aryan languages of northern India: Bengali (also the language of Bangladesh), Hindi (the official language of the Republic of India since 1947), Rajasthani, Punjabi, Gujarati, Marathi, Kashmiri, Oriya, Assamese, and Sindhi, each of which produced a literature of its own. Their names are derived from the regions in which they are spoken, regions with uncertain boundaries, where the different dialects fused at the borders. They all retained a close family resemblance that made bilingualism easy and a fact of Indian literary life.

Far more marked was the difference between Indo-Aryan speech and the languages of the Dravidian family, which are structurally wholly different, though in time a measure of convergence took place. Among them, the oldest recorded is Tamil, now the language of Tamil Nadu (Madras) state and of northern Sri Lanka, whose literature goes back to the early centuries of the Christian Era. Later to be put to literary uses were the cognate Telugu (Andhra Pradesh), Kannada (or Kanarese, Mysore state), and Malayalam (Kerala state) languages.

Influence of Sanskrit

In spite of this linguistic differentiation, the literatures composed in all of these languages reflect, in different degrees, the monumental influence of Sanskrit literature, Sanskrit being the universal Indian language of culture. This influence was one of both substance and form: in substance it provided the basic themes of literary enterprise, notably through the epics, the *Mahābhārata* and *Rāmāyaṇa*, the Hindu popular texts of the *Purāṇas*, especially the *Bhāgavata*, and the mythological repertory that came with Sanskritic Hinduism; in form, Sanskrit belles lettres bequeathed models of literary composition, and Sanskrit poetics provided the aesthetic theory underlying the models. The impact of Islām created a new language, Urdu (from Persian: Camp), based on Hindi; Urdu was the lingua franca of the army. Urdu was used later for literature and at present is the mother tongue of most Indian Muslims and their brethren in Pakistan. Its influence, however, does not compare with that of Sanskrit.

Comparable to the impact of Sanskrit, but far more alien, is that of English, which began to assert itself in the 18th century. The language brought with it new literary forms that were gradually adapted to the old ones, producing new genres—without necessarily giving up the older ones—in the local languages and giving rise to an

interesting literature in the English language. Once more, a universal cultural language to a large extent unified aims in the scattered languages; English still plays this role, though it appears to be slowly declining.

SANSKRIT, PĀLI, AND PRĀKRIT LITERATURES: 1400 BC–AD 1200

Sanskrit: formative period (1400–400 BC). The oldest document in the literature of South Asia is the Rigveda, or Veda of the Stanzas (*c.* 1400 BC), the fundamental text of Brahminical Hinduism. Not literary but religious-magical in its purposes, it is mostly a compilation of hymns, dedicated to a number of gods of the Vedic religion. They have the regular structure of an invocation: the attention of the god is evoked; a brief account of some of his feats is given, to hold his attention; and an exhortation for his help concludes the hymn. The poets, of whom little is known, appear to have come at the close of a priestly poetical tradition, rivalling one another in allusions to obscure exploits, in language often opaque and at times intended to mystify. Nevertheless, the Rigvedic hymns include lines of great beauty. They may occur in a riddling verse, such as "When the ancient Dawns first dawned, the great Syllable was born in the footsteps of the Cow," alluding to the birth of speech at the beginning of creation. Or they may occur in poetry addressed to a deity whose beauty inspires the poet to well-turned lines. To the Dawns, for example: "They approach equally in the east, spreading themselves equally from the same place./ The Goddesses waking from the seat of order, like herds of kine set loose, the Dawns are active"; or to the goddess of the night: "Night coming on, the goddess shines/ In many places with her eyes:/ All-glorious she has decked herself./ Immortal goddess, far and wide/ She fills the valleys and the heights:/ Darkness with light she overcomes."

Nonsacred verses are very rare in the Rigveda, but, when they occur, they can be quite powerful, as in a hymn of a gambler, who is speaking:

> It pains the gambler when he sees a woman,
> Another's wife, and their well-ordered household:
> He yokes these brown steeds early in the morning,
> And, when the fire is low, sinks down an outcast.
>
> "Play not with dice, but cultivate thy cornfield;
> Rejoice in thy goods, deeming them abundant:
> There are thy cows, there is thy wife, O gambler."
> This counsel Savitri the kindly gives me.

Influence of the Rigveda on Sanskrit poetry

Although not literary in purpose, the Rigveda had a decisive influence on the form of Sanskrit poetry: except for narrative verse, the basic unit of all subsequent poems (no matter how many verses they consist of) is the single stanza that contains one complete thought.

The second Veda (*c.* 1200 BC), the Yajurveda (Veda of the Yajus [Formulas]), contains sacred formulas recited by a group of priests at the great Vedic sacrifices; and the third (*c.* 1100 BC), the Sāmaveda (Veda of the Chants), is in essence an anthology of the Rigveda. More literary interest attaches to the fourth Veda (1200 BC), the Atharvaveda (an *atharvan* was a special priest), which contains hymns, incantations, and many magic charms.

The succeeding literature (*c.* 1000–700 BC), the *Brāhmaṇas* ("Disquisitions About the Ritual"), continues not the poetry but the liturgical concerns of the Rigveda. They were written in a dry, expository prose, so that only their narrative portions have any literary interest. Much the same is true of the next layer of Vedic texts (800–600 BC), the *Āraṇyakas* ("Books Studied in the Forest").

The *Upaniṣads*

But the picture changes in the *Upaniṣads* (*c.* 1000–500 BC; "Collections of Esoteric Equations"). These prose texts at times convey the actual mode of teaching of a revered sage, in a style that can be strikingly intimate:

> "Bring me a fruit of that *nyagrodha* (banyan) tree."
> "Here it is, venerable Sir."
> "Break it."
> "It is broken, venerable Sir."
> "What do you see there?"
> "These seeds, exceedingly small, venerable Sir."
> "Break one of these, my son."
> "It is broken, venerable Sir."
> "What do you see there?"
> "Nothing at all, venerable Sir."
> The father said: "That subtle essence, my dear, which you do not perceive there—from that very essence this great *nyagrodha* arises. Believe me, my dear."

While the older *Upaniṣads* are in prose, the later ones, dating from around 500 BC, mark a shift back to verse. They are the oldest examples of didactic verse, a genre that later gained enormous popularity.

The contribution of late-Vedic texts to later literature is preeminently that of the development of an expository prose style and the evolution of a sacred language, which, in order to be effective, must be completely correct. Thus, the Vedic religion evolved a science of phonetics and, later, of grammar, which was summed up in the 5th or 6th century BC by the grammarian Pāṇini in *Aṣṭādhyāyī* ("Eight Chapters"), a book that was to become basic to Sanskrit education. This language, Sanskrit, remained the language *par excellence* for later literature and was used for literary purposes until the 13th century and, epigonically, until today.

Sanskrit: epic and didactic literature (400 BC–AD 1000). After the formative period of the Vedic age, literature moved in several different directions. The close of the Vedic period was one of great cultural renewal, with the founding of the new monastic religions of Buddhism and Jainism (6th century BC) and the more slowly emerging rearticulation of Brahminism into Hinduism. Neither the earliest Buddhists nor the Jains availed themselves of Sanskrit in their preachings, apparently viewing the language as the preserve of a Brahmin elite. Sanskrit continued in derivative works of Vedic inspiration and above all in the *Mahābhārata* and the *Rāmāyaṇa*.

Mahābhārata. From references in Vedic literature it appears that side by side with the ritual texts there flourished a more secular literature carried on by bards. Originally charioteers to noblemen and thus witnesses of their feats, they chronicled the martial history of the families to which they were attached. From these beginnings, part chronicle, part panegyric, developed the epic style.

Like most Sanskrit poetry, the *Mahābhārata* consists of couplets, two successive lines with the same metre. Generally, one metre is used throughout the poem, though for stylistic effects other metres may be interspersed. The epic metre, or *śloka,* is a very fluid one that lends itself excellently to improvisation. The *Mahābhārata* is the longest poem in history, with about 100,000 couplets, more than seven times the size of Homer's *Iliad* and *Odyssey* combined. Its characters go back to around 1000 BC, but in its present form the epic could not have been composed before 400 BC. From that time until AD 400, it underwent continuous elaboration, by insertions of episodes (one of which is related in the religious poem called the *Bhagavadgītā*), accounts of separate adventures of the heroes, tales generated by their ancestors, and so on; and in the end it became a storehouse of general Hindu lore, with lengthy didactic books inserted.

The main narrative of the *Mahābhārata* recounts the growing up of two sets of cousins, both of whom aspire to a throne, the title to which is clouded. The protagonists, the Pāṇḍavas, stake their possessions in a dice game with the antagonists, the Kauravas, who are in effective control of the realm; they lose, and must live for 13 years in exile. This the five brothers do, along with the wife they hold in common. Upon their return from exile, they are refused their promised share of the kingdom, and, though parleys are held, war is inevitable. All of the Indian dynasties and tribes take sides in a war that lasts for 18 days, which only seven warriors, among them the Pāṇḍavas, survive. Noteworthy is the picture of gloom and doom that the *Mahābhārata* draws: there is little extolling of the heroic virtues of prowess and gallantry; rather, the wastefulness and bloodshed of war are pointed up, prefiguring a later concern with *ahiṃsā,* or nonviolence.

This summary does no justice to an extremely complex story with hundreds of participants, but it sketches the general outline of epic events. The main story has an unmistakable epic and heroic tone, and some of the events and encounters are completely comparable to those in epics of other peoples. But narrative and stylistic unity

are disrupted by the inserted quasi-related and unrelated secondary episodes, each of which has a style of its own, ranging from light badinage to sonorous morality tales. It was in these episodes that the *Mahābhārata* lived on and greatly influenced succeeding literature; the story of Śakuntalā, for example, which the great 5th-century classical poet Kālidāsa embroidered, the slaying of Śiśupāla, the battle of the hero Arjuna with the mountain man, the story of Nala, and so on. But the most celebrated episode surely is the *Bhagavadgītā*.

The *Bhagavadgītā*

The influence of the *Bhagavadgītā* ("Song of the Lord") has mainly been on the development of Hindu religion and philosophy. Still, it is open to doubt whether it would have exerted this influence were it not for its poetry. Like most of the *Mahābhārata*, the style is simple and direct, not given to embellishment; nevertheless, the poem often reaches the height of expressiveness, as in its evocation of the theophany of Krishna as Vishnu, in the 11th of its 18 chapters. It led to imitations such as the *Īśvaragītā*, ("Song of the Lord [Śiva]"), also in the *Mahābhārata*, in which the god Śiva (Shiva) is celebrated.

Rāmāyaṇa. While the unity of the *Mahābhārata* has been disrupted by interpolations, the unity of the second epic, the *Rāmāyaṇa*, has been remarkably preserved. It is less an epic than a romance, recounting the story of prince Rāma and his wife Sītā. The first book, a later addition, tells of the youth of the prince, who later, by the trickery of one of his father's wives, is excluded from the throne to which he is heir. He goes into voluntary exile in the forests with his wife and his brother Lakṣmaṇa. There a demon, Rāvaṇa, abducts Sītā to his island kingdom of Laṅkā. In the course of his quest for her, Rāma allies himself with a monkey nation, whose general, Hanumān, later revered as a god, discovers Sītā on Laṅkā. A monumental battle ensues. "As the sky can only be likened to the ocean and the ocean to the sky, so the battle of Rāma and Rāvaṇa can only be likened to the battle of Rāvaṇa and Rāma." After his victory, Rāma is restored to the throne, but (in what appears to be a later addition) the populace accuses Sītā of misbehaviour, probable adultery, while in Laṅkā. Rāma thus abandons her to a hermitage (the sage of the hermitage, Vālmīki, is credited with the authorship of the *Rāmāyaṇa*), where she gives birth to their twin sons. Ultimately, Rāma takes Sītā and his sons back. In the later additions, the first and probably the last books, King Rāma is accepted as an incarnation of the god Vishnu, rather than merely a perfect man and hero.

It is the main story of the romance that has made an indelible impression on Indian culture, morally as well as literarily. Rāma is the perfect, just king; Sītā, the model of an Indian wife; Lakṣmaṇa (the brother), the paragon of fraternal love; and the monkey Hanumān, the epitome of a servitor's loyalty. It was translated into and adapted in many modern Indian languages, and (like parts of the *Mahābhārata*) it found its way into Java. Vālmīki himself was hailed by later classical poets as the first true poet (*kavi*), and indeed much of his work has a poetic freshness and literary intention that is largely absent from the *Mahābhārata*. Vālmīki's great tools are metaphor and simile, as is also true of later literature. He delights in description of pastoral scenes, in lamentations and grand martial spectacles, and in the idyll of the hermitage, which depicts a serene sage leading a life of quiet meditation and living on simple forest fare in a tranquil woodland close to a sacred river. And the entire work is suffused with a confident, unwavering morality, for which the heroes of the *Mahābhārata* are still searching.

Harivaṃśa and Purāṇas. The role of the *Mahābhārata* as the storehouse of Hindu lore was supplemented by the *Harivaṃśa* ("Genealogy of Hari"—that is, the god Vishnu), which deals with the ancestry and exploits of Krishna, the Pāṇḍavas' friend and adviser in the epic but now wholly deified and identified with the great god Vishnu. Then, from perhaps the 4th century, the literature of the *Purāṇas* took over. Encyclopaedic works, often of considerable length, the *Purāṇas* deal with the mythology of time and space and of deities, with sagas of great heroic dynasties, and with legends of saints and ascetics; their interest is largely religious. Aesthetically, the most important of them is the *Bhāgavata-Purāṇa* (9th or 10th century), which celebrates the blessed lord (*bhagavat*) Vishnu in his many theophanies but is particularly evocative in its celebration of Vishnu's incarnation as Krishna and the playful story of his youth. The influence of the *Bhāgavata-Purāṇa*, particularly the 10th book, on Indian religion, art, and literature has been monumental. In the opinion of one scholar, this book constitutes the greatest poem ever written; and so it is in the popular estimation of the Hindus. It was adapted in many Indian languages and provided themes and scenes for the flourishing miniature styles of the Middle Ages.

Pāli and Prākrit literature (c. 200 BC–AD 200). No more than the Vedic literature do the literatures of early Buddhism and Jainism have a literary intention. Their texts, written in dialects other than Sanskrit, articulate the teachings of the religious founders and their successors. Because they were transmitted orally for a considerable time before they were written down in the form they would retain, they underwent the inevitable censorship of the centuries, both negative in the form of documents dropped out of use and positive in the form of newer documents added. The dates given here are only approximations of the time of the documentary fixation of the dates.

Buddhist texts. The earliest records of Buddhism are not textual but inscriptional, in the famous edicts of the Mauryan emperor Aśoka, who reigned *c.* 269–232 BC. Among these inscriptions on stone, the so-called 13th rock edict—in which Aśoka, after the massacre of the Kaliṅgas (modern Orissa), abjures war—is the most moving document of any dynastic history. The inscriptions were written in a variety of Prākrits; that is, Indo-Aryan languages closely cognate to, but considerably later than, the earliest stabilized Sanskrit.

Pāli, the language of textual literature

The vehicle of the extant textual literature is the Pāli language, which is held to be a western Indian dialect on a substratum of several central and eastern ones. It was the language in use by the Theravāda school of Buddhism; but, since that school became the dominant one among many in early Buddhism, the Pāli language is often identified with the Buddha's own speech. Most of the canonical literature is exclusively of religious interest, but interspersed in it are works of considerable literary interest.

Foremost perhaps are discourses put into the Buddha's mouth—for example, his sermon "In the Deer Park"—and no doubt deriving from fairly accurate memories. With their straightforward, lively, and incisive style, homely similes, and simple humour, they are excellent examples of the homiletics of early Buddhist preaching. Incorporated in the canon, too, are more general works of literature. The *Dhammapada* ("Verses on the Buddhist Doctrine") is a fine example of the moralistic, aphoristic strain in Indian literature, in which virtue is extolled and vice condemned. It has remained a work of considerable diffusion in all Buddhist countries, and, as in the case of the *Bhagavadgītā* in Hinduism, much of its popularity is due to its literary style. The *Suttanipāta* collection of the Buddhist canon, composed in a more formal style, contains 55 narrative and didactic poems, in the form of dialogues and ballads; they are composed in a metre akin to the Sanskrit *śloka*. Of great interest are the *Theragāthā* and the *Therīgāthā* ("Hymns of the Senior Monks" and "Hymns of the Senior Nuns"), which give at times a vivid insight into the ambience in which a conversion to Buddhism took place: a monk celebrates his newfound freedom in an idyll of the hermit's life; and a nun reminisces over the pains of deserting her home and child, yet without regrets, since she has won the freedom of Buddhism. The prosodic variety of Buddhist lyrics is great; about 30 different metres can be distinguished. Pāli poems, with their new metres (often based on a musical phrase), stylistic features, figures of speech, and choice diction, foreshadow classical *kāvya* literature in Sanskrit, whose extant specimens date from a later period.

The *Jātakas*

Of great importance is a huge volume called *Jātakas* ("Birth Stories"), recounting some 500 episodes supposedly having occurred in the Buddha's earlier lives. Only those parts in archaic verse are canonical; the prose portion was written later (*c.* 3rd century AD), probably in

Ceylon. The *Jātakas* consist of fairy tales, animal stories and fables (the future Buddha may be incarnate in an animal), ballads, and anecdotes. Though their setting is often imaginary, they provide significant material for the historian of society and culture. These mostly short tales abound in moving, delicate, often rustic touches that have made them the delight of the Buddhist world. Their themes are illustrated in bas-reliefs of Buddhist shrines (or *stūpas*) at Bhārhut and Sānchi and monumentally on the great *stūpa* of Java, the Borobuḍur.

Of considerable literary as well as historical interest is the Pāli text *Milinda-pañha* ("The Questions of Milinda"). Milinda is identical to the Greek Menander, the name of a Bactrian Indo-Greek king (*c.* 140–110 BC) who was skeptical of the verities of Buddhism and was enlightened by the teaching of an elder, Nāgasena. The extensive Buddhist erudition that the sage displays is artfully presented in the form of simile and parable, and the work has contributed importantly to the edification of audiences in the countries where Buddhism came to be established. The style, in spite of the repetitions so typical of Buddhist doctrinal texts, is lively and presents the reader with an invaluable picture of contemporary Indian life.

Jaina texts. Less interest attaches to Jaina canonical works, which were written in an adapted and stabilized literary dialect called Ardhamāgadhī (Semi-Māgadhī, Māgadhī being the dialect of the ancient kingdom of Magadha, in present day Bihār). The belletristic contribution of Jaina literature is discussed below.

Classical Sanskrit kāvya (200–1200). Prepared for by the systematization of the Sanskrit language by Pāṇini, the development of the great epics, notably the *Rāmāyaṇa,* and the refinements of prosody represented by the Pāli lyrics, there arose, in the first centuries AD, a Sanskrit literary style that governed canons of taste for a millennium and remained influential far later through modern Indian languages and their literatures. The style, called *kāvya,* is characterized by an extremely self-conscious effort on the part of the writer to compose poetry pleasing to both the ear and the mind. It evolved an elaborate poetics of figures of speech, among which the metaphor and simile, in their many manifestations, predominate; a careful use of language, governed by the stated norms of grammar; an ever-increasing tendency to use compound nouns instead of drawing on the quite plentiful possibilities of Sanskrit inflection; a sometimes ostentatious display of erudition in the arts and sciences; an adroitness in the use of varied and complicated, if appropriate, metres—all applied to traditional themes such as the epic had provided and to the rendering of emotions, most often the love between men and women.

Characteristics of the *kāvya* style

The style finds its classical expression in the so-called *mahākāvya* ("great poem"), most akin to the epyllion ("miniature epic") art form of the Alexandrian poets (a school of Greek poets, *c.* 3rd–1st centuries BC); the strophic lyric (a lyric based on a rhythmic system of two or more lines repeated as a unit); and the Sanskrit theatre. It can also be extended to narrative literature, especially the prose novel. The great masters in the *Kāvya* form (which was also exported to Java) were Aśvaghoṣa, Kālidāsa, Bāṇa, Daṇḍin, Māgha, Bhavabhūti, and Bhāravi.

The earliest surviving *kāvya* literature was written by a Buddhist, Aśvaghoṣa, said to have been a contemporary of the Kuṣāṇa (Kushān) king Kaniṣka (1st century AD). Aśvaghoṣa's work also marks a shift away from the Pāli of the Theravāda branch of Buddhism back to the more and more accepted Sanskrit of the Mahāyāna branch. Two works are extant, both in the style of *mahākāvya:* the *Buddhacarita* ("Life of the Buddha") and the *Saundarānanda* ("Of Sundarī and Nanda"). Compared with later examples, they are fairly simple in style but reveal typical propensities of writers in this genre: a great predilection for descriptions of nature scenes, for grand spectacles, amorous episodes, and aphoristic observations. The resources of the Sanskrit language are fully exploited; stylistic embellishments (*alaṅkāra*) of simile and metaphor, alliteration, assonance, and the like are employed, often quite felicitously. The original *Buddhacarita,* rediscovered in 1892, had been known from Tibetan and Chinese translations. The Sanskrit text is fragmentary, breaking off in the 14th canto (major division of the poem) with the enlightenment of the Buddha, while the other versions take the story through the Buddha's Nirvāṇa. Though intended to instruct the reader to turn away from the sensuous life and follow the Buddha's path, the work is at its best in descriptions of that very life. This is even more apparent in the *Saundarānanda,* which recounts a well-known story of how the Buddha converted his half-brother Nanda, who was deeply in love with his wife, Sundarī, and with the good life, to the monastic life of austerity. In his mastery of the intricacies of prosody and the subtleties of grammar and vocabulary, Aśvaghoṣa shows himself the complete forerunner of the Hindu *mahākāvya* authors.

The mahākāvya. In its classical form, a *mahākāvya* consists of a variable number of comparatively short cantos, each composed in a metre appropriate to its particular subject matter. The subject matter of the *mahākāvya* itself is taken from the epic, which is not, however, followed slavishly. Most *mahākāvya*s display such set pieces as descriptions of cities, oceans, mountains, the seasons, the rising of the sun and moon, games, festivals, weddings, embassies, councils, war, and triumph. It is typical of the genre that, while each strophe, or stanza, is intended to be part of a narrative sequence, it more often stands by itself, a discrete unit conveying one idea or developing one image. In this, the tendency of the Rigvedic stanza (see above *Sanskrit: formative period [1200–400 BC]*) continues in the classical literature. Although the lines of the classical stanza are long enough to convey their meaning quite explicitly, it is the pride of the poet to suggest rather than to express. Sometimes this is done by simple collocation of words: for example, in the first line of Kālidāsa's *Meghadūta* a *yakṣa* (a mischievous elf-like creature) is afflicted by a curse, "the more painful because it spelt separation from his beloved"; the next word notes that he had been negligent in his duties; taken together, the two words, though syntactically unrelated, suggest that it was his amour that made him neglect his duties. Another common suggestive device is the double meaning, or play on words. These double meanings often add a certain graceful playfulness to the poetry, reminding one that the poem was written first of all to give pleasure to the man of taste.

Traditionally there are six model *mahākāvyas,* three by Kālidāsa and one each by Bhāravi, Māgha, and Śriharṣa, to which sometimes the *Bhaṭṭikāvya* is added.

The works of Kālidāsa

Nothing is known with certainty of the life of Kālidāsa, the greatest of Sanskrit poets, but there is substantial agreement that at one time he lived in Ujjayinī (Ujjain, in the present state of Madhya Pradesh), the capital of Avanti and an important centre of Sanskrit culture in a commercially busy area. His name, which means Servitor of Kālī, indicates that he was a follower of that goddess, whom he was to celebrate as Pārvatī, the daughter of the mountain, in the *Kumārasaṃbhava.* Probably he lived during the reign of Candra Gupta II Vikramāditya (*c.* 380–*c.* 415), and there are reports that he died, by the hand of an envious courtesan, while a guest of King Kumāradāsa of Ceylon.

Compared with those of others, Kālidāsa's style might be called simple, but it is a very studied, very felicitous simplicity, hiding the actual complexity of his constructions. In two of his *mahākāvyas,* Kālidāsa draws on epic lore. The first, and probably earlier one, is the *Kumārasaṃbhava* ("Birth of the War God"), which describes the courting of the ascetic Śiva, who is meditating in the mountains, by Pārvatī, the daughter of the Himalayas; the destruction of the god of love (after his arrow has struck Śiva) by the fire from Śiva's third eye; and the wedding and lovemaking of Śiva and Pārvatī, which results in the conception of the war god. The original is in eight cantos, but a sequel was added by an imitator. The second *mahākāvya,* the *Raghuvaṃśa* ("Dynasty of Raghu"), deals with themes from the *Rāmāyaṇa:* it describes the vicissitudes of the Solar dynasty of the ancient Indian barons, culminating in the *Rāmāyaṇa* story of Rāma and Sītā. The *Raghuvaṃśa* is famous for its beautiful descriptions and incidental narratives, which give the poem a somewhat episodic character; among them are a description of

the six seasons (spring, summer, rainy, autumn, winter, and dewy) and the story of a young hermit who went to the river to fill a water jar for his parents and was killed by a stray arrow.

Unique in Sanskrit love poetry is Kālidāsa's *Meghadūta,* in which the poet tries to go beyond the strophic unity of the short lyric (see below), which normally characterizes love poems, by stringing the stanzas into a narrative. This innovation did not take hold, though the poem inspired imitations along precisely the same story line. The *Meghadūta* is the lament of an exiled *yakṣa* who is pining for his beloved on a lonely mountain peak. When, at the beginning of the monsoon, a cloud perches on the peak, he asks it to deliver a message to his love in the Himalayan city of Alakā. Most of the poem, composed in an extremely graceful metre, consists of a description of the landmarks, cities, and the like on the cloud's route to Alakā. It must be considered among the finest poems, if not the finest poem, written in Sanskrit. Kālidāsa also wrote for the theatre (see below) and was no doubt the most versatile author of Sanskrit literature; his works became well-nigh canonical models.

Bhāravi (6th century) probably hailed from the south during the reign of the Pallava dynasty. He took up a *Mahābhārata* theme in his *Kirātārjunīya* ("Arjuna and the Mountain Man"), recounting the Pāṇḍava prince Arjuna's encounter and ensuing combat with a wild mountaineer who in the end proves to be the god Śiva. Bhāravi's language and style are more difficult than Kālidāsa's, but the poem is highly regarded in Indian literary tradition.

Māgha, who wrote in the 8th century, was a conscious rival of Bhāravi, whom he attempted to surpass in every respect. His *Śiśupālavadha* ("The Slaying of King Śiśupāla") is based on an episode of the *Mahābhārata* in which the rival King Śiśupāla insults the hero-god Krishna, who beheads him in the ensuing duel. Māgha is a master of technique in the strict Sanskrit sense of luscious descriptions; intricate syntax; compounds that, depending on how they are split, deliver quite different meanings; and the full register of stylistic embellishments.

To some critics, the preoccupation with technique, the triumph of form over substance, appears to have spelled the doom of the *mahākāvya.* A curious but entirely Sanskritic phenomenon, for example, is the *Bhaṭṭikāvya,* a poem by Bhaṭṭi (probably 6th or 7th century). It again deals with the story of Rāma and Sītā, but at the same time it illustrates in stanza after stanza, in exactly the proper sequence, the principal rules of Sanskrit grammar and poetics. Less artificial is the *Naiṣadhacarita* ("The Life of Nala, King of Niṣadha"), written by the 12th-century poet Śrīharṣa and based on the story of Nala and Damayantī in the *Mahābhārata.* An example of another kind of excess indulged in by *mahākāvya* writers is the *Rāmacarita* ("Deeds of Rāma"), by the 12th-century poet Sandhyākāra, which celebrates simultaneously the hero-god Rāma and the poet's own king, Rāmapāla of Bengal. Many other works were written in this style, and, even today, one may encounter a *mahākāvya* treatment of a great man such as Mahatma Gandhi or Jawaharlal Nehru.

Jayadeva's *Gītagovinda*

Difficult to classify is the work of the 12th-century Bengal poet Jayadeva, who wrote the *Gītagovinda* ("Cowherd Song"). The basic structure of this long poem, in which the poet recounts the youthful loves of the cowherd hero and god Krishna, largely based on the story of the *Bhāgavata-Purāṇa,* is that of the *mahākāvya.* Generously interspersed between cantos, however, are erotic-religious lyrics of extremely musical assonances, which were, and still are, sung. Jayadeva's work, rather lacking in the grammatical rigidity of the other *mahākāvya* writers, has been extremely popular and affords a fine example of the devotional lyric (see below).

The short lyric. It is in the short, one-stanza lyric that Sanskrit poetry is revealed most intimately in its real aims. As noted, almost all of high Sanskrit poetry is strophic in fact; in the lyric it is so in intention. It is eminently a genre of the poetic moment, making an aesthetic observation and placing it within the Sanskritic universe of discourse. It may be an observation of anything: a fish glintingly jumping from a pond, aboriginal tribesmen engaged in a bloody rite, love in all its manifestations, a glimpse of God perceived or remembered. But in the monumental lyric collections that have been preserved, and in the many stray verses still circulating among educated Hindus in India as so-called *subhāṣita*s ("well-turned" couplets), the more common topics are praise of the god of one's devotion and the vagaries of love.

In the short lyric it is hard to make a distinction that depends on the language in which it is composed; for, although the language may be different, the subject matter and forms are the same. Many love lyrics, especially when they describe feelings experienced by women, are composed not in Sanskrit but, instead, in one of the Prākrits, or Middle Indo-Aryan languages, among which the dialect called Māhārāṣṭrī is particularly popular. The collection of 700 poems in this language, compiled by Hāla under the name of *Sattasaī* ("The Seven Hundred"), tends to be simpler in imagery and in the emotion portrayed than their Sanskrit counterparts, but essential differences are difficult to pinpoint.

The devotional lyric, a short verse expressing the author's devotion to a god, is linked with both the hymnal poetry of the Rigveda—though far less determined by a desire for compelling magic—and the temple worship of Hinduism. Though by no means always, there is often a particularism about them: the deity is invoked as it appears in a specific iconic stance or in a local temple or in a manifestation especially pleasing to the poet. The number of such verses is countless; every major religious and philosophic leader is held to have added to their stock. Some are especially famous: the *Sūryāṣṭaka* ("Eight Strophes for the Sun"), by Mayūra; the collections attributed to the philosopher Śaṅkara, the *Saundaryalaharī* ("The Wavy River of the Beautiful Sky"); and the *Kṛṣṇakarṇāmṛta* ("The Elixir of Hearing of Krishna"), by Bilvamaṅgala, among others. These *stotra* ("lyrics of praise") quite often were set to music, and people continue to sing them today—without necessarily comprehending the full intention of the Sanskrit, much as hymns in Latin were traditionally sung by Roman Catholic believers.

The love lyric

The entire erotic experience, from budding love to the aftermath of consummation, is represented brilliantly in lyric poetry. But among the many themes inspired by love, poets have been most attracted to the lament of separated lovers. It is mostly the sufferings of the woman that are portrayed, but the grief of the man is also depicted—in Kālidāsa's *Meghadūta,* for example. The love lyrics consist of single verses, many of which seek to suggest the mood of *śṛṅgāra* (physical love). While often extremely erotic, they are very rarely obscene. Sanskrit norm banned all coarse expressions for sexual play; and, although much probably escapes the modern reader, blunt allusions to genital organs are rare and, where allusions occur, extremely veiled. Bodily parts with less overt sexual connotations, such as breasts and buttocks, are frankly mentioned and described—in fact, celebrated. In allusions to sexual intercourse the terminology of the *Kāmasūtra* of Vātsyāyana is frequently invoked, as though this ancient textbook of Indian erudition was a protection against possible opprobrium—not unlike Latin terms resorted to in the West for actions that most know by shorter, more colloquial names.

The erotic and the devotional lyric merge freely, and at times it is impossible to make out whether the free sexual imagery employed is to be taken literally or as an allegory of the human soul courting the love of its god. The task—not a very pressing one—is made more difficult by the fact that some *bhakti* (devotion) religions have developed the poetics of love poetry into a kind of theology, a phenomenon quite characteristic of Bengal Krishnaism (see below *Indo-Aryan literatures: 12th–18th century*).

Authors of *subhāṣita*s often collected them themselves, the favourite form being that of the *śataka* ("century" of verses), in which 100 short lyrics on a common theme were strung together. Mention has been made of Hāla's *Sattasaī* ("The Seven Hundred," consisting of lyrics in the Māhārāṣṭrī dialect). Four well-known Sanskrit collections, of the 7th century, are the famous "century" of Amaru, king of Kashmir, and the three "centuries" by the poet

Bhartṛhari; one of the latter's collections is devoted to love, another to worldly wisdom—a very popular theme in epigrammatic verse—and the third to dispassion. Of the same type but in a different vein is *Caurapañcāśikā* ("Fifty Poems on Secret Love"), in which the 12th-century poet Bilhaṇa fondly recalls the pleasure of his clandestine amours with a local princess.

The theatre. Of all the literary arts, the Indians esteemed the play most highly, and it is in this form that most of the other arts were wedded together. Its origins are obscure, but there is reason to assume that the play developed out of recitations of well-known epic stories by professional reciters. It is an extremely rich genre with a number of outstanding playwrights.

The style is extremely varied. Although it might be called a Sanskrit play, Sanskrit is by no means the only language used, for the less educated characters, including all women, speak Prākrits of different degrees of niceness. The action is carried by prose, but at the least provocation—indeed, at any of the poetic moments characteristic of the strophic lyric—the author reverts to verse, sometimes in mid-sentence. Two principal types of play are distinguished: the *nāṭaka,* which is based on epic material, and the *prakaraṇa,* which is of the author's invention, though often borrowed from narrative literature.

Principal types of drama

Characteristic of the Sanskrit theatre are elements of sacrality. The play begins and ends with a benediction, many of which consist of subject matter taken from sacred texts. It is also expressed in numerous taboos: the play must have a happy outcome in which harmony, interrupted by the drama of the play, is restored; improper scenes, such as eating, dressing and undressing, and sexual intercourse, are not to be portrayed; no violence among the higher characters is permitted; war, which often occurs, should simply be reported on, often by lower characters, not in any way staged.

Fragments of Buddhist plays prior to the flowering of Hindu theatre have survived, but no complete plays earlier than 13 ascribed to the playwright Bhāsa. There is considerable controversy over the authenticity of the Bhāsa plays, but at least some of them must be authentic, perhaps dating back to the 3rd century. The plays are based on the epic and on the *Bṛhat-kathā* narrative cycle (see below); among the latter, the *Svapnavāsavadattā* ("The Dream of Vāsavadattā") is the most famous. Of considerable interest also is the *Daridra-Cārudatta* ("The Poverty of Cārudatta"), which became the basis for the play *Mṛcchakaṭika* ("Little Clay Cart") of Śūdraka (see below).

It must be assumed that there was an efflorescence of poetry and theatre in the city of Ujjayinī, one of the capitals of the Gupta Empire, in the 5th century, for a number of authors can be placed there during this reign; among these were Viśākhadatta, Śūdraka, Śyāmilaka, the writer of one of the best farces, and Kālidāsa, who at the beginning of the development of the genre produced some of the greatest plays in the tradition.

Kālidāsa's plays

Three plays by Kālidāsa remain, one of which is the *Mālavikāgnimitra* ("Agnimitra and Mālavikā"), a harem play of amorous intrigue at a royal court. The other two are based on old themes. *Vikramorvaśī* ("Urvaśī Won by Valour") is based on a story as old as the Rigveda, that of the nymph Urvaśī, who is loved by King Purūravas, whom she marries on the condition that she shall never see him nude. The accident happens, and the nymph returns to heaven, leaving her husband crazed with longing, until a final reunion. But the Indian tradition holds the *Abhijñānaśakuntalā* ("Śakuntalā and the Token of Recognition") to be the greatest of all Sanskrit plays. It recounts a *Mahābhārata* story—rather freely to be sure—of a hermit girl secretly married to a visiting king, who leaves with her a keepsake that will serve her as a token of recognition. She gives birth to a son, Bharata, and goes to the King's court; on the way she loses the ring in a river, where a fish swallows it. The King fails to recognize her and rejects her, and her mother, a nymph, carries her to heaven. When the ring is recovered by a fisherman and the King's memory is restored, he searches for Śakuntalā but does not find her. In the end he meets a boy who proves to be his son and is restored to him.

Kālidāsa's great forte is the portrayal of emotions—ordinary enough in themselves (budding love, love consummated, rejection, despair, a father's love for his son)—but Kālidāsa applies to them a mastery of expression and image that makes the play a work of perennial beauty.

Next to nothing is known of Śūdraka except that he must have hailed from Ujjayinī. His is the most charming of all *prakaraṇa* plays (those that are not based on epic material): the *Mṛcchakaṭikā* ("Little Clay Cart"), the story of an impoverished merchant and a courtesan who love each other but are thwarted by a powerful rival who tries to kill the woman and place the blame on the hero, Cārudatta. The play offers a fascinating view of the different layers of urban society. Viśākhadatta, the author of a rare semi-historical play called *Mudrārākṣasa* ("Minister Rākṣasa and his Signet Ring"), apparently was a courtier at the Gupta court. His play is a dramatization of the Machiavellian political principles expounded in the book *Arthaśāstra,* by Kauṭilya, who appears as the hero of the play.

To the 7th-century king Harṣa of Kanauj are attributed three charming plays: *Ratnāvalī* and *Priyadarśikā,* both of which are of the harem type; and *Nāgānanda* ("The Joy of the Serpents"), inspired by Buddhism and illustrating the generosity of the snake deity Jīmūtavāhana.

The plays of Bhavabhūti

Ranked by Indian tradition close to Kālidāsa himself, Bhavabhūti (early 8th century) was the author of three plays, two of which are based on the *Rāmāyaṇa* story. The *Mahāvīracarita* ("The Exploits of the Great Hero") treats of Rāma's battle with Rāvaṇa and the *Uttararāmacarita* ("The Later Deeds of Rāma") treats of the life of Rāma after he has abandoned Sītā. Bhavabhūti lacks the elegance and grace of Kālidāsa but is more pensive—even brooding—than his predecessor. His style is also very forceful. His *prakaraṇa Mālatī-Mādhava* ("Mālatī and Mādhava") is a complex love intrigue intermingled with sorcery and Tantric practices, including a human sacrifice and much violence.

This list by no means concludes that of the playwrights in the Sanskrit tradition. The writing of plays, mostly derivative from the great models, has continued until the present day.

Apart from the more seriously intended plays described above, the Sanskrit theatre also has a rich repertory of farces, which are usually in one act. Most interesting of these are the *bhāṇas,* which may be monologues in which an actor addresses imaginary persons and is answered by them, as he paints a picture of town life full of personal and social satire. Among the best in this little-studied genre is Śyāmilaka's 5th-century *Pādataḍitaka* ("The Courtesan's Kick").

Narrative literature. Sanskrit narrative literature is extremely rich, so rich in fact that at one time it was believed that all folktales originally came from India. Many indeed have, and they have found a place in *The Arabian Nights' Entertainment,* Boccaccio's *Decameron,* and other such works down to the fairy tales of Hans Christian Andersen and the fables of Jean de La Fontaine. Certain collections of animal tales, some of which go back to the Buddhist *Jātaka* stories, had incredible histories. The most famous is the *Pañca-tantra* ("The Five Chapters"), which, within a framework of a lesson in the art of politics addressed to young princes, presents a number of animal characters who in their actions both admonish and exhort the reader to a life certain to lead to worldly success. A shorter version, partly drawn from the *Pañca-tantra,* is the *Hitopadeśa* ("Good Advice"). The *Pañca-tantra* found its way to the West through translations into Persian, Arabic, Syrian, Hebrew, and Latin, until most of the medieval literatures possessed their own versions of it. No less extensive were its migrations to Southeast and East Asia.

The *Pañca-tantra*

The principal work of the novelistic and picaresque tale is the *Bṛhat-kathā* ("Great Story") of Guṇāḍhya, written in Prākrit and now lost, save for Sanskrit retellings. The most important among these Sanskrit versions is the *Kathā-saritsāgara* ("Ocean of Rivers of Stories") of Somadeva (11th century), which includes so many subsidiary tales that the main story line is frequently lost. Perhaps more faithful to the original—in any case far less distracting—is the *Bṛhatkathāślokasaṃgraha* ("Summary in Verse of the

Great Story"), by Budhasvāmin (probably 7th century), one of the most charming of Sanskrit texts. Other collections of tales include the *Vetāla-pañcaviṃśatikā* ("Twenty-five Tales of a Ghost"), *Śūkasaptati* ("The Seventy Stories of a Parrot"), and the *Siṃhāsana-dvātrim-sātikā* ("Thirty-two Stories of a Royal Throne").

Related to the *Bṛhat-kathā* cycle, though the exact relationship is unclear, is the Jain Prākrit text of the *Vāsudevahiṇḍī*, "The Roamings of Vāsudeva" (before 6th century), describing the acquisition of numerous wives by Krishna Vāsudeva.

Though the tales are often artless, sometimes they are elaborately embroidered in the Sanskrit *kāvya* style. A fine example is the *Daśakumāracarita* ("Tales of Ten Princes"), by Daṇḍin (6th/7th century), in which, within the framework of a boxing story, the picaresque adventures of 10 disinherited princes are described in prose. While tending overly to description, the work remains eminently readable for the modern reader, a quality that cannot be attributed to the prose novels of the 7th-century writer Bāṇa: the *Harṣacarita*, "The Life of Harṣa" (king of Kanauj and the author of three plays, discussed above), which is important for its information on culture and society; and the *Kādambarī* (the name of the heroine), which describes the affairs of two sets of lovers through a series of incarnations, in which they are constantly harassed by a cruel fate. (J.A.B.v.B.)

DRAVIDIAN LITERATURE: 1ST–19TH CENTURY

Of the four literary Dravidian languages, Tamil has been recorded earliest, followed by Kannada, Telugu, and Malayalam. Tamil literature has a classical tradition of its own, while the literatures of the other languages have been influenced by Sanskrit models.

Early Tamil literature (1st–10th century). *Caṅkam literature.* Early classical Tamil literature is represented by eight anthologies of lyrics, 10 long poems, and a grammar called the *Tolkāppiyam* ("Old Composition"). According to a fanciful Tamil tradition, this literature was produced by poets of three "academies," or *caṅkams*, that in the hoary past were centred in the southern Indian city of Madurai and supposedly lasted 4,400, 3,700, and 1,850 years, respectively. The *Tolkāppiyam* was ascribed to the second *caṅkam*, the eight anthologies and 10 long poems to the third; according to tradition, nothing is extant from the first *caṅkam*. The early literature, itself known as *caṅkam*, comprises 2,381 poems, ranging from four to nearly 800 lines each and assigned to 473 poets who are known by name or epithet; about 100 poems are anonymous. Though the literature does not go back as far as native tradition would have it, it is generally ascribed to the first three centuries of the Christian Era and represents the oldest non-Sanskrit literature to be found on the South Asian subcontinent.

The eight anthologies and their contents, excluding opening invocations that were added later, are as follows: *akam* anthologies consisting of (1) *Kuṟuntokai*, 400 love poems, (2) *Naṟṟiṇai*, 400 love poems, (3) *Akanāṉūṟu*, 400 love poems, (4) *Aiṅkuṟunūṟu*, 500 love poems, each 100 (assigned to a different poet) dealing with one of five phases of love, (5) *Kalittokai*, 150 love poems in a metre called *kali;* and *puṟam* anthologies consisting of (6) *Puṟanāṉūṟu*, 400 poems, (7) *Patiṟṟuppattu* ("The Ten Tens"), 100 poems on kings (the first and last decades are missing), and (8) *Paripāṭal*, a collection of 70 religious poems. *Paripāṭal* and *Kalittokai* appear to be the latest of the anthologies; *Kuṟuntokai* and *Puṟanāṉūṟu* probably contain the earliest compositions. The remarkable work of grammar and rhetoric, *Tolkāppiyam*, is the crucial text for an understanding of early Tamil language and literature. Divided into three sections (each consisting of *cūṭtirams*, or aphorisms)—sounds, words, and meaning—the *Tolkāppiyam* details, in the third, the canons of *caṅkam* poetic traditions.

Characteristics of *caṅkam* poetry

In the *Tolkāppiyam* and the anthologies, poems are classified by theme into *akam* ("interior") and *puṟam* ("exterior"), the former highly structured love poems, the latter heroic poems on war, death, personal virtues, the ferocity and glory of kings, and the poverty of poets. Both the *akam* and the *puṟam* had well-defined *tiṇai*s (genres) that paralleled one another: *e.g.*, the *kuṟiñci* genre, in love poetry, which dealt with the lovers' clandestine union on a hillside by night; and the *veṭci* genre, in heroic poetry, which dealt with the first onset of war, by nocturnal cattle stealing. Both *kuṟiñci* and *veṭci* are names of flowers that grow on the hillside, here symbolic of the poetic genre, the mood, and the theme. By such pairings across *akam* and *puṟam*, love and war become part of the same universe and metaphors for one another; the same poets—for example, Paraṇar and Kapilar—wrote great poems in both genres. The basic technique depended on a taxonomy of Tamil nature and culture, of culturally defined time, space, nature, and human nature. For example, matched in metaphor with five phases of *akam* love (union; infidelity; anxious waiting; patient waiting; and the lover or lovers eloping or journeying for wealth, knowledge, and so on) are six seasons, six parts (dawn, forenoon, noon, afternoon, evening, and night) of the day, and five landscapes (hill, seashore, forest, pasture, and wasteland, named after characteristic flowers—*kuṟiñci, neytal, mullai,* and *marutam*—and the evergreen tree, *pālai*) and their contents (including gods, foods, birds, beasts, drums, occupations, lutes, musical styles, flowers, and kinds of running or standing water). Each landscape becomes a repertoire of images—anything in it, bird or drum, tribal name or dance, may evoke a specific feeling. A favourite poetic device is *uḷḷuṟai* (*i.e.*, metonymy, a figure of speech consisting of the description of one thing used to evoke that of another with which it is associated). Thus, the natural scene implicitly evokes the human scene; for example, bees making honey out of *kuṟiñci* flowers evokes the lovers' union. Not only is the poet's language Tamil, but the landscapes, the personae, and the appropriate moods and situations formulate the realities of the Tamil world into a code of symbols. For some five or six generations, the *caṅkam* poets spoke this common language of symbols, creating a body of lyrical poetry probably unequalled in passion, maturity, and delicacy by anything in any Indian literature.

Eighteen Ethical Works. The *Patiṟeṇ-kīṛkkaṇakku* ("Eighteen Ethical Works"), usually dated as post-*caṅkam* (4th–7th centuries), are all affected by Jainism and Buddhism. Of these the *Tirukkuṟaḷ* ("Sacred Couplets"), ascribed to Tiruvaḷḷuvar, is the most celebrated. Its 1,330 hemistichs (half lines of verse) are probably the final distillation of different periods. There are many parallels in the work to the Sanskrit *Kāma-sūtra*, the treatise on erotic love, to *Manu-smṛti*, an ancient treatise on special obligation and religious law, and to *Artha-śāstra*, Kauṭilya's treatise on politics. The *Kuṟaḷ* has three sections: *aṟam*, or virtue (Sanskrit *dharma*); *poruḷ*, government and society (Sanskrit *artha*); and *kāmam*, love (Sanskrit *kāma*). There is no special treatment of *mokṣa*, or salvation, though *aṟam* seems to include it. In the *aṟam* (virtue) section, the *Kuṟaḷ* sums up a world-affirming wisdom, the wisdom of human sympathy, expanding from wife, children, and friends to clan, village, and country. In the *poruḷ* (government and society) section, the aphorisms project a vision of an ideal state, based on educated human nature, and relate the good citizen to the good man. Prostitution, disease, drink, and gambling are listed, with foreign enemies, as dangers to the state. In the *kāmam* (love) section, the *Kuṟaḷ* follows the *caṅkam's* love—eros, or sexual love—yet anticipates agape, the perfecting of love through many lives, which appears in religious poetry of the next age.

Epics. The age of the Pallavas (300?–900), a warrior dynasty of Hindu kings, is known for its epics, beginning with *Cilappatikāram* ("The Jewelled Anklet") and *Maṇimēkalai* ("The Girdle of Gems") and including an incomplete narrative, *Peruṅkatai* ("The Great Story"), the *Cīvakacintāmaṇi* ("The Amulet of Cīvakaṉ") by Tiruttakkatēvar, and *Cūḷāmaṇi* ("The Crest Jewel") by Tōlāmoḻittēvar. The last three works depict Jaina kings and their ideals of the good life, nonviolence, and the attainment of salvation through self-sacrifice. They are also characterized by excellent descriptions of city and country and by a mixture of supernatural and natural elements. In their episodic methods of narration and set descriptions of erotic, heroic, and religious themes, these Jaina

epics became both models and sources for later epic works.

The *Cilappatikāram*

The *Cilappatikāram,* by Iḷaṅkō Aṭikaḷ, is in three books, set in the capitals of the three Tamil kingdoms: Pukār (the Cōḷa capital), Maturai (*i.e.,* Madurai, the Pāṇṭiya [Pāṇḍya] capital), and Vañci (the Cēra capital). The story is not about kings but about Kōvalaṉ, a young Pukār merchant, telling of his marriage to the virtuous Kaṇṇaki, his love for the courtesan Mātavi, and his consequent ruin and exile in Maturai, where he dies, unjustly executed when he tries to sell his wife's anklet to a wicked goldsmith who had stolen the Queen's similar anklet and charged Kōvalaṉ with the theft. Kaṇṇaki, the widow, comes running to the city and shows the King her other anklet, breaks it to prove it is not the Queen's—Kaṇṇaki's contains rubies, and the Queen's contains pearls—and thus proves Kōvalaṉ's innocence. Kaṇṇaki tears off one breast and throws it at the kingdom of Maturai, which goes up in flames. Such is the power of a faithful wife. The third book deals with the Cēra king's victorious expedition to the north to bring Himalayan stone for an image of Kaṇṇaki, now become a goddess of chastity (*pattiṉi*).

The *Cilappatikāram* is a fine synthesis of mood poetry in the ancient Tamil *caṅkam* tradition and the rhetoric of Sanskrit poetry—even the title is a blend of Tamil and Sanskrit—including in the epic frame *akam* lyrics, the dialogues of *Kalittokai* (poems of unrequited or mismatched love), chorus folk song, descriptions of city and village, lovingly technical accounts of dance and music, and strikingly dramatic scenes of love and tragic death. One of the great achievements of Tamil genius, the *Cilappatikāram* is a detailed poetic witness to Tamil culture, its varied religions, town plans and city types, the commingling of Greek, Arab, and Tamil peoples, and the arts of dance and music.

Maṇimēkalai (the heroine's name, "Girdle of Gems"), the second, "twin," epic (the last part of which is missing), by Cātaṉār, continues the story of the *Cilappatikāram;* the heroine is Mātavi's daughter, Maṇimēkalai, a dancer and courtesan like her mother. Maṇimēkalai is torn between her passion for a princely lover and her spiritual yearnings, the first encouraged by her grandmother, the second by her mother. She flees the attentions of the prince, and, while he pursues her, she attains magical powers: she changes forms; survives prison, lecherous villains, and other dangers; converts the Queen; and finally goes to Pukār, which is being destroyed by oceanic erosion, worships Kaṇṇaki, and arrives in Vañcī to work in famine relief and to perform "penance." Unlike the *Cilappatikāram,* the *Maṇimēkalai* is partisan to Buddhism. It is known for its poetry and its lively discussions of religion and philosophy.

Bhakti poetry. From the 6th century onward, a movement with religious origins made itself heard in literature. The movement was that of *bhakti,* or intense personal devotion to the two principal gods of Hinduism, Śiva and Vishnu. The earliest *bhakti* poets were the followers of Śiva, the Nāyaṉārs (Śiva Devotees), whose first representative was the poetess Kāraikkāl Ammaiyār, who called herself a *pēy,* or ghostly minion of Śiva, and sang ecstatically of his dances. Tirumūlar was a mystic and reformer in the so-called Siddhānta (Perfected Man) school of Śaivism, which rejected caste and asceticism, and believed that the body is the true temple of Śiva. There were 12 early Nāyaṉār saints. Similar poets, in the tradition of devotion to the god Vishnu, also belonged to this early period. Called Āḻvārs (Immersed Ones), they had as their first representatives Poykai, Pūtaṉ, and Pēyār, who composed "centuries" (groups of 100) of linked verses (*antāti*), in which the final line of a verse is the beginning line of the next and the final line of the last verse is the beginning of the first, so that a "garland" is formed. To these Āḻvārs, God is the light of lights, lit in the heart.

The Nāyaṉārs

The most important Nāyaṉārs were Appar and Campantar, in the 7th century, and Cuntarar, in the 8th. Appar, a self-mortifying Jain ascetic before he became a Śaiva saint, sings of his conversion to a religion of love, surprised by the Lord stealing into his heart. After him, the term *tēvāram* ("private worship") came to mean "hymn." Campantar, too, wrote these personal, "bone-melting" songs for the common man. Cuntarar, however, who sees a vision of 63 Tamil saints—rich, poor, male, female, of every caste and trade, unified even with bird and beast in the love of God—epitomizes *bhakti.* To him and other Bhaktas, every act is worship, every word God's name. Unlike the ascetics, they return man to the world of men, bringing hope, joy, and beauty into religion and making worship an act of music. Their songs have become part of temple ritual. Further, in *bhakti,* erotic love (as seen in *akam*) in all its phases became a metaphor for man's love for God, the lover.

In the 9th century, Māṇikkavācakar, in his great, moving collection of hymns in *Tiruvācakam,* sees Śiva as lover, lord, master, and guru; the poet sings richly and intimately of all sensory joys merging in God. Minister and scholar, he had a child's love for God.

Āṇṭāḷ (8th century), a Vaiṣṇava poetess, is literally lovesick for Krishna. Periyāḻvār, her father, sings of Krishna in the aspect of a divine child, originating a new genre of celebrant poetry. Kulacēkarar, a Cēra prince, sings of both Rāma and Krishna, identifying himself with several roles in the holy legends: a *gopī* in love with Krishna or his mother, Devakī, who misses nursing him, or the exiled Rāma's father, Daśaratha. Tiruppāṇāḻvār, an untouchable poet (*pāṇaṉ*), sang 10 songs about the god in Śrīraṅgam, his eyes, mouth, chest, navel, his clothes, and feet. To these Bhaktas, God is not only love but beauty. His creation is his jewel; in separation he longs for union, as man longs for him. Tirumaṅkaiyāḻvār, religious philosopher, probably guru (personal religious teacher and spiritual guide in Hinduism) to the Pallava kings, and poet of more than 1,000 verses, was apparently responsible for the building of many Vaiṣṇava temples. The last of the Āḻvārs, Nammāḻvār (Our Āḻvār), writing in the 9th century, expresses poignantly both the pain and ecstasy of being in love with God, revivifying mythology into revelation.

Period of the Tamil Cōḷa Empire (10th–13th century). The next period, the time of the Tamil Cōḷa Empire (10th–13th centuries), saw an awakening of neighbouring literatures: Kannada, Telugu, and Malayalam. The first extant Kannada work is the 9th-century *Kavirājamārga* ("The Royal Road of Poets"), a work of rhetoric rather indebted to Sanskrit rhetoricians, containing the first descriptions of the Kannada country, people, and dialects, with references to earlier works. From the 10th century on, *campū* narratives (part prose, part verse) became popular both in Kannada and in Telugu, as did renderings of the Sanskrit epics *Rāmāyaṇa* and *Mahābhārata* and Jaina legends and biography.

In Kannada, this period was dominated by the "three gems" of Jaina literature, Pampa, Ponna, and Ranna, as well as by Nāgavarma I, a 10th-century Kannada grammarian. Pampa was the *ādikavi* ("first of poets"), having attained that stature with two great epics: *Vikramārjuna Vijaya* and *Ādipurāṇa.* The former is a rendering of the *Mahābhārata,* with the hero, Arjuna, identified with the poet's royal patron, Arikēsari. This felicitous epic is known for its succinct, powerful characterizations, its rich descriptions of Kannada country and court, its moving sentiments, and its harmonious blend of Sanskrit and Kannada. While the *Vikramārjuna* is a secular work, Pampa's *Ādipurāṇa* tells the story of the Jaina hero-saint Purudēva, his previous lives, his life from birth to marriage to holy death, as well as the lives of his sons, Bharata and Bāhubali.

Telugu had its *ādikavi* ("first of poets"), in the Brahmin Nannaya Bhaṭṭa (1100–60), who, in *campū* style, wrote three books of a version of the *Mahābhārata,* later finished by Tikkana (13th century) and by Errāpraggaḍa. Like other regional versions of the *Mahābhārata,* the Telugu version is not a literal translation but an interpretation, with many local elements and differences of emphasis; for example, Nannaya emphasizes the importance of Vedic religion. Such works have made the Sanskrit epics and *Purāṇas* part of a live and growing tradition, both oral and literary, in the regional language.

The work of Kampaṉ

This period also saw the eminence of Kampaṉ's Tamil version of the *Rāmāyaṇa* (12th century). In him there is

a climactic blend of earlier *caṅkam* poetry, Tamil epics, the Āḻvārs' fervour of personal *bhakti* (devotion) toward Rāma, folk motifs, and Sanskrit stories, metres, and poetic devices. Instead of a just king and a perfect man, Rāma is an incarnation of Vishnu and an intense object of devotion, dwarfing the Vedic gods; Kampaṉ called his work *Irāmāvatāram* ("Rāma's Incarnation"); yet the emphasis is not on Vishnu but on *dharma* ("the law"), localized and Tamilized. More like Sanskrit than *caṅkam* poets, Kampaṉ revels in elaborate metaphor, hyperbole, and fanciful descriptions of virtue and nature. The work is long, consisting of about 40,000 lines; the *Yuttakāṇṭam* ("War Canto") alone, with 14 battles, equals the *Iliad* in length. The poem is also justly known for its variety of style, its exploitation of the resources of Tamil and Sanskrit both in form and content, its humour, and its handling of the narrative, dramatic, and lyric modes.

Kampaṉ's popularity extended not only into all of Tamil country but apparently into the north, influencing some episodes of Tulsī's Hindi version of the *Rāmāyaṇa*, and into northern Kerala, where 32 plays based on Kampaṉ are enacted ritually with marionettes in Śiva temples.

Pre-15th-century Tamil influence on early Malayalam, the language of Kerala, was strong and led to the literature of *pāṭṭu* ("song"), in which only Dravidian, or Tamil, phonemes may occur and Tamil-like second-syllable rhymes are kept. The best known *pāṭṭu* is *Rāmacaritam* (*c.* 12th–13th century; "Deeds of Rāma"), probably the earliest Malayalam work written in a mixture of Tamil and Malayalam. Other *pāṭṭus* in Tamilized Malayalam, written by a family of poets (14th–15th centuries) from Niraṇam in central Travancore, appear in *Kaṇṇassan Pāṭṭukaḷ*, in which Tamil conventions of metre and phonology are loosened and more Sanskrit is allowed. Similar in style is a version of the *Rāmāyaṇa* by Rāma Paṇikkar, an abridged *Bhagavadgītā* by his uncle Mādhava Paṇikkar, and a condensed *Mahābhārata* and the 10th book of the *Bhāgavata-Purāṇa* by another uncle, Śaṅkara Paṇikkar.

As strong as Tamil influence was, the predominant influence on Malayalam was Sanskrit, in language as well as literary form. The influence on language led early to a mixture of Sanskrit and Malayalam in a literary dialect called *maṇipravāḷa* (meaning "necklace of diamonds and coral"). The author of the *Līlātilakam*, a 14th-century treatise on grammar and poetics, describes both the Tamilizing and Sanskritizing trends and genres and insists on harmonious blendings. Many kinds of poems were composed in *maṇipravāḷa* styles: *kūḍiyāṭṭams* (dramatic presentations using Sanskrit *ślokas*, or epic metres, for hero and heroine, *maṇipravāḷa* for the clown, and Malayalam for explanations intended for the laity); didactic works such as the 11th-century *Vaiśikatantram* ("Advice to a Courtesan by Her Mother"); 13th- and 14th-century *campūs* (narratives combining prose and verse) on dancers, such as *Unniyati Caritam* by Dāmōdara Cākkiyār; and several short poems in praise of women and kings. *Maṇipravāḷa* poems like these are essentially artifical expressions of courtly high-caste poets, preoccupied with eroticism and harlots. The *Candrōtsavam* (*c.* 1500; "Moon Festival") is a satire on the voluptuary *maṇipravāḷa* tradition, jostling together all the famed courtesans of the period.

Coexisting with the Tamilized and Sanskritized Malayalam poems produced by scholars was a live *pacca* ("pure, fresh") Malayalam tradition represented mostly by folk songs and ballads—for example, *Vaḍukkan Pāṭṭukaḷ* (hero ballads of the northern Malabar Coast); songs sung during weddings, deaths, or festivals; and work songs. All three styles—the indigenous folk style, the Tamil, and the Sanskrit—began to converge and influence each other by the 15th century in works such as *Kṛṣṇa Pāṭṭu* ("Song of Krishna") and *Gāthā* ("Song"). Such grafting reached its full flowering in the 16th-century poet Eḻuttaccan (Father [or Leader] of Letters), who popularized the *kiḷippāṭṭu* ("parrot song"), a genre in which the narrator is a parrot, a bee, a swan, and so on. His outstanding works are *Adhyātma Rāmāyaṇam*, *Bhāratam*, and *Bhāgavatam*, all based on Sanskrit originals yet powerfully re-created with masterly language craft.

While Vaiṣṇava works were proliferating in Malayalam, Śaiva movements swept the other three languages, Tamil, Kannada, and Telugu. In Tamil, the hymns of the Nāyaṉārs were arranged and anthologized for scriptural and recitative use by the 11th century. Another such consolidation of sacred materials was Cēkkiḻār's 12th-century *Toṇṭar Purāṇam*, or *Periyapurāṇam*, narrating in epic style the lives of the 63 great Śaiva saints and creating a tradition for all Śaivas, even in the Kannada and Telugu areas. The theology of the Siddhānta (Perfected Man) school of Śaivism was elaborated in Meykaṇṭār's *Civañāṇapōtam* (13th century).

The new Kannada genre of the 13th century

By the 12th century, a new Kannada genre, the *vacana* ("saying" or "prose poem"), had come into being with the Vīraśaiva saints. In the language of the people, the saints expressed their radical views on religion and society, rejected both Brahminical ritualism and Jaina ascetic world negation, called all men to the *anubhāva* ("experience") of God, and broke the bonds of caste, creed, and sexual difference. Five important poet-saints were Dāsimayya; Basava, a self-searching social reformer and a minister of the Jaina king Bijjaḷa; Allama Prabhu, the elder and metaphysical master of them all; Mahādēviyakka, a woman saint singing love poems to Śiva; and Cannabasava, a brilliant theologian of the movement, who elaborated the theory of "six stages" of mystic ascent for the devotee. The many-facetted lyrics written by the poet-saints were in the spoken dialects of Middle Kannada, yet they drew on archetypal human images as well as ancient pan-Indian symbology for their intense and searing expressions of *bhakti*. Inspired by these lyrics, Harihara, in the late 12th century, wrote some 120 *ragaḷe* (blank verse) biographies of the Śaiva saints, including the Vīraśaiva (or Liṅgāyat) and the earlier Tamil Nāyaṉārs. In the early 13th century, his disciple and nephew, Rāghavāṅka, wrote, in *ṣaṭpadis* (six-line stanzas), of the lives of saints, in well-structured works such as *Sōmanātha Carite* and *Siddharāma Caritra;* his most mature work is *Hariścandrakāvya*, an unequalled reworking of an ancient Job-like story of Hariścandra, who suffered every ordeal for his love of truth. The Vīraśaiva saints' lives and the *vacana* ("saying" or "prose poem") literature were codified in a masterpiece called *Śūnya Sampādane* ("The Achievement of Nothing"), consisting of dialogues interweaving the saints' *vacanas*, with the poet Allama Prabhu as the central figure.

Contemporary with the 13th-century Vīraśaiva saints were Telugu Śaiva poets such as Pālkuriki Sōmanātha, who composed the *Basavapurāṇam* employing popular metres and idiomatic Telugu. His *Paṇḍitārādhya Caritra* is a life of the Śaiva devotee Paṇḍitārādhya as well as a book of general knowledge including social customs, arts, crafts, and particularly music. His *Vṛṣādhipa Śatakam* consists of verses in Tamil, Kannada, Marathi, Sanskrit, and Telugu. This work was probably the first of the genre of *śatakas* ("centuries" of verses) literature, particularly popular in Telugu but also written in the other three languages as well as in Sanskrit (see above *Sanskrit: formative period* [*1200–400 BC*]).

Also of the 13th century is Āṇḍayya's *Kabbigara Kāva* ("The Poet's Defender"), in Kannada, a linguistic tour de force, eschewing unmodified Sanskrit forms; and Mallikārjuna's *Sūktisudhārṇava*, an excellent Kannada anthology of lyrics and passages. From 1240 to 1326, poets of Telugu produced over 100 verse renderings of the Sanskrit epic *Rāmāyaṇa* and many more in prose, the earliest being *Raṅganātha Rāmāyaṇa*, assigned to Gōna Buddhā Reḍḍi.

14th–19th century. The next age, from the 14th to the 16th century, is the great age of the Vijayanagar Empire. In this period, Kannada and Telugu were under the aegis of one dynasty and were also hospitable to the influence of neighbouring Muslim Bahmanī kingdoms. Śrīnātha was a 15th-century poet honoured in many courts for his scholarship, poetry, and polemics. He rendered Sanskrit poems and wrote *Haravilāsam* (Four Śaiva Tales); *Krīḍābhirāmam*, a charming, often vulgar account of social life in Warangal; and *Palanāṭi Vīra Caritra*, a popular ballad on a fratricidal war. Many erotic *cāṭus*, or stray epigrams, are also attributed to him. Bammera Pōtana, a great Śaiva devotee in life and poetry, unschooled yet a scholar, is widely known for his *Bhāgavatam*, a masterpiece that

is said to excel the original Sanskrit *Bhāgavata-Purāṇa.* Tāḷḷapāka Annāmācārya, son of a great family of scholars, fathered an exciting new genre of devotional song, all addressed to the god Śrī Veṅkaṭeśvara of Tirupati (a form of Vishnu). His *Saṅkīrtana Lakṣaṇam* is a collection of 32,000 songs in Sanskrit and Telugu, which made a significant contribution to Karnatic (southern Indian) musical technique.

The 16th century was an age of patronage by Vijayanagar kings, beginning with Kṛṣṇa Dēva Rāya, himself a poet versed in Sanskrit, Kannada, and Telugu. The *rāyala yugam* ("age of kings") was known for its courtly *prabandhas,* virtuoso poetic narratives by and for pandits (learned men). Among the most famous court poets were Piṅgaḷi Sūranna, whose verse novel, *Kalāpurṇōdayam* (1550)—a story full of surprises, magic, and changes of identity—is justly celebrated for its artistry; and Tenāli Rāmakṛṣṇa, known for his clownish pranks and humour, whose writings are the centre of a very popular cycle of tales in all four Dravidian languages.

During the 16th century and for the next few centuries, Telugu poets also flourished outside the Telugu country, especially in Tanjore (Thanjavūr) and Madurai, in Tamil country, and Pudukkoṭṭa and Mysore, in Kannada country. Their most important contribution was to native Kannada and Telugu dance drama on mythological themes, called *yakṣagāna.* The form is comparable to *kathākali* in the Malayalam area and to *terukkūttu* ("street drama") and *kuṟavañci* ("gypsy drama") in the Tamil area. The earliest Telugu *yakṣagāna* text is *Sugrīva Vijayam* (*c.* 1570), by Kandukuru Rudra Kavi; the earliest in Kannada is probably Śāntavīra Dēśika's *Saundarēśvara* (1678). The most celebrated of Kannada *yakṣagāna* dramatists is the versatile Pārti Subba, who flourished around 1800 and is known for his moving *Rāmāyaṇa* episodes and songs.

Contribution of poets to native dance drama

The 15th and 16th centuries produced some of the most popular classics in Kannada. Of these the greatest is Gadugu's *Kumāra Vyāsa,* or *Nāraṇappa*'s, 10 cantos of the *Mahābhārata;* recited in assemblies as well as in households, these are a continual delight, abounding in humour, passion, and memorable poetry. In *Prabhuliṅgalīle,* Cāmarasa made poetry out of the life of the poet-saint Allama. The *Jaimini Bhārata* and the many versions of *Rāmāyaṇa* episodes (especially Sītā's abandonment in the forest) written by the distinguished Śaiva epic poet Lakṣmīśa are known for their melodious verses and moving scenes. Ratnākaravarṇi's *Bharateśa Vaibhava* is a great Jaina story, tersely told in a Kannada song metre and celebrated for its depiction of many *rasas* ("moods"), especially the erotic.

Kannada Vaiṣṇava *dāsas* ("servants [of God]") wrote in a song genre called *pada,* parallel and often indebted to the Vīraśaiva *vacanas* ("sayings" or "prose poems"). Purandaradāsa, a rich 16th-century merchant turned mendicant, saint, and poet, composed *bhakti* (devotional) songs on Viṭṭhala (a manifestation of the god Vishnu), criticizing divisions of caste and class and calling on the mercy of God. His *padas* and *kīrtanas* ("lauds") are also landmarks in Karnatic music. Karnatic music. Kanakadāsa, his contemporary and a shepherd by birth, wrote *padas* and longer popular works. *Dāsa* songs are part of the repertory of all South Indian musicians.

The folk *tripadi* ("three-line verse") of Sarvajña (1700?) is a household word for wit and wisdom, like the *Kuṟaḷ* in Tamil (see above *Eighteen Ethical Works*) and the "century" of four-line verses in Telugu by Vēmana (15th century). The moral, social, satiric, and wise proverb-like aphorisms of Vēmana and Sarvajña are widely quoted by pundit and layman alike. Equally popular in the Malayalam region is the 18th-century folk poet of *tuḷḷals* (a song-dance form), Kuñcan Nampiyār, unparalleled for his wit and exuberance, his satiric sketches of caste types, his versions of Sanskrit *Purāṇa* narratives projected on the backdrop of Kerala, and his humorous renderings even of mythic characters.

The 17th and 18th centuries also saw Tamil court poetry—*Purāṇas,* translations from the Sanskrit, and praise poems, known more for their learning and imitative character than for their genius. This was also a period of many schisms and the founding of monasteries in Śaivism and Vaiṣṇavism, which led to many sectarian and polemic works. Muslims and Christians also wrote epics in the Hindu *Purāṇa* style; for example, Umaṟu-p-pulavar's 17th-century *Cīṟā-p-purāṇam,* on the life of the prophet Muḥammad, and Father Beschi's *Tēmpāvaṇi,* on the life of St. Joseph, with echoes from both Kampaṉ and the 16th-century Italian poet Torquato Tasso.

Probably the most impressive Tamil poetry of this period is that of Arunakiriv's learned and melodious *Tiruppukaḷ* (praise of Munikaṉ) and of the Cittars, eclectic mystics known for their radical, fierce folk songs and common-speech style. Tāyumāṇavar (18th century) and Paṭṭiṉattār (and later, in the 19th century, Rāmaliṅkar) are poets of unconditioned love, self-search, and rejection of corrupt society.

The 17th and 18th centuries are also periods of datable folk expression, which include many *tiruviḷaiyāṭal* ("stories of God's sport") *purāṇas;* temple tales (about miracles that took place in the temple); *kuṟavañci* (*i.e.,* "gypsy," a kind of musical dance drama); *paḷḷus* (plays about village agricultural life); realistic *noṇṭi-nāṭakams* ("dramas of the lame"), in which a Hindu temple god cures lameness; *kummi* songs sung by young girls, clapping as they dance round and round; and *ammāṇai* ballads. Noteworthy historical ballads are *Kaṭṭa Pommaṉ,* about a chieftain who revolted against the British, and *Tēciṅku-rācaṉ Katai,* about the prince of Gingi and his Muslim friend. Malayalam *āṭṭakkatha,* the literature associated with *kathākali,* the complex traditional dance drama, was also written during this period. Royal poets such as Kōṭṭayattu Tampurān, in the 17th century, and Kārttika Tiruṇal, in the 18th, wrote *āṭṭakkathās.* (A.K.R.)

INDO-ARYAN LITERATURES: 12TH–18TH CENTURY

It is difficult to pinpoint the time when the Indo-Aryan dialects first became identifiable as languages. Around the 10th century AD, Sanskrit was still the language of high culture and serious literature, as well as the language of ritual. The spoken language, however, had continued to develop, and at the turn of the millennium there began to appear, at different times during the subsequent two or three centuries, the languages now known as the regional languages of the subcontinent: Hindi, Bengali, Kashmiri, Punjabi, Rajasthani, Marathi, Gujarati, Oriya, Sindhi (which did not develop an appreciable literature), and Assamese; Urdu did not develop until much later (see below *Islāmic literatures: 11th–19th century*).

Regional languages

The literatures in their early stages show three characteristics: first, a debt to Sanskrit that can be seen in their use of Sanskrit lexicon and imagery, in their use of myth and story preserved in that refined language, and frequently in their conformity to ideals and values put forward in Sanskrit texts of poetics and philosophy; second, a less obvious debt to their immediate Apabhraṃśa past (dialects that are immediate predecessors of the modern Indo-Aryan vernaculars); third, regional peculiarities.

The narratives in the early stages of the development of the languages are most often mythological tales drawn from the epics and *Purāṇas* of classical Hindu tradition (see above *Sanskrit, Pāli, and Prākrit literatures: 1400 BC–AD 1200*), though in later times, in the 17th and 18th centuries, secular romances and heroic tales were also treated in narrative poems. Although the themes of the narratives are based on *Purāṇa* tales, often they include materials peculiar to the area in which the narrative was written.

In addition to themes, regional literatures frequently borrowed forms from the Sanskrit; for example, the *Rāmāyaṇa* appears in a 16th-century Hindi version by Tulsīdās, called the *Rāmcaritmānas* ("Lake of Rāma's Deeds"), which has the same form, though a different emphasis, as the Sanskrit poem. The stylized conventions and imagery of Sanskrit court poetry also appear, though here, too, with different emphasis; for example, in the work of the 15th-century Maithili (Eastern Hindi) lyric poet Vidyāpati. Even the somewhat abstruse rhetorical speculations of the Sanskritic poetic schools of analysis were used as formulas for the production of 17th-century Hindi court poetry; the

Rasikapriyā ("Beloved of the Connoisseur") of Keśavadāsa is a good example of this kind of tour de force.

There are other characteristics common to the regional literatures, some of which come not from Sanskrit but most likely from the Apabhraṃśa. There are two poetic forms, for example, that are found in many northern Indian languages: the *bārah-māsā* ("twelve months"), in which 12 beauties of a girl or 12 attributes of a deity might be extolled by relating them to the characteristics of each month of the year; and the *caūtīs* ("thirty-four"), in which the 34 consonants of the northern Indian Devanāgarī alphabet are used as the initial letters of a poem of 34 lines or stanzas, describing 34 joys of love, 34 attributes, and so on.

Finally, there are common characteristics that may have come either through Apabhraṃśa or through the transmission of stories and texts from one language to another. The stories of Gopi-candra, the cult hero of the Nātha Yogī sect, a school of mendicant *sannyāsins*, were known from Bengal to the Punjab even in the early period. And the story of the Rājput heroine Padmāvatī, originally a romance, was beautifully recorded, with a Ṣūfī (mystic) twist, by the 16th-century Muslim Hindi poet Malik Muḥammad Jāyasī and later by the 17th-century Bengali Muslim poet Ālāol. From the late 13th through the 17th century, bhakti (devotional) poetry took hold in one region after another in northern and eastern India. Beginning with the *Jñāneśvarī*, a Marathi verse commentary on the *Bhagavadgītā* written by Jñāneśvara (Jñānadeva) in the late 13th century, the devotional movement spread through Mahārāshtra, in the works of the poet-saints Nāmdev and Tukārām; through Rājasthān, where it is represented by the works of Mīrā Bāī; through northern India, in the poetry of Tulsīdās, Sūrdās, Kabīr, and others; through Mithilā, in the work of the great poet Vidyāpati; and into Bengal, where Caṇḍīdās and others sang of their love of God. Because of the *bhakti* movement, beautiful lyric poetry and passionate devotional song were created; and in some cases, as in Bengal, serious philosophical works and biographies were written for the first time in a regional language rather than in Sanskrit. The languages and their literatures gained strength as mediums of self-expression as well as exposition. And, although there is much Sanskrit imagery and expression in the poetry and song, as well as similarities to Sanskrit textual models, its basic character is not Sanskritic: true to the nature of any spoken, everyday language, it is more vital than polished, more vivid than refined.

Spread of *bhakti* poetry

One more historical generality can be stated regarding regional Indian literature before considering the characteristics peculiar to the several "Indian literatures." In all of the early literatures, writing was lyrical, narrative, or didactic, entirely in verse, and all in some way related to religion or love or both. In the 16th century, prose texts, such as the Assamese histories known as the *buranji* texts, began to appear.

Hindi. What is commonly spoken of as Hindu is actually a range of languages, from Maithili in the east to Rajasthani in the west. The first major work in Hindi is the 12th-century epic poem *Pṛthvīrāj Rāsau*, by Chand Bardaī of Lahore, which recounts the feats of Pṛthvīrāj, the last Hindu king of Delhi before the Islāmic invasions. The work evolved from the bardic tradition maintained at the courts of the Rājputs. Noteworthy also is the poetry of the Persian poet Amīr Khosrow, who wrote in the Awadhi dialect. Most of the literature in Hindi is religious in inspiration; in the late 15th and early 16th centuries, the reform-minded Kabīr, for example, wrote sturdy short poems in which he sought to reconcile Islām and Hinduism.

The most celebrated author in Hindi is Tulsīdās of Rājāpur (died 1623), a Brahmin who renounced the world early in life and spent his days in Benares (Vārānasi) as a religious devotee. He wrote much, mostly in Awadhi, and focussed Hinduism on the worship of Rāma. His most important work is the *Rāmcaritmānas* ("Sacred Lake of the Acts of Rāma"), which is based on the Sanskrit *Rāmāyaṇa*. More than any other work it has become a Hindu sacred text for the Hindi-speaking area and annually has been staged in the popular Rām Līlā festival.

Outstanding among the followers of Vallabha, philosopher and *bhakti* ("devotion") advocate of the Middle Ages, is the blind poet Sūrdās (died 1563), who composed countless *bhajans* (chants) in praise of Krishna and Rādhā, which are collected in the *Sūrsāgar* ("Ocean of Sūrdās"). While many of the *bhakti* poets were of modest origin, an exception was Mīrā Bāī, a princess of Jodhpur, who wrote her famous lyrics both in Hindi and Gujarati; the quality of her poetry, still very popular, is not as high, however, as that of Sūrdās. Significant also is the religious epic *Padmāvatī* by Jāyasī, a Muslim from former Oudh state. Written in Awadhi (*c.* 1540), the epic is composed according to the conventions of Sanskrit poetics.

The 18th century saw the beginning of a gradual transformation from the older forms of religious lyric and epic to new literary forms influenced by Western models that began to be known. The new trends reached their pinnacle in the work of Prem Chand (died 1936), whose novels (especially *Godān*) and short stories depict common rural life; and in the work of Harishchandra of Benares (died 1885), honoured as Bhāratendu (Moon of India), who wrote in the Braj Bhasa dialect.

Bengali. While developments in Bengali literature began somewhat earlier, they followed the same general course as those in Hindi. The oldest documents are Buddhist didactic texts, called *caryā-padas* ("lines on proper practice"), which have been dated to the 10th and 11th centuries and are the oldest testimony to literature in any Indo-Aryan language.

The three genres of Bengali poetry

Bengali poetry, including poetry by Bengalis in other dialects, is largely written in three distinct genres. It is certain that well before the 15th century there existed texts in a typically Bengali genre called *maṅgal-kāvya* ("poetry of an auspicious happening"), which consists of eulogies of gods and goddesses; such poetry is likely to have had a considerable history in oral transmission before it was committed to writing. A good example of an orally transmitted *maṅgal* poem is the *Caṇḍī-maṅgal* ("Poem of the Goddess Caṇḍī"), by Mukundarāma, which was put into written form in the latter part of the 15th century. *Maṅgal* poetry remained a favourite genre well into the 18th century, when Bhārat-candra wrote the *Annadā-maṅgal* ("Maṅgal of the Goddess Annadā [the Giver of Food]"), a witty and sophisticated poem that bears little resemblance to its more rustic forebears. Despite this popularity, it is the devotional lyrics to the divine pair Krishna and Rādhā that are still known and sung today in Bengal, and these lyrics are the gems of medieval Bengali literature.

Poems of the second genre, the *mahākāvya* ("great poem," but not to be confused with the Sanskrit *mahākāvya* genre), are based mainly on the Sanskrit models of the *Mahābhārata*, *Rāmāyaṇa*, and *Purāṇas*. Kṛttibās Ojhā (late 14th century) stands at the beginning of this literature; he wrote a version of the *Rāmāyaṇa* that often differs from the Sanskrit original, for he includes many local legends and places the setting in Bengal. Kavīndrā (died 1525) wrote on the *Mahābhārata* theme, as did Kāsiram Dās in the 17th century.

The third genre, *padāvalī* ("string of verse") songs, is also found elsewhere; inspired by the religious *bhakti* movement, the songs resemble the devotional poetry of the Nāyaṇārs and Āḻvārs in Tamil. It was such poetry that established Bengali as a significant literary language. The earliest work in what may be considered a distinctively Bengali style is the *Śrīkṛṣṇa-kīrtana* ("Praise of the Lord Krishna"), a long *padāvalī* poem by Caṇḍīdās, which is dated to the early 15th century. In it the poet praises the virtues and celebrates the loves of Krishna, a theme that had remained popular in Bengal ever since its first glorification by the Bengali Sanskrit poet Jayadeva, who composed his *Gītagovinda* ("The Cowherd Song") in the 12th century. *Padāvalī* songs describe and glorify all phases of Krishna's love for the cowherds' wives (especially Rādhā, who later became a goddess), and it is love poetry before it is religious poetry. After the great Bengali mystic and saint Caitanya (died 1533), love *is* religion, and the erotic is inspirited with religious fervour. The great flowering of this poetry occurred in the 16th and 17th centuries.

Religious edification took the forms not only of *maṅgals*

and *padāvalī*s but also of biography (more like hagiography) and philosophy. Important in that style is the long hagiography *Caitanya-caritāmṛta* ("Elixir of the Life of Caitanya"), by the 16th-century author Kṛṣṇadās.

While most of the literature is Hindu in theme and inspiration, there arose a secular Bengali literature among Bengali Muslims. One of the outstanding Muslim poets is Ālāol, author of the *Padmāvatī* (*c.* 1648), which was written after the poem of the same name by the Hindi poet Jāyasī.

Assamese. The earliest text in a language that is incontestably Assamese is the *Prahlāda-caritra* of Mena Sarasvati (13th century); in a heavily Sanskritized style it tells the story, from the *Viṣṇu-Purāṇa,* of how the mythical king Prahlāda's faith and devotion to Vishnu saved him from destruction and restored the moral order. The first great Assamese poet was Kavirāja Mādhava Kandalī (14th century), who translated the Sanskrit *Rāmāyaṇa* and wrote *Devajit,* a narrative on the god Krishna. In Assamese, too, the *bhakti* movement brought with it a great literary upsurge; the most famous Assamese poet of the period was Śaṅkaradeva (died 1568), whose 27 works of poetry and devotion are alive today and who inspired such poets as Mādhava-devi to write lyrics of great beauty. Peculiar to Assamese literature are the *buranjī*s, chronicles written in a prose tradition brought to Assam by the Ahoms of Burma. These date in Assamese from the 16th century, while in the Ahom language they are much earlier.

Oriya. *Mādaḷā-pāñji* ("The Drum Chronicle") texts in Oriya, the chronicles of the great temple of Jagannātha in Puri, date from the 12th century. They are in prose, and as such they represent the earliest prose in a regional Indo-Aryan language, although they cannot be said to be literary texts. The 14th century was productive for Oriya literature. Dating from this period are the anonymous *Kalasa-cautīśa,* which tells in 34 verses the story of the marriage of the god Śiva and the mountain goddess Pārvatī, and the famous *Caṇḍī-purāṇa* of Saraladāsa. But the *bhakti* period was once again the most stimulating one; the best known medieval Oriya poet is Jagannātha Dās (whose name means Servant of Jagannātha), a 16th-century disciple of the Bengali Vaiṣṇava saint Caitanya, who spent the better part of his life in Puri. Among the many works of Jagannātha Dās is a version of the Sanskrit *Bhāgavata-Purāṇa* that is still popular in Orissa today.

Marathi. With Bengali, Marathi is the oldest of the regional literatures in Indo-Aryan, dating from about AD 1000. In the 13th century, two Brahminical sects arose, the Mahānubhāva and the Varakari Panth, both of which put forth vast quantities of literature. The latter sect was perhaps the more productive, for it became associated with *bhakti,* when that movement stirred Mahārāshtra in the early 14th century, and particularly with the popular cult of Viṭṭhoba at Pandharpur. It was out of this tradition that the great names of early Marathi literature came: Jñāneśvara, in the 13th century; Nāmdev, his younger contemporary, some of whose devotional songs are included in the holy book of the Sikhs, the *Ādi Granth;* and the 16th-century writer Eknāth, whose most famous work is a Marathi version of the 11th book of the *Bhāgavata-Purāṇa.* Among the *bhakti* poets of Mahārāshtra the most famous is Tukārām, who wrote in the 16th century. A unique contribution of Marathi is the tradition of *povāḍā*s, heroic stories popular among a martial people. There is no way of dating the earliest of these; but the literary tradition is particularly vital at the time of Śivajī, the great military leader of Mahārāshtra (born 1630), who led his armies against the might of the Mughal emperor Aurangzeb.

Tradition of *povāḍā*s

Gujarati. The oldest examples of Gujarati date from the writings of the 12th-century Jaina scholar and saint Hemacandra. The language had fully developed by the late 12th century. There are works extant from the middle of the 14th century, didactic texts written in prose by Jaina monks; one such is the *Bālāvabodha* ("Instructions to the Young"), by Taruṇa-prabha. A non-Jaina text from the same period is the *Vasanta-vilāsa* ("The Joys of Spring"). The two Gujarati *bhakti* poets, both of the 15th century, are Narasiṃha Mahatā (or Mehtā) and Bhālaṇa (or Puruṣottama Mahārāja); the latter cast the 10th book of the *Bhāgavata-Purāṇa* into short lyrics. By far the most famous of the *bhakti* poets is the woman saint Mīrā Bāī, who lived in the first half of the 16th century. Mīrā, though married, thought of Krishna as her true husband, and the lyrics telling of her relationship with her god and lover are among the warmest and most movingly personal in any Indian literature. One of the best known of the non-*bhakti* Gujarati poets is Premānanda Bhaṭṭa (16th century), who wrote narrative poems based on *Purāṇa*-like tales; although his themes were conventional, his characters were real and vital, and he infused new life into the literature of his language.

Punjabi. Punjabi developed a literature later than most of the other regional languages of the subcontinent; and some of the early writings, such as those of the first Sikh Gurū, Nānak (late 15th and early 16th centuries), are in Old Hindi rather than true Punjabi. The first work identifiable as Punjabi is the *Janam-sākhī,* a 16th-century biography of Gurū Nānak by Bala. In 1604, Arjun, the fifth Gurū of the Sikhs, collected the poems of Nānak and others into what is certainly the most famous book to originate in the Punjab (though its language is not entirely Punjabi), the *Ādi Granth* ("First Book"). Writing that is not merely incidentally Punjabi began in the 17th century and is almost entirely by Muslims. Between 1616 and 1666, a writer named ʿAbdullāh, for example, composed a major work called *Bāra Anva* ("Twelve Topics"), which is a treatise on Islām in 9,000 couplets. Muslim Ṣūfīs, such as Bullhē Shāh (died 1758), also contributed many devotional lyrics, and Ṣūfī Islām can be said to have been the main stimulus to Punjabi literature in the medieval period. There are also many romances in the language (as in Rajasthani) which, being oral literature, are undatable.

Kashmiri. The hitherto commonly accepted period of Old Kashmiri is 1200–1500; but in fact the earliest example of the language is found in 94 four-line stanzas embedded in the Sanskrit philosophical work *Mahānaya-prakāśa* ("Illumination of the Highest Attainment"), which some scholars now date as late as the 15th century. As is true for Gujarati, the most famous poets of Kashmiri in this period are women. Lallā (14th century) wrote poems about the god Śiva; and Hubb Khātun (16th century) and especially Arani-mal (18th century) are famous for their hauntingly beautiful love lyrics. Despite these outstanding poets in Kashmiri, the great literary language of Kashmir in the medieval period was Persian, which was encouraged by many rulers of the country, such as Zayn-ul-ʿĀbidīn, in whose 15th-century court were many scholars and poets writing in both the Kashmiri and Persian languages.

(E.C.D.)

ISLĀMIC LITERATURES: 11TH–19TH CENTURY

The adventure of Islām in India began in the 8th century with the conquest of Sind (the extreme western province), but it was only in the 11th and 12th centuries that Muslim literary and cultural traditions reached the Indian heartland. Then, in the 13th century, refugee noblemen, soldiers, and men of letters from Iran and Central Asia came pouring into India. Although the causes changed, the attraction of India as a place of refuge and gracious patronage did not decline for several subsequent centuries. At the same time Muslim soldier-adventurers continued with their conquests, joining hands with their non-Muslim Indian counterparts in many instances, establishing minor or major kingdoms all over the subcontinent. The political map of India remained very much in flux—except for a brief period during the reign of Akbar—until Queen Victoria declared herself empress of India in 1858. The period of Muslim influence thus extends over 800 years.

At the time of the spread of Muslim power and culture in India, Sanskrit was the chief language of Hindu cultural, learned, and religious expression, while Buddhism and Jainism had lent their prestige and patronage to various Prākrits. The progress of and developments in these literatures remained unaffected by the advent of Islām in India. The emergence of the new Indo-Aryan languages out of the Prākrit and Apabhraṃśa stages of Sanskrit, however, was furthered by the newcomers, who preferred these regional languages over Sanskrit and encouraged the development

Effect of Islām on Sanskrit and Prākrit literatures

of popular regional literatures. The conversion to Islām of a large number of indigenous people enhanced these developments. Thus, the vehicles of literary expression used by those professing Islām in India were regional dialects and languages, both Indo-Aryan and Indo-Iranian, such as Braj, Awadhi, Sindhi, Baluchi, Urdu, Dakhini, and Bengali, as well as the foreign Arabic, Turkish, and Persian spoken by the Muslim immigrants and conquerors. Of these, only Persian and Urdu require detailed consideration; the others will be discussed only briefly.

Arabic. Arabic was the language of the conquerors of Sind. But it enjoyed more permanent prestige as the language of the Qur'ān, the sacred book of Islām; as such it was extensively used for religious scholarship during the medieval period. Even as late as the 18th century, Shāh Walī Allāh, the greatest theologian to have lived in India, wrote his most important treatises in Arabic. Arabic was also used early for historiography and for making Indian scientific books available to the Middle East in translation. One does not find, however, much in the way of significant Arabic belles lettres in India.

Turkish. Although the earliest Muslim conquerors in northern India were Turks, their language was Persian. It was only during the reigns of Bābur and his son Humāyūn (1526–56) that Turkish flourished for a while as a medium of learned expression. Bābur himself was the foremost contributor. Although his memoirs are better known, he also left a volume of verses of considerable merit.

Regional languages. The literatures of the Indo-Iranian languages of Baluchi and Pashto are exclusively creations of Muslim writers. In the Indo-Aryan languages of Kashmiri, Sindhi, and Punjabi, Muslims were the most influential contributors; the names of Lallā (14th century) for Kashmiri, Shāh ʿAbd-ul-Laṭīf (17th–18th century) for Sindhi, and Wāriš Shāh (18th century) for Punjabi exemplify that fact. Muslim chieftains gave impetus to the growth of Bengali literature through their patronage of writers and through their efforts to have Sanskrit classics translated into Bengali. There are also many famous Muslim names during the medieval period of Bengali literature, such as Dawlat Qāzī and Ālāol in the 17th century. In the heartland of northern India, notable contributions were made by Muslims to Hindi literatures in the Braj and Awadhi dialects. Malik Muḥammad Jāyasī, Raḥīm, and Manjhan (all 16th century) and ʿUsman (17th century) are some of the important names. In the 16th, 17th, and 18th centuries in India there was a tremendous production of mystic (Ṣūfī and *bhakti*) poetry in all of the important dialects and languages. It was a period of great mystic, syncretic movements, and the Muslim contribution in the form of love narratives and lyrics was considerable. Quite often metres, motifs, and assorted rhetorical features of Persian *mašnavīs* and *ghazals* (see below *Urdu*) were used in a new medium. Moreover, interaction and assimilation took place between the Muslim Ṣūfī traditions, thought, and practices and the Indian *bhakti* schools. Muslim *bhakti* poets either expressed Ṣūfī ideas, which were close to monotheistic orthodoxy as well as to the doctrines of Indian saints Kabīr and Nānak, in the Indian dialects through narrative poems modelled on Persian *mašnavīs* or chose the path of ecstasy and became devotees of Krishna (which was still close to the more orthodox forms of Ṣūfīsm). None of them followed the devotional style of Tulsīdās, their contemporary and a devotee of Rāma.

It was, however, in Persian and Urdu that Muslim men of letters made the greatest contributions—contributions that led in the former case to the establishment of an "Indian" school of Persian poetry and influenced profoundly the development of poetry in Afghanistan and Tadzhikistan and, in the latter case, led to the emergence of a unique pan-Indian language and literature in Urdu.

Persian. Maḥmūd of Ghazna, with whom the chain of Muslim conquests in northern India began, was also the patron of Ferdowsī, one of the greatest of Persian poets. The later conquerors admired literature no less. Since the language of all of them was Persian, the growth of Persian literature in India kept pace with its conquest by the Muslims.

Masʿūd Saʿd Salmān (born 1046 in Lahore), who later became the governor of Jullundhur, was the first noteworthy person of Indian origin to have written poetry in Persian. The first truly great poet was Amīr Khosrow, who wrote in the 13th and 14th centuries. Of Turkish descent, born in the district of Etah in northern India, Khosrow was connected with royal courts all his life, even after 1272, when he became a disciple of the great mystic Niẓām-ud-Dīn Awliyā. He wrote five books of poems, or *dīvāns*, composed of *ghazals* (see below *Urdu*), panegyrics and several *mašnavīs*—altogether some 200,000 couplets. In poetry, his innovative spirit displayed itself in *waṣf-nigārī*—that is, descriptions of natural objects in short poems, which Khosrow incorporated within longer ones. His keenness of observation is also evident in his use of local fauna and flora as poetic images. Khosrow's distinction lies not so much in the fact that he is an innovator, however, as in the fact that he is equally superb in narrative poetry, panegyrics, and lyrics. The range of his popularity and influence can best be gauged by the fact that, in northern Indian folk literature, one comes across numerous songs and riddles consistently attributed to Amīr Khosrow.

The poems of Amīr Khosrow

In the centuries that followed Khosrow, until the end of the Islāmic period, India contributed to Persian literature in two ways: first, through the production of dictionaries that helped to standardize the language and consolidate its vocabulary; second, through the development of the so-called Indian style of Persian poetry.

It is generally agreed that this Indian style, *sabk-e hindī*, did not originate within the geographic confines of India, though it reached its most sublime form there at the hands of poets who either were born in India or spent their most productive years at various Indian courts. Some of the characteristics of the style are (in the words of one modern critic) the emphasis on

> parallel statement . . . ; on complex conceit like that of the seventeenth century English "metaphysical" poets, arising out of economy of expression and telescoping into a single image a variety of emotional states; on "cerebral" artifice in pushing familiar images to unfamiliar and unexpected lengths; and on the creation of a synthetic poetic diction in which a whole phrase constitutes a single image.

The keen observation of daily life that is also characteristic of Indian Persian poetry could have been inspired by the traditions of classical Sanskrit poetry, with which these poets must have been familiar through the extensive translations done during the reign of the Mughals.

The century (1556–1657) of the reigns of Akbar, Jahāngīr, and Shāh Jahān was the most glorious period for Persian poetry in India, though, except for Fayẓī, all of the important poets were immigrants from Persia who found relief from religious and political persecution as well as generous patronage at the hands of the great Mughals and the lesser kings of southern India. The great men of letters of that period were ʿUrfī, Ṭālib Āmulī, Naẓīrī, Ẓuhūrī, Kalīm, and Ṣāʾib.

The greatest poet of the Indian style, however, was ʿAbdul Qādir Bēdil, born in 1644 in Patna, of Uzbek descent. He came early under the influence of the Ṣūfīs, refused to be attached to any court, and travelled widely throughout India during his long life. Bēdil's 16 books of poetry contain nearly 147,000 verses and include several *mašnavīs*. Though ignored by the Iranians, Bēdil's poetry had an impact on Tadzhik and Uzbek literatures, and its influence is still evident in Afghanistan. A poet of great virtuosity and philosophic bent, he was well acquainted with Indian religions and philosophy. His anti-feudal views and his critical and skeptical attitude toward all kinds of dogma make his poetry relevant even today. His style is difficult, his metaphors and syntax quite complex (though the language itself is quite simple); and yet, as a modern critic puts it, "the intensity of his subjective assessment is so acute and factual, and his metaphysical experience so intense, that genuine poetry emerges in all its splendour."

The works of ʿAbdul Qādir Bēdil

Urdu. Earlier varieties of Urdu, variously known as Gujari, Hindawi, and Dakhani, show more affinity with eastern Punjabi and Haryani than with Khari Boli, which provides the grammatical structure of standard modern Urdu. The reasons for putting together the literary products of these dialects, forming a continuous tradition with

those in Urdu, are as follows: first, they share a common milieu, consisting of Ṣūfī and Muslim court culture, increasingly dominated by the life and values of the urban elite; second, they display wholesale acceptance of Perso-Arabic literary traditions, including genres, metres, and rhetoric; third, they show an increasing acceptance of Perso-Arabic grammatical devices and vocabulary; and fourth, they tend to prefer Perso-Arabic forms over indigenous forms for learned usage.

Apart from themes and metaphysics, the influence of Ṣūfī hospices and royal courts can be seen in two practices that were essential to the development of Urdu poetry (and also unique to the Urdu milieu in the medieval period) and that still exist in modified forms. First, Urdu poets generally chose an *ustād,* or master, just as a Ṣūfī novice chose a *murshid,* or preceptor, and one's poetic genealogy was always a matter of much pride. Second, poets read poetry in private or semiprivate gatherings, called *mushā'irah,* which displayed hierarchies, status consciousness, and rivalries reminiscent of royal courts.

Urdu literature began to develop in the 16th century, in and around the courts of the Quṭb Shāhī and 'Ādil Shāhī, kings of Golconda and Bījāpur in the Deccan (central India). In the later part of the 17th century, Aurangābād became the centre of Urdu literary activities. There was much movement of the literati and the elite between Delhi and Aurangābād, and it needed only the genius of Walī Aurangābādī, in the early 18th century, to bridge the linguistic gap between Delhi and the Deccan and to persuade the poets of Delhi to take writing in Urdu seriously. In the 18th century, with the migration of poets from Delhi, Lucknow became another important centre of Urdu poetry, though Delhi never lost its prominence.

The first three centuries are dominated by poetry. Urdu prose truly began only in the 19th century, with translations of Persian *dāstāns,* books prepared at the Delhi College and the Fort William College at Calcutta, and later with the writers of the Aligarh movement.

To focus on essential matters, the discussion that follows forgoes a chronological account of the poetry, concentrating instead on characteristics of particular genres and the achievements of the most significant of their practitioners up to 1857. There is one poet, however, who cannot be described as a practitioner of the classical Perso-Arabic traditions adopted by his fellow poets. Naẓīr Akbarābādī, who wrote in the late 18th and early 19th centuries, was a poet of consummate skill who chose to display it in short poems (in various forms) written in the language of popular speech as well as of literature. His themes show similar eclecticism. In his voluminous body of work, there are poems on such diverse topics as popular festivals, the seasons, the vanities of life, erotic pleasures and pursuits, dancing bears, and niggardly merchants. He is a master of the telling detail that immediately brings any event to life. Generally ignored by elitist poets and literary chroniclers of his time, Naẓīr has gained increasing respect and recognition as the first and best poet of the people.

The works of Naẓīr Akbarābādī

Qasīdahs. *Qasīdah*s are poems written with a "purpose"—the purpose being worldly gain, in the case of poems praising kings and noblemen, or benefit in the afterworld, in the case of poems praising God, the prophet Muḥammad, and other holy personages. These panegyrics are generally overly long and are written in a highly ornate and hyperbolic style, the poets vying to display their prowess by using as many rhymes and discovering as many associative themes as possible. Because of their style and language they are of special interest to lexicographers. Not much scholarly work has been done on the *qasīdah*s written in the Deccan, but in northern India a number of poets are regarded highly for their achievements in this genre: in the 18th century, Sawdā and Inshā', and in the 19th, Żawq and Ghālib.

Ḥaju and shahr-āshūb. Less ornate, if not less elaborate, and more edifying are the *ḥaju* (derogatory verses, personal and otherwise) and the *shahr-āshūb* (poems lamenting the decline or destruction of a city). They provide useful information about the mores and morals of the period from the 18th to mid-19th century and truly depict the problems facing the society at large. The poems are not formally restricted to any particular metre or stanza pattern. Sawdā again is one of the more famous names.

Marsiyeh. *Marsiyeh* means "elegy," but in Urdu literature it generally means an elegy on the travails of the family and kinsmen of Ḥusayn (grandson of Muḥammad) and their martyrdom in the field of Karbalā, Iraq. These elegies and other lamentatory verses were read at public gatherings, especially during the month of Muḥarram. Although a large number of *marsiyeh*s were written in the Deccan and at Delhi, it was in Lucknow, with the patronage of Shī'ite elite and royalty, that *marsiyeh*s gained the tenor and magnitude of epic poetry. The two great masters of that 19th-century period were Mīr Anīs and Mīrzā Dabīr, who together established *musaddas* (a six-line stanza with an *aaaa bb* rhyme scheme) as the preferred form for *marsiyeh*s and added several new topics and details to the ranks of associated themes, thus carrying the form beyond a simple lament. An interesting aspect of these elegies is that, although the scene and personae are Arab, there is no attempt at verisimilitude: Arab gallants and maidens speak and gesture like the elites of Lucknow. Perhaps this added to the pathos and effectiveness of the poems at public readings.

Urdu lamentatory elegies

Maśnavī. *Maśnavī* was the preferred genre for all descriptive and narrative purposes, for it allows the most freedom (only the lines of each couplet must rhyme). In the Deccan, all major poets wrote at least one long *maśnavī,* but lack of knowledge of the dialect has prevented their full appreciation. Thus, the more famous *maśnavī*s are by later poets of Delhi and Lucknow, such as Mīr, Mīr Ḥasan, Dayā Shankar Nasīm, and Mīrzā Shawq. The topics of descriptive *maśnavī*s range from mundane events of life, hunting trips of kings, and the vagaries of nature's seasons to autobiographical discourses. Narrative *maśnavī*s are considerably longer, running into hundreds of couplets. In the Deccan several poets wrote abridged versions of Persian *maśnavī*s, but many others wrote original compositions utilizing Indian romances as well as the better known Persian and Arabic ones. Apart from the names of the protagonists in the *maśnavī*s inspired by Persian and Arabic poems, all else is always local; the landscape, cityscape, processions, customs and rituals, social values and taboos, even the physical characteristics of the people are totally Indian, though dominantly Muslim and feudal. Despite their length, these narratives gained much popularity and, at least in northern India, were often read in public places, in much the same way as storytellers told stories. The *maśnavī* form was also used by some of the Hindi Ṣūfī poets.

Ghazal. For the most part, the history of Urdu poetry in India is the story of Urdu *ghazal,* which has been the favourite of both poets and their audiences in every period. A short lyric, with prosodic requirements of both metre and rhyme, *ghazal* demands great skill and thought from the poet, for its couplet must be a complete semantic entity and fully express a whole, well-integrated poetic experience. Favourite themes are erotic love, Ṣūfī love, and metaphysics. Naturally, Urdu poets began by closely imitating, often even plagiarizing, Persian masters, but later on they spoke in a more authentic voice. They continued, however, to employ a vocabulary of love that owed almost everything to Persian and shared very little with the traditions of lyrical poetry in other Indian languages. For example, with few exceptions, the lover is always masculine; expression of love is never made by a woman. Unique, too, is the use of masculine grammatical forms and imagery for the beloved, even when, in every other way, the poem is clearly celebrating heterosexual love. This peculiarity, as well as other traditions borrowed from Persian masters, gives a *ghazal* couplet a tremendously wide range of interpretations. It is amazing indeed what a master poet can condense into one terse couplet.

Characteristics of the *ghazal*

The two greatest *ghazal* writers in Urdu are Mīr Taqī Mīr, in the 18th century, and Mīrzā Asadullāh Khān Ghālib, in the 19th. They are in some ways diametrical opposites. The first prefers either very long metres or very short, employs a simple, non-Persianized language, and restricts himself to affairs of the heart. The other writes in metres of moderate length, uses a highly Persianized vo-

cabulary, and ranges wide in ideas. Mīr speaks of passion and pathos; Ghālib betrays a skeptic's mind and leaves nothing unquestioned, not even his feelings. But both have left indelible marks on the ideas and emotions of succeeding generations. Ghālib wrote poetry in Persian as well as Urdu and also published a couple of volumes of letters in Urdu that helped usher in modern prose. In many ways he bridges the gap separating the medieval sensibility from the modern. The contemporary mind, however, is also moved by the authentic passion of Mīr, idolizing him for the sublimity of his concept of love and for his personal integrity. The poems of Ghālib and Mīr represent the best of the Urdu *ghazal;* and the Urdu *ghazal,* as an anonymous wit has remarked, is the Muslims' greatest gift to India, after the Tāj Mahal. (C.M.N.)

SINHALESE LITERATURE: 10TH CENTURY AD TO 19TH CENTURY

The island nation of Ceylon (now called Sri Lanka), formally a part of South Asia, has been little noticed by the subcontinent, apart from the fact that according to an uncertain tradition it is celebrated in the *Rāmāyaṇa* as the island called Laṅkā. Buddhist sway was introduced there early, during the reign of Aśoka Maurya (*c.* 269–232 BC); and, while on the subcontinent Buddhism prospered, declined, and finally disappeared, in Ceylon it has continued until today. Although there are obvious borrowings in Ceylon from subcontinental literature, notably Sanskrit, and there was rather precarious communication with India through the island's Hindu community of Tamils, Ceylon never became culturally continuous with the mainland. The language itself, although of Indo-Aryan stock, is strongly mixed with a substratum of Dravidian. Also, it was Ceylon's fate early to fall victim to European colonialism, first to the Portuguese, then to the Dutch, and finally to the British, before it regained nationhood in 1948.

While there are inscriptions that antedate the Christian Era, no texts appear to survive from before the 10th century AD. The first texts that emerged were aids in Sinhalese—glossaries, paraphrases, and the like—to the study of the Pāli texts of Buddhism. More interesting are Sinhalese renderings of the life and virtues of the Buddha. Important in this genre, hagiographic rather than literary, is the *Amāvatura* ("Flood of the Ambrosia"), by Guruḷugōmī, which in 18 chapters purports to narrate the life of the Buddha, with specific emphasis on one of his nine virtues—his capacity to tame recalcitrant people or forces. In a similar vein is the literature of devotion and counsel, in which Buddhist virtues are celebrated.

Historical records

Exceptional in the context of the South Asian subcontinent is the early and persistent interest in historical records. Such interest had begun in Pāli with the *Dīpavaṃsa* ("Chronicle of the Island") and had continued with the *Mahāvaṃsa* ("Great Chronicle") and *Cūlavaṃsa* ("Lesser Chronicle"), but it had a life of its own in Sinhalese. The most important, and possibly the oldest, of such chronicles is the *Thūpavaṃsaya* ("Chronicle of the Great Stupa"), by Pārakrama Paṇḍita. Subsequent chronicles, or genealogies of places, comprise the history of all of the major Buddhist monuments. Several chronicles were also inspired by the Tooth Relic, received from Kaliṅga in the 4th century by King Kīrtiśrīmēghavarṇa. Such chronicling included that of the kings who protected the relic.

All of this literature was mostly in prose, but poetry as a literary form no doubt antedated it, as evidenced by early inscriptions. Much poetry was occasioned by Pāli *Jātakas* (stories of the Buddha's previous births) and other Buddhist stories, though Hindu stories were not lacking; for example, a version of the Sanskrit *Mahābhārata* (received through a Tamil source) was cast in the style of a *Jātaka* in the *Mahāpadaraṅga-Jatakaya.*

Likewise of Hindu Indian origin was a genre that took off from the Sanskrit poet Kālidāsa's "Meghadūta" (see above *Classical Sanskrit kāvya* [*200–1200*]), in which an exiled lover sends a message to his beloved by way of a monsoon cloud, thus giving the poet the opportunity to dwell on the description of landmarks in a poetic travelogue. This genre, so-called *saṃdeśa* literature, by no means unknown on the mainland, proliferated widely on Ceylon.

Of a different style are panegyrics and war poems, the earliest of which is the *Parakumbasirita* ("History of Parakramabahu VI," king in Jayavardhanapura from 1410 to 1468). Again reminiscent of the mainland and the religious tradition are the plentiful eulogies of the Buddha. Popular, too, was didactic verse, among the most notable of which is the *Kusajātaka,* 687 stanzas of epigrams and exempla by the 17th-century poet Alagiyavanna Mohoṭṭāla.

MODERN PERIOD: 19TH AND 20TH CENTURIES

The modern period was ushered in by the arrival of the British, the influence of Western models becoming discernible in the early 19th century. Reform-minded Hindus, led by Ram Mohun Roy, took a positive attitude to Western literature and urged on their countrymen a Western type of education. Newly formed literary clubs spread the influence of predominantly British works, thereby opening the Indian educated elite to Western culture and literature in general. After a period of translation, authors sought to imitate Western models and eventually to be independently creative in the new styles.

Effects of Westernization

The most striking result of Westernization was the introduction of prose on a major scale. Vernacular prose, rarely looked upon previously as a medium for art, was now used as a literary vehicle, and such hitherto unknown forms as the novel, novella, and short story began to emerge. In poetry the thrall of tradition was stronger, and verse in the older forms continued to be written. With modernity, realism appeared, as well as symbolism in some quarters, and there was new psychological and social interest.

From Bengal spread a new sense of national purpose, which became the principal motivation for much English as well as vernacular literature. Three trends can be distinguished in the products of this increasing literary activity. The old traditionalism was transformed into romanticism, which looked to the past, to Indian history, for inspiration and sought to preserve what was considered valuable in the past; a tendency to mysticism went hand in hand with the romantic mood (a mood that was also widespread in 19th-century Europe). Greater social awareness in European literature was reflected in the literature of Indian progressives, in whose works a somewhat romantic Marxism prevailed. Finally, there was a humanistic trend. The teachings of Mahatma Gandhi, combining social concerns with traditional ethics, later exerted a very great influence on literature.

In the years preceding and following India's independence (1947) and control of the princely states, the fervour of writers sometimes turned to an increasingly articulate progressivism of various Marxist schools, sometimes to disappointment and bitterness, and most recently, it appears, to a mood of introspection. These developments, which occurred with a different pace in different regions, are described briefly below. A complete coverage of the most modern literature has not been attempted, but an endeavour has been made to mention persons who are considered to be representative.

Bengali. Except for the iconoclastic poet Michael Madhusudan Datta, poetic activity in the mid-19th century was giving ground to experimentation with the new prose style learned from English. During this period, Bengali literature produced a spate of novels—satiric, social, and picaresque. While Michael's work *Mēghanādavadh* (1861; a long poem on the Rāma theme in which Rāma and Lakṣmaṇa become the villains and Rāvaṇa the hero) caused a stir, the literary event of the period was the appearance on the scene of Bankim Chandra Chatterjee, whose first novel, *Durgeśanandinī* ("Daughter of the Lord of the Fort"), appeared in 1865. While not at first overtly nationalist, Bankim Chandra became more and more an apologist for the Hindu position. In *Kṛṣṇacaritra,* Christ suffers in comparison with Krishna, and in his best known work, *Ānanda-maṭh* (1892; "The Abbey of Bliss"), the motherland in the person of the goddess Durgā is extolled.

Perhaps first among novelists of the late 19th and early 20th centuries is Saratchandra Chatterjee, whose social concerns with the family and other homely issues made his work popular. But the early 20th century is certainly best known for the poet who towers head and shoulders

above the rest, Rabindranath Tagore. Poet, playwright, novelist, painter, essayist, musician, social reformer, Rabindranath produced works, still not completely collected, that fill 26 substantial volumes. The winner of the Nobel Prize for Literature in 1913, primarily for his little book of songs called *Gītāñjali,* which was much praised by Ezra Pound and William Butler Yeats, Tagore is more known for these devotional poems than for the wit and clear thought with which his later work is filled. He was the last of an era, looking back as he did to the religious and political history of Bengal for his inspiration. Those who followed him were more concerned with introspection and dramatic imagery.

If Tagore was the last poet in the Bengali tradition, Jibanananda Das was the first of a new breed. Musing and melancholy, yet known for vivid and unusual imagery Jibananada is a poet who has much influence on younger writers in Bengal. There have been many other poets in the 20th century who are equally powerful but stand somewhat apart from the mainstream. One of these was Sudhindranath Datta, a poet much like Pound in careful and etymological use of language; another is the poet and prose writer Buddhadeva Bose.

Bose has been termed a progressive, and indeed he consciously turned away from the tradition orientation of Tagore and sought inspiration in schools foreign to Bengal—for example, the French Symbolists. He is the leader of an artistic faction, the Kallol school, and editor of an influential literary magazine, *Kavitā.* Unjustifiably called obscene, his writing has been experimental, probing into social and psychological realities of Bengali life.

While there have been, and still are, literary factions associated with political positions, they have been less definitive than some in other parts of India. Bengali writers in the 20th century have tended to be personal and individual rather than propagandist for political positions.

Assamese. Assamese literature began with Hemchandra Baruwa, a satirist and playwright, author of the play *Bahiri-Rang-Chang Bhitare Kowabhaturi* (1861; "All That Glitters Is Not Gold"). The most outstanding among the early modern writers was Lakshminath Bezbaruwa, who founded a literary monthly, *Jōnāki* ("Moonlight"), in 1889, and was responsible for infusing Assamese letters with 19th-century Romanticism. Later 20th-century writers have tried to remain faithful to the ideals of *Jōnāki.* The short story in particular has flourished in the language; notable practitioners are Mahichandra Bora and Holiram Deka.

The year 1940 marked a shift toward psychology, but World War II effectively put an end to literary development. When writers resumed after the war, there was a clear break with the past, in experimental verse and the growth of the novel form.

Hindi. Modern Hindi literature began with Harishchandra in poetry and drama, Mahavir Prasad Dvivedi in criticism and other prose writings, and Prem Chand in fiction. This period, the second half of the 19th century, saw mainly translations from Sanskrit, Bengali, and English. The growth of nationalism and social reform movements of the Arya Samaj led to the composition of long narrative poems, exemplified by those of Maithili Sharan Gupta; dramas, by those of Jayashankar Prasad; and historical novels, by those of Prasad, Chatureen Shastri, and Vrindavan Lal Varma. The novels drew mainly on the periods of the Maurya, Gupta, and Mughal empires.

Gandhi's influence on poetry

This period was followed by the Non-cooperation and *satyāgraha* movements of Mahatma Gandhi, which inspired poets such as Makhan Lal Chaturvedi, Gupta, and Subhadra Chauhan and novelists such as Prem Chand and Jainendra Kumar. Eventual disillusionment with Gandhian experiments and the increasing influence of Marxism on European literature influenced writers such as Yashpal, Rangeya Raghava, and Nagarjuna.

S.N. Pant, Prasad, Nirala, and Mahadevi Varma, the most creative poets of the 1930s, drew inspiration from the Romantic tradition in English and Bengali poetry and the mystic tradition of medieval Hindi poetry. Reacting against them were the Marxist poets Ram Vilas Sharma and Nagarjuna and experimentalists such as H.S. Vatsyayan "Agyeya" and Bharat Bhuti Agarwal. Nirala, who developed from a mystic-romantic into a realist and experimentalist, was the most outstanding poet of the 1950s; and Sarweshwar Dayal Saxena, Kailash Vajpeyi, and Raghubir Sahay were the most creative poets of the 1960s.

Two trends, represented by the work of Prem Chand and Jainendra Kumar, led Hindi fiction in two different directions: while social realists like Yashpal, Upendranath Ashk, Amritlal Nagar, Mohan Rakesh, Rajendra Yadav, Kamleshwar, Nagarjuna, and Renu faithfully analyzed the changing patterns of Indian society, writers such as Ila Chandra Joshi, "Agyeya," Dharm Vir Bharati, and Shrikant Varma explored the psychology of the individual, not necessarily within the Indian context.

Among the dramatists of the 1930s and 1940s were Govind Ballabh Pant and Seth Govind Das; because of their highly Sanskritized language, their plays have had a limited audience. Plays by minor writers such as Ramesh Mehta, however, are repeatedly staged by professional theatres. In between these extremes there are some notable playwrights.

Gujarati. In Gujarāt, too, the advent of British rule deeply influenced the literary scene. The year 1886 saw the *Kusumamālā* ("Garland of Flowers"), a collection of lyrics by Narsingh Rao. Other poets include Kalapi, Kant, and especially Nanalal, who experimented in free verse and was the first poet to eulogize Gandhi. Gandhi, himself a Gujarati, admonished poets to write for the masses and thus inaugurated a period of poetic concern with changes in the social order. Many incidents in Gandhi's life inspired the songs of poets. The Gandhi period in Gujarāt as elsewhere gave way to a period of progressivism in the class-conflict poetry of R.L. Meghani and Bhogilal Gandhi. In post-independence India, poetry has tended to become subjectivist and alienated without, however, fully superseding the traditional verse of devotion to God and love of nature.

Among novelists, Govardhanram stands out; his *Sarasvatīchandra* is a classic, the first social novel. In the novel form, too, the influence of Gandhiism is clearly felt, though not in the person of Kanaiyalal Munshi, who was critical of Gandhian ideology but still, in several *Purāṇa*-inspired works, tended to preach much the same message. In the period after independence the modernists embraced existentialistic, surrealistic, and symbolistic trends and gave voice to the same kind of alienation as the poets.

Marathi. The modern period in Marathi poetry began with Kesavasut and was influenced by 19th-century British Romanticism and liberalism, European nationalism, and the greatness of the history of Mahārāshtra. Kesavasut declared a revolt against traditional Marathi poetry and started a school, lasting until 1920, that emphasized home and nature, the glorious past, and pure lyricism. After that, the period was dominated by a group of poets called the Ravikiraṇ Maṇḍal, who proclaimed that poetry was not for the erudite and sensitive but was instead a part of everyday life. Contemporary poetry, after 1945, seeks to explore man and his life in all its variety; it is subjective and personal and tries to speak colloquially.

Among modern dramatists, S.K. Kolhatkar and R.G. Gadkari are notable. Realism was first brought to the stage in the 20th century, by Mama Varerkar, who tried to interpret many social problems.

Novelists of the 20th century

The *Madhalī Sthiti* (1885; "Middle State"), of Hari Narayan Apte, began the novel tradition in Marathi; the work's message was one of social reform. A high place is held by V.M. Joshi, who explored the education and evolution of a woman (*Susīlā-cha Diva,* 1930) and the relation between art and morals (*Indu Kāḷe va Saralā Bhoḷe,* 1935). Important after 1925 were N.S. Phadke, who advocated art for art's sake, and V.S. Khandehar, who countered the former with an idealistic art for life's sake. Noteworthy contemporary novelists are S.N. Pendse, V.V. Shirwadkar, G.N. Dandekar, and Ranjit Desai.

Punjabi. Modern Punjabi literature began around 1860. A number of trends in modern poetry can be discerned. To the more traditional genres of narrative poetry, mystic verse, and love poems was added nationalist poetry in a humorous or satiric mood and experimental verse. Among

the more important Punjabi poets are Bhai Vir Singh, in the 19th century, and Purana Singh, Amrita Pritam, and Baba Balwanta, in the 20th century.

Modern prose is represented by Bhai Vira Singha, Charana Singha, and Nanaka Singha, all of whom wrote novels; the same writers, as well as Gurbhaksh Singh and Devendra Satyarathi, also wrote short stories. Among playwrights mention may be made of I.C. Nanda, Harcharan Singh, and Santa Singh Sekhon.

Rajasthani. It is generally agreed that modern Rajasthani literature began with the works of Suryamal Misrama. His most important works are the *Vamsa Bhaskara* and the *Vira satsaī*. The *Vamsa Bhaskara* contains accounts of the Rājput princes who ruled in what was then Rājputāna (at present the state of Rājasthān), during the lifetime of the poet (1872–1952). The *Vira satsaī* is a collection of couplets dealing with historical heroes. Two other important poets in this traditional style are Bakhtavara Ji and Kaviraja Muraridana.

The period of nationalist strife against the British inspired a number of poets to verse that was both nationalist and in the traditional heroic vein; among them are Hiralala Sastri, Manikyalala Varma, and Jayanarayana Vyasa. This period was followed by one in which progressive social ideals inspired such poets as Ganeshilala Vyasa, Murlidhara Vyasa, and Satyaprakasha Jodhi.

Primarily known for their lyrics are Kanhaya Lal Sethiya and Megharaja Mukula, among others, and known for their narrative poems are Manohara Sharma, Shrimanta Kumara, and Naraina Singha Bhati.

Modern prose is represented in the novel, short story, and play. Among the novelists are Shiva Candra Bharatiya, Shri Lal Jodhi, Vijaya Dana Detha, and Yadavendra Sharma Chandra; the short-story writers are Rani Lakshmi Kumari Chandavata, Narasingh Rajapurohita, Dinadayala Ojha, and Purushottama Lala Menariya. Vijaya Dana Detha and Rani Lakshmi Kumari Chandavata are also known for their retelling of Rajasthani folktales. Among the playwrights is Shivachandra Bharatiya.

Tamil. In the second half of the 19th century two tendencies were present in Tamil literature. One was the old traditional prose style of the *Patiṉeṇ-kīḻkkaṇakku*, or "Eighteen Ethical Works" (see above *Dravidian literature: 1st–19th century*), learned and severely scholastic; among others, V.V. Svaminatha Iyer and Arumuga Navalar wrote in this style. Another tendency, begun by Aruṇācala Kavirāyar in the 18th century, sought to bring the spoken and written languages together. This tendency developed on one side into such works as the operatic play *Nantaṇār Carittarak Kīrttaṇai* by Gopalakrishna, and on the other into ballads, often based on the lore of the Sanskrit *Purāṇas*. Despite attempts to effect a synthesis between the two languages, however, the scholastic style has continued to have a profound influence on modern Tamil literature; the normal spoken language, in fact, never became a literary medium.

First Tamil novel

The first novel in Tamil appeared in 1879, the *Piratāpamutaliyār Carittiram*, by Vetanayakam Pillai, who was inspired by English and French novels. In important respects Pillai's work is typical of all early modern Tamil fiction: his subject matter is Tamil life as he observed it, the language is scholastic, and the inspiration comes from foreign sources. Not strictly a novel, his work, which has a predominantly moral tone, is a loosely gathered string of narratives centred around an innocent hero.

Quite different is the *Kamalāmpāḷ Carittiram* ("The Fatal Rumor"), by Rajam Aiyar, whom many judge to be the most important prose writer of 19th-century Tamil literature. In this work, the author created a series of characters that appear to have become classics; the story is a romance, yet life in rural Tamil country is treated very realistically, with humour, irony, and social satire. In language Aiyar follows the classical style, which he intermixes with informal conversation, a style that has been imitated by modern authors.

The turn of the century saw the development of the *centamiḻ* style, which in many respects is a continuation of the medieval commentatorial style. The best representative is V.V. Swaminathan, who also is responsible for the rediscovery of the Tamil classical legacy, usually called "Tamil Renaissance," which tended to direct the mood of writers back to the glorious past. The pride in Tamil subsequently gave rise to a purist tradition and a second style, called *tuyattamiḻ*, or "pure Tamil." With exaggerated Tamilian self-consciousness, the language was purged of all non-Tamil loanwords, particularly Sanskrit, which removed the literary language even further from the spoken one. This style was not ineffective in verse but led easily to rhetoric.

The purist trend brought forth a reaction in *putumaṇipravāla naṭai*, "the new *maṇipravāla*" (see above *Dravidian literature: 1st–19th century*), which was Sanskritized with a vengeance and is of little literary interest.

The scholastic and formalist character of Tamil prose was predominant in the literature until the advent, in the early 20th century, of the poet and prose writer Subrahmanya Bharati. Bharati sought to synthesize the popular and the scholastic traditions of Tamil literature, and he created thereby a Tamil that was amenable to all literary expression. This synthesis, however, did not extend to the literary language itself, which in grammar continued the formal language, though for syntax, vocabulary, etc., he drew upon colloquial speech. In doing so he saved the language from the Sanskrit tradition of *Purāṇa* writing. His style is the *maṟumaḻarcci naṭai*, the "renaissance style."

In the first half of the 20th century, R. Krishnamurthy was an immensely popular writer. Under the pseudonym Kalki, he was an influential journalist who wrote voluminous historical romances.

In the 1930s there was a literary movement inspired by a journal called *Manikkoti*. Writers in this movement contributed extremely important new works, both in verse and prose, to Tamil letters. Among them was Putumaippittan, who wrote realistically, critically, and even bitterly about the failings of society.

Contemporary literature is represented by T. Janakiraman, who writes novels, short stories, and plays with themes from urban Tamil middle-class family life; Jayakanthan, a sharp and passionate writer, with a tendency to shock his readers; and L.S. Ramatirthan, probably the finest stylist at work in Tamil today, who started by writing in English.

Malayalam. In Malayalam the modern movement began in the late 19th century with Asan, who was temperamentally a pessimist—a disposition reinforced by his metaphysics—yet all his life was active in promoting his downtrodden Ezhava community. Ullor wrote in the classical tradition, on the basis of which he appealed for universal love, while Vallathol (died 1958) responded to the human significance of social progress.

Contemporary poetry records the encounter with problems of social, political, and economic life. The tendency is toward political radicalism.

Drama, native in Malayalam tradition, emerged in the modern period as farce, comedy, and satire but turned in the 1920s to a more sombre appraisal of outdated social conventions. The novel dates back to the late 1880s and was early concerned with social realism. At present the general tendency is introspective.

Emergence of modern Kannada poetry

Kannada. Modern Kannada poetry emerged about the beginning of the 20th century and showed a spirit of national purpose that pervaded other literature as well. By 1920, after major translations from Western models had been published, new literary forms such as the lyric and the short story came to the fore in the works of Panje Mangesh Rao and B.M. Srikantiah. Other prominent Kannada writers were D.V.G. Masti, Govinda Pai, and K.V. Puttappa ("Kuvempu"). In recent years a modernist movement has influenced the literature.

Urdu. The modern period in Urdu literature coincides with the mid-19th-century emergence of a middle class that saw in Western thought and science a means to needed social reform. Naẕīr Aḥmad wrote novels about the conflicts of Muslim middle class people. Shiblī, a poet and critic, wrote on the lives of great Muslims. The more famous novelists of the later period are Ratan-Nāth Sharshār, ʿAbd-ul-Ḥalim Sharar, and Mīrzā Ruswā. The fathers of modern Urdu poetry were Ḥālī and Muḥammad

Ḥusayn Āzād, the latter particularly characterized by a fine sensitivity for the past.

The greatest modern poet is Iqbāl. Writing in the early 20th century, he was influenced by the general sense of national purpose and the freedom movement. His poetic imagery, the power of his expression, and his philosophical outlook won the admiration of his fellow Muslims. In prose the most important writer of short stories was Prem Chand, who late in his career took to writing in Hindi. The 1930s saw the influence of progressivism, which attempted to make literature an arm of social revolution. Among the representative writers of this period are Sajjad Zahir, Upendranath Ashk, and Ismat Chughtai, the last a woman who is considered among the best.

English. There has been Indian literary activity in English for the last 200 years. It began with the insistence of the reformist Rammohan Ray and other like-minded Hindus that, for India to take its rightful place among nations, a knowledge of and education in English were essential. English literary activity took on a new aspect with the independence movement, whose leaders and followers found in English the one language that united them.

Among the first poets were Henry Derozio, Kashiprasad Ghose, and Michael Madhusudan Datta, all of whom wrote narrative verse. In the following generation there was Toru Dutt, important among women poets in this genre. Carrying on her work was Sarojini Naidu, judged by many the greatest of women poets; among her writings are *The Golden Threshold* (1905), *The Bird of Time* (1912), and *The Broken Wing* (1917). Best known of the Indian poets in English was the Bengali Rabindranath Tagore (see above *Bengali*), who, however, wrote most of his verse first in Bengali, and then translated it. A very different figure from Tagore is Sri Aurobindo, who started out as an ardent nationalist and was jailed by the British. After his conversion from activism to introspection, which took place in jail, he established a hermitage in Pondicherry. He left behind a rich *oeuvre* of verse that has inspired a contemporary school of mystic poets. Other modern poets show the influence of T.S. Eliot and Ezra Pound.

The independence movement gave strong impetus to expository prose. Important contributors to this genre were Bal Gangadhar Tilak, who edited the English journal *Mahratta,* Lala Lajpat Rai, Kasturi Ranga Iyengar, and T. Prakasam. Mahatma Gandhi, too, wrote widely in English and edited *Young India* and the *Harijan.* He also wrote the autobiography *My Experiments with Truth* (originally published in Gujarati, 1927–29), now an Indian classic. In this he was followed by Jawaharlal Nehru, whose *Discovery of India* is justly popular.

Prose fiction

Prose fiction in English began in 1902 with the novel *The Lake of Palms,* by Romesh Chunder Dutt. The next important novelist is Mulk Raj Anand, who fulminated against class and caste distinction in a series of novels, *The Coolie* (1936), *Untouchable* (1935), *Two Leaves and a Bud* (1937), and *The Big Heart* (1945). Less fierce, though a better craftsman, is R.K. Narayan, who has published nine novels (as well as many short stories), among them *The Guide* (1958), *The Man-Eater of Malgudi* (1961), and *The Vendor of Sweets* (1967); his work has a wider circle of readers outside India than within. Other Indian novelists in the English medium are Santha Rama Rau, Manohar Malgonkar, Kamala Markandeya, and Khushwant Singh. The most popular is Raja Rao, whose novels *Kanthapura* (1938), *The Cow of the Barricades* (1947), and *The Serpent and the Rope* have attracted a wide following.

Sinhalese. Traditional contemporary poetry continues to be Buddhist in subject matter and sentiment. A more modern literature arose under the influence of Western models; notable among the contemporary representatives of Sinhalese literature are Kumaranatunga, a critic, Matin Wickremasinghe, a novelist, and Tennakoon, a poet.

Music

FOLK, CLASSICAL, AND POPULAR MUSIC

Rural areas. The wide field of musical phenomena in South Asia ranges from the relatively simple two- or three-tone melodies of some of the hill tribes in central India to the highly refined art music heard in concert halls in the large cities. This variety reflects the heterogeneous population of the subcontinent in terms of race, religion, language, and social status. In the villages, music is not just a form of entertainment but is an essential element in many of the activities of daily life and plays a prominent part in most of the rituals. These include life-cycle events, such as birth, initiation, marriage, and death; events of the agricultural cycle, such as planting, transplanting, harvesting, and threshing; and a variety of work songs. Much of this music could be described as functional, for it serves a utilitarian purpose; for instance, a harvest song might well give thanks to God for a bountiful harvest, but underlying this is the idea that singing this song in its traditional manner will help to ensure that the next harvest will be equally fruitful. These songs are usually sung by all of the members participating in the activity and are not sung for a human audience. They are often sung in the form of leader and chorus, and the musical accompaniment, if any, is generally provided by drone instruments (those sustaining or reiterating a given note or notes), usually of the lute family, or percussion instruments, such as drums, clappers, and pairs of cymbals. Occasionally, a fiddle or flute might also accompany the singers, who often dance while they sing.

In each area and even within a single area, different social groups have their own individual songs whose origins are lost in antiquity. The songs are passed on from one generation to another, and in most cases the composers are unknown. Apart from folk songs, one also hears outdoor instrumental music in villages. The music is provided by an ensemble of varying size, which consists basically of an oboe type of instrument (usually a *sheh'nai* in North India and *nagaswaram* in the south) and a variety of drums. Sometimes straight, curved, or S-shaped horns may be added. These groups play at weddings, funerals, and religious processions. The musicians are professional or semiprofessional and usually belong to a very low caste. Such ensembles are found in tribal as well as folk societies and in villages as well as in cities.

Itinerant musicians

Other professional music is also found in the rural regions. Most areas are visited by religious mendicants, many of whom travel around the countryside singing devotional songs, accompanying themselves either with a one-, two-, or three-stringed lute that generally provides only a drone or with a frame (tamborine-like) drum. They carry with them a small begging bowl and maintain themselves entirely on what they receive in alms. There are also itinerant magicians, snake charmers, acrobats, and storytellers who travel in the rural areas, often providing the only entertainment available in the villages. Music is often involved in their acts, and the storyteller generally sings his tales, which may be taken from the two epics, the *Mahābhārata* and the *Rāmāyaṇa,* or from the *Purāṇas,* the legends that describe the adventures of the incarnations of God as they rid the world of evil. Sometimes the narrative songs are concerned with historical characters and describe the wars and the heroic deeds of the regional rulers. Some storytellers specialize in generally tragic stories of romance and of lovers.

During certain religious festivals, the villages might be visited by a travelling band of players who enact some of the mythological episodes connected with the festival. Such performances are accompanied by music and may also include dances. During the festivals villagers may visit neighbourhood shrines or temples, there encountering religious mendicants singing devotional songs and perhaps watching elaborate enactments of the episodes connected with the festival. Thus, the villagers become familiar with the mythological and philosophical aspects of their religion, in spite of the low level of literacy in the rural areas and the difficulties of communication, often limited to a narrow dirt road traversed by bullock carts.

In modern times, rural areas are being influenced to a greater extent by urban culture. The principal impact has come through the introduction of relatively inexpensive transistorized radios, which have found their way into fairly remote villages. In addition, travelling cinemas, set

up quickly and easily in tents, have visited the rural areas for some years. As a result, the traditional rural forms of music and dance are in the process of change.

Classical music. In the cities many different forms of music can be heard. Of these the best known in the West are the classical music of North India, including Pakistan, sometimes called Hindustani music, and that of South India, or Karnatic music. Both classical systems are supported by an extensive body of literature and elaborate musical theory. Until modern times, classical music was patronized by the princely courts and to some extent also by the wealthy noblemen. Since India gained independence in 1947, and with the abolition of the princely kingdoms, the emphasis has shifted to the milieu of large concert halls. The concertgoer, radio, and the cinema are now the main patrons of the classical musicians. In recent times the growth of university music programs, particularly involving classical music, has placed greater emphasis on music history and theory and has provided a further source of income for musicologists and musicians. The traditional system of private instruction, however, still continues to this day.

Raga and *tāla*

Classical music is based on two main elements, raga and *tāla*. The word raga is derived from a Sanskrit root meaning "to colour," the underlying idea being that certain melodic shapes, involving specific intervals of the scale, produce a continuity of emotional experience and "colour" the mind. Since neither the melodic shapes nor their sequence are fixed precisely, a raga serves as a basis for composition and improvisation. Indian music has neither modulation (change of key) nor changing harmonies; instead, the music is invariably accompanied by a drone that establishes the tonic, or ground note, of the raga and usually its fifth (*i.e.*, five notes above). These are chosen to suit the convenience of the main performer, as there is no concept of fixed pitch. While a raga is primarily a musical concept, specific ragas have acquired, particularly in North Indian music, a number of extramusical elements and are associated with particular periods of the day, seasons of the year, colours, deities, and specific moods.

The second element of Indian music, *tāla,* is best described as time measure and has two main constituents: the duration of the time measure in terms of time units that vary according to the tempo chosen; and the distribution of stress within the time measure. *Tāla,* like raga, serves as a basis for composition and improvisation.

Indian classical music is generally performed by small ensembles of not more than five or six musicians. Improvisation plays a major part in a performance, and great emphasis is placed on the creativity and sensitivity of the soloist. A performance of a raga usually goes through well-defined stages, beginning with an improvised melodic prelude that is followed by a composed piece set in a particular time measure. The composition is generally quite short and serves as a frame of reference to which the soloist returns at the conclusion of his improvisation. There is no set duration for the performance of a raga. A characteristic feature of North Indian classical music is the gradual acceleration of tempo, which leads to a final climax.

Nonclassical music of the cities. Classical music interests only a small proportion of the peoples of South Asia, even in the cities. Since about the 1930s a new genre, associated with the cinema, has achieved extraordinary popularity. Most Indian films are very much like Western musicals and generally include six or more songs. Film music derives its inspiration from a number of sources, both Indian and Western; classical, folk, and devotional music are the main Indian sources, while Western influence is seen most obviously in the use of large orchestras that employ both Western and Indian instruments. The influence of Western popular music, too, is very evident. In spite of the eclectic nature of Indian film music, most of the songs maintain an Indian feeling that arises largely from the vocal technique of the singers and the ornamentation of the melody line. This music is an experimental and developing form, and there have been attempts to add harmony and counterpoint, some of which may seem rather naïve to the Western ear. But the film music differs from typical Western music in that the melody line is generally not dictated by harmonic progressions and in that the harmonies used are incidental additions.

Film music

Aside from classical and film music, there are several other forms of urban music, some of which closely resemble the music of the rural areas. In city streets one is likely to encounter an outdoor band of oboes and drums announcing a wedding or a funeral. Street musicians, religious mendicants, snake charmers, storytellers, and magicians perform at every available opportunity, and work songs are sung by construction workers and other labourers. In private homes still other forms of music are performed, ranging from religious chanting to traditional folk and devotional songs. In public places of entertainment, the listener may encounter, apart from classical and film music, theatrical music from one of the relatively modern forms of regional theatre; and in the lowbrow places of entertainment courtesans still sing and dance in traditional fashion. In the larger cities there are performances of Western chamber music and occasionally symphony concerts, as well as popular dance music, rock, and jazz in the night clubs.

ANTIQUITY

In a musical tradition in which improvisation predominates, and written notation, when used, is skeletal and more a tool of the theorist than of the practicing musician, the music of past generations is irrevocably lost. References to music in ancient texts, aesthetic formulations, and depictions and written discussions of musical instruments can offer clues. In rare instances an ancient musical style may be preserved in unbroken oral tradition. For most historical eras and styles, surviving treatises explaining musical scales and modes—the framework of melody—provide a particularly important means of recapturing at least a suggestion of the music of former times, and tracing the musical theory of the past makes clear the position of the present musical system.

Little is known of the musical culture of the Indus Valley civilization of the 3rd and 2nd millennia BC. Some musical instruments, such as the arched, or bow-shaped, harp and more than one variety of drum, have been identified from the small terra-cotta figures and among the pictographs on the seals that were probably used by merchants. Further, it has been suggested that a bronze statuette of a dancing girl represents a class of temple dancers similar to those found much later in Hindu culture. It is known that the Indus civilization had established trade connections with the Mesopotamian civilizations, so that it is possible that the bow harp found in Sumeria would also have been known in the Indus Valley.

Vedic chant. *Compilation of hymns.* It is generally thought among scholars that the Indus Valley civilization was terminated by the arrival of bands of semi-nomadic tribesmen, the Aryans, who descended into India from the northwest, probably in the first half of the 2nd millennium BC. An important aspect of Aryan religious life was the bard-priest who composed hymns in praise of gods, to be sung or chanted at sacrifices. This tradition was continued in the invaders' new home in northern India until a sizable body of oral religious poetry had been composed. By about 1000 BC this body of chanted poetry had apparently grown to unmanageable proportions, and the best of the poems were formed into an anthology called Rigveda, which was then canonized. It was not committed to writing, but text and chanting formula were carefully handed down by word of mouth from one generation to the next, up to the present period. The poems in the Rigveda are arranged according to the priestly families who used and, presumably, had composed the hymns. Shortly after this a new Veda, called the Yajurveda, basically a methodical rearrangement of the verses of the Rigveda with certain additions in prose, was created to serve as a kind of manual for the priest officiating at the sacrifices. At approximately the same time, a third Veda, the Sāmaveda, was created for liturgical purposes. The Sāmaveda was also derived from the hymns of the Rigveda, but the words were distorted by the repetition of syllables, pauses, prolongations, and phonetic changes.

as well as the insertion of certain meaningless syllables believed to have magical significance. A fourth Veda, the Atharvaveda, was accepted as a Veda considerably later and is quite unrelated to the other three. It represents the more popular aspects of the Aryan religion and consists mostly of magic spells and incantations.

Each of these Vedas has several ancillary texts, called the *Brāhmaṇas, Āraṇyakas,* and *Upaniṣads,* which are also regarded as part of the Vedas. These ancillary texts are concerned primarily with mystical speculations, symbolism, and the cosmological significance of the sacrifice. The Vedic literature was oral and not written down until very much later, the first reference to a written Vedic text being in the 10th century AD. In order to ensure the purity of the Vedas, the slightest change was forbidden, and the priests devised systems of checks and counterchecks, so that there has been virtually no change in these texts for about 3,000 years. Underlying this was the belief that the correct recitation of the Vedas was "the pivot of the universe" and that the slightest mistake would have disastrous cosmic consequence unless expiated by sacrifice and prayer. The Vedas are still chanted by the Brahmin priests at weddings, initiations, funerals, and the like, in the daily devotions of the priests, and at the now rarely held so-called public sacrifices.

Ritual accuracy of recitation

From the Vedic literature it is apparent that music played an important part in the lives of the Aryan peoples, and there are references to stringed instruments, wind instruments, and several types of drums and cymbals. Songs, instrumental music, and dance are mentioned as being an integral part of some of the sacrificial ceremonies. The bow harp (*vīṇā*), a stringed instrument (probably a board zither) with 100 strings, and the bamboo flute were the most prominent melody instruments. Little is known of the music, however, apart from the Vedic chanting, which can still be heard today.

Chant intonation. The chanting of the Rigveda and Yajurveda shows, with some exceptions, a direct correlation with the grammar of the Vedic language. As in ancient Greek, the original Vedic language was accented, with the location of the accent often having a bearing on the meaning of the word. In the development of the Vedic language to Classical Sanskrit, the original accent was replaced by an automatic stress accent, whose location was determined by the length of the word and had no bearing on its meaning. It was thus imperative that the location of the original accent be inviolate if the Vedic texts were to be preserved accurately. The original Vedic accent occurs as a three-syllable pattern: the central syllable, called *udātta,* receives the main accent; the preceding syllable, *anudātta,* is a kind of preparation for the accent; and the following syllable, *svarita,* is a kind of return from accentuation to accentlessness. There is some difference of opinion among scholars as to the nature of the original Vedic accent; some have suggested that it was based on pitch, others on stress; and one theory proposes that it referred to the relative height of the tongue.

In the most common style of Rigvedic and Yajurvedic chanting found today, that of the Tamil Aiyar Brahmins, it is clear that the accent is differentiated in terms of pitch. This chanting is based on three tones; the *udātta* and the nonaccented syllables (called *pracaya*) are recited at a middle tone, the preceding *anudātta* syllable at a low tone, and the following *svarita* syllable either at the high tone (when the syllable is short) or as a combination of middle tone and high tone. The intonation of these tones is not precise, but the lower interval is very often about a whole tone, while the upper interval tends to be slightly smaller than a whole tone but slightly larger than a semitone. In this style of chanting the duration of the tones is also relative to the length of the syllables, the short syllables generally being half the duration of the long.

Verbal accent and musical pitch

The more musical chanting of the Sāmaveda employs five, six, or seven tones and is said to be the source of the later secular and classical music. From some of the phonetic texts that follow the Vedic literature, it is apparent that certain elements of musical theory were known in Vedic circles, and there are references to three octave registers (*sthāna*), each containing seven notes (*yama*). An auxiliary text of the Sāmaveda, the *Nāradīśikṣā,* correlates the Vedic tones with the accents described above, suggesting that the Samavedic tones possibly derived from the accents. The Samavedic hymns as chanted by the Tamil Aiyar Brahmins are based on a mode similar to the D mode (D-d on the white notes of the piano; *i.e.,* the ecclesiastical Dorian mode). But the hymns seem to use three different-sized intervals, in contrast to the two sizes found in the Western church modes. They are approximately a whole tone, a semitone, and an intermediate tone. Once again, the intervals are not consistent and vary both from one chanter to another and within the framework of a single chant. The chants are entirely unaccompanied by instruments, and this may account for some of the extreme variation of intonation.

The changes brought by the 20th century have weakened the traditional prominent position of the Vedic chant. The Atharvaveda is seldom heard in India now. Samavedic chant, associated primarily with the large public sacrifices, also appears to be dying out. Even the Rigveda and Yajurveda are virtually extinct in some places, and South India is now the main stronghold of Vedic chant.

The classical period. The ritual of the Vedas involves only the three upper classes, or castes, of Aryan society: the Brahmin, or priestly class; the Kṣatriya, or prince-warriors; and the Vaiśya, or merchants. The fourth caste, the Śūdras, or labourers, were excluded from Vedic rites. The primary sources of religious education and inspiration for the Śūdra were derived from what is sometimes called the fifth Veda: the epic poems *Rāmāyaṇa* and *Mahābhārata,* as well as the collections of legends, called the *Purāṇas,* depicting the lives of the various incarnations of the Hindu deities. The *Rāmāyaṇa* and the *Mahābhārata* were originally secular in character, describing the heroic deeds of kings and noblemen, many of whom are not recorded in history. Subsequently, religious matter was added, including the very famous sermon *Bhagavadgītā* ("Song of the Lord"), which has been referred to as the most important document of Hinduism; and many of the heroes of the epics were identified as incarnations of the Hindu deities. The legends were probably sung and recited by wandering minstrels and bards even before the advent of the Christian Era, in much the same way as they still are. The stories were also enacted on the stage, particularly at the time of the religious festivals. The earliest extant account of drama is to be found in the *Nāṭya-śāstra* ("Treatise on the Dramatic Arts"), a text that has been dated variously from the 2nd century BC to the 5th century AD and even later. It is virtually a handbook for the producer of stage plays and deals with all aspects of drama, including dance and music.

Music and drama

Theatrical music of the period apparently included songs sung on stage by the actors, as well as background music provided by an orchestra (which included singers) located offstage, in what was very like an orchestra pit. Melodies were composed on a system of modes, or *jātis,* each of which was thought to evoke one or more particular sentiments (*rasa*) by its emphasis on specific notes. The modes were derived in turn from the 14 *mūrchanās*—seven pairs of ascending seven-note series beginning on each of the notes of two closely related heptatonic (seven-note) parent scales, called *ṣaḍjagrāma* and *madhyamagrāma.* The *mūrchanās* were thus more or less analogous to the European modal scales that begin progressively on D, E, F, G, etc. A third parent scale, *gāndhāragrāma,* was mentioned in several texts of the period and some even earlier but is not included in the system laid out in the *Nāṭya-śāstra.*

Qualities of the scales. The two parent scales differed in the positioning of just one note, which was microtonally flatter in one of the scales. The microtonal difference, referred to as *pramāṇa* ("measuring") *śruti,* presumably served as a standard of measurement. In terms of this standard it was determined that the intervals of the *mūrchanās* were of three different sizes, consisting of two, three, or four *śrutis,* and that the octave comprised 22 *śrutis.* An interval of one *śruti* was not used. Several modern scholars have suggested that the *śrutis* were of unequal size; from the evidence in the *Nāṭya-śāstra,* it would appear, however, that they were thought to be equal. There

has been no attempt to determine the exact size of the *śrutis* in any of the traditional Indian musical treatises until relatively modern times (18th century). The term *śruti* was also used to define consonance and dissonance, as these terms were understood in the period. In this connection, four terms are mentioned: *vādī,* comparable to the Western term sonant, meaning "having sound"; *saṃvādī,* to the Western consonant (concordant; reposeful); *vivādī,* to dissonant (discordant; lacking repose); and *anuvādī,* to assonant (neither consonant nor dissonant). As in the ancient Greek Pythagorean system, which influenced Western music, only fourths and fifths (intervals of four or five tones in a Western scale) were considered consonant. In the Indian system of measurement, tones separated by either nine or 13 *śrutis* correspond in size to Western fourths and fifths and are described as being consonant to each other. "Dissonant" in this system referred only to the minor second, an interval of two *śrutis,* and to its inversion (complementary interval), the major seventh (20 *śrutis*). All other tones, including the major third, were thought to be assonant.

Melodically important microtonal differences

The musical difference between the two parent scales is best seen not in terms of the microtonal deviation mentioned earlier but rather in terms of a musically influential consonance found in one but lacking in the other and vice versa. In each of the parent scales there are two nonconsonances, one of which is the tritone (interval of three Western whole tones, such as F-B) of 11 *śrutis* inevitable in all diatonic scales (seven-note scales of the major scale and *mūrchanā* type) and which in Europe during the Middle Ages was described as *diabolus in musica* ("the devil in music").

The second is a microtonal nonconsonance unique to this ancient Indian system. It can be illustrated by referring in the subsequent explanation to Table 1, in which the seven Indian notes *ṣaḍja, ṛṣabha, gāndhāra, madhyama, pañcama, dhaivata,* and *niṣāda* are given in their commonly abbreviated forms, *ṣa, ṛi, ga, ma, pa, dha,* and *ni.*

The nonconsonance arises from variances of one *śruti* from the fundamental consonances of the fourth and the fifth—a variance of about a quarter tone. In the *ṣaḍjagrāma* scale the interval *ṛi-pa* (E⁻ to A) contains 10 *śrutis; i.e.,* one more than the nine of the consonant fourth. Comparably, in the *madhyamagrāma* scale the interval *ṣa-pa* (D to A⁻) contains 12 *śrutis,* or one fewer than the consonant fifth. These variances involve the consonant relationships of two melodically prominent notes, the first and the fifth. In the *madhyamagrāma* the first note, *ṣa,* has no consonant fifth, and perhaps for this reason this scale is said to begin not on the *ṣa* (D) but on its fourth, the note *ma* (G); hence, it resembles the G mode—*i.e.,* the ecclesiastical Mixolydian mode—whereas the *ṣaḍjagrāma* resembles the D mode, the ecclesiastical Dorian.

There is a striking resemblance of the *ṣaḍjagrāma* scale to the intervals used by the Tamil Aiyar Brahmins in their chanting of the Sāmaveda. Not only are their hymns set in a mode similar to the D mode, but they seem to use three different-sized intervals, the intermediate one corresponding to the three-*śruti* interval. The *Nāṭya-śāstra* claims to have derived song (*gīta*) from the chanting of the Sāmaveda, and the resemblances between the two may not be entirely fortuitous.

The two parent scales are complementary and between them supply all the consonances found in the ancient Greek Pythagorean scale. Thus, if in a mode the consonance *ṛi-pa* (E–A) were needed, one would tune to the *madhyamagrāma* scale. But, if the consonance *ṣa-pa* (D–A) were important, it could be obtained with the *ṣaḍjagrāma* tuning. There was a further development in this system caused by the introduction of two additional notes, called *antara ga* (F♯) and *kākalī ni* (C♯), which could be substituted for the usual *ga* (F) and *ni* (C). The *antara ga* eliminates the 11-*śruti* tritone between *ga* and *dha* (F–B), but its use creates a further tritone between F♯ and C. The second additional note, *kākalī ni* (C♯), eliminates this tritone but once again creates a new one, this time between C♯ and G. This process of adding notes, if carried further, would eventually lead to the circle, or, rather, the spiral, of fourths or fifths found in Western music (whereby a sequence of fifths, such as C–G, G–D, D–A, etc., leads eventually back to a microtonally out-of-tune C); there is no evidence that such a circle or spiral was known in ancient India.

Introduction of new notes

Mode, or jāti. From each of the two parent scales were derived seven modal sequences (the *mūrchanās* described above), based on each of the seven notes. The two *mūrchanās* of a corresponding pair differered from each other only in the tuning of the note *pa* (A), the crucial distinction in the tunings of the two parent scales. One of each pair was selected as the basis for a "pure" mode, or *śuddha-jāti;* in the groups of seven pure modes, four used the tuning of the *ṣaḍjagrāma* and three that of the *madhyamagrāma.* In addition to these seven pure modes, a further 11 "mixed" modes, or *vikṛta-jātis,* are also mentioned in the *Nāṭya-śāstra.* These were derived by a combination of two or more pure modes, but the text does not explain just in what way these derivations were accomplished.

The *jātis* were similar to the modern concept of raga in that they provided the melodic basis for composition and, presumably, improvisation. They were not merely scales, but were also assigned 10 melodic characteristics: *graha,* the initial note; *aṃśa,* the predominant note; *tāra,* the note that forms the upper limit; *mandra,* the note that forms the lower limit; *nyāsa,* the final note; *apanyāsa,* the secondary final note; *alpatva,* the notes to be used infrequently; *bahutva,* the notes to be used frequently; *ṣāḍavita,* the note that must be omitted in order to create the hexatonic (six-note) version of the mode; and *auḍavita,* the two notes that must be omitted to create the pentatonic (five-note) version of the mode.

No written music survives from this early period. It is not clear from the description whether or not the music was like that of the present period. There is no mention of a drone, nor do the instruments of the orchestra—consisting of the *vipañcī* and *vīṇā* (bow harps?), bamboo flute, a variety of drums, and singers—appear to include any specifically drone instrument, such as the modern tamboura. The evidence tends rather to suggest, from the emphasis on consonance and some of the playing techniques, that some form of organum (two or more parts paralleling the same melody at distinct pitch levels) and even some type of rudimentary harmony may have been characteristic.

Table 1: Intervals of Ṣaḍjagrāma and Madhyamagrāma Parent Scales*

Ṣaḍjagrāma

				10 *śrutis*							
Indian notes:	(*ni*)		*ṣa*	*ṛi*	*ga*	*ma*	*pa*	*dha*	*ni*		(*ṣa*)
Śruti intervals:		4	3	2	4	4	3	2	(4)		
Comparable Western notes†:	(C)		D	E⁻	F	G	A	B⁻	c		(d)
					11 *śrutis*						

Madhyamagrāma

				12 *śrutis*							
Indian notes:	(*ni*)		*ṣa*	*ṛi*	*ga*	*ma*	*pa*	*dha*	*ni*		(*ṣa*)
Śruti intervals:		4	3	2	4	3	4	2	(4)		
Comparable Western notes†:	(C)		D	E	F	G	A⁻	B⁻	c		(d)
					11 *śrutis*						

*Minus signs indicate slightly lower pitch. †Without reference to precise pitch.

MEDIEVAL PERIOD

Precursors of the medieval system. It is not clear just when the *jāti* system fell into disuse, for later writers refer to *jāti*s merely out of reverence for Bharata, the author of the *Nāṭya-śāstra.* Later developments are based on musical entities called *grāma-rāga*s, of which seven are mentioned in the 7th-century Kuṭimiyāmalai rock inscription in Tamil Nadu state. Although the word *grāma-rāga* does not occur in the *Nāṭya-śāstra,* the names applied to the individual *grāma-rāga*s are all mentioned. Two of them, *ṣaḍjagrāma-rāga* and *madhyamagrāma-rāga,* are obviously related to the parent scales of the *jāti* system. The other five seem to be variants of these two *grāma-rāga*s in which either or both the altered forms of the notes *ga* and *ni* (F♯ and C♯) are used. In the *Nāṭya-śāstra,* the reference to the various *grāma-rāga*s is far removed from the main section in which the *jāti* system is discussed, and there is no obvious connection between the two. Each of the *grāma-rāga*s is said to be used in one of the seven formal stages of Sanskrit drama. They have been reconstructed as shown in Table 2.

Character and possible origin of the raga

Further development of the grāma-rāgas. In the next significant text on Indian music, the *Bṛhaddeśī,* written by the theorist Mātaṅga about the 10th century AD, the *grāma-rāga*s are said to derive from the *jāti*s. In some respects, at least, the *grāma-rāga*s resemble not the *jāti*s but their parent scales. The author of the *Bṛhaddeśī* claims to be the first to discuss the term raga in any detail. It is clear that raga was only one of several kinds of musical entities in this period and is described as having "varied and graceful ornaments, with emphasis on clear, even, and deep tones and having a charming elegance." The ragas of this period seem to have been named after the different peoples living in the various parts of the country, suggesting that their origin might lie in folk music. Mātaṅga appears to contrast the two terms *mārga* and *deśī. Mārga* (literally "the path") apparently refers to the ancient traditional musical material, whereas *deśī* (literally "the vulgar dialect spoken in the provinces") designates the musical practice that was evolving in the provinces, which may have had a more secular basis. Although the title *Bṛhaddeśī* ("The Great Deśī") suggests that the latter music might have been the focus of the treatise and that the *grāma-rāga*s were possibly out of date by the time it was written, the surviving portion of the text does not support such a theory.

The mammoth 13th-century text *Saṅgītaratnākara* ("Ocean of Music and Dance"), composed by the theorist Śārṅgadeva, is often said to be one of the most important landmarks in Indian music history. It was composed in the Deccan (south central India) shortly before the conquest of this region by the Muslim invaders and thus gives an account of Indian music before the full impact of Muslim influence. A large part of this work is devoted to *mārga*—that is, the ancient music that includes the system of *jāti*s and *grāma-rāga*s—but Śārṅgadeva mentions a total of 264 ragas. Despite the use in both the *Bṛhaddeśī* and the *Saṅgītaratnākara* of a notation equivalent to the Western tonic sol–fa (*i.e.,* with syllables, as do–re–mi . . .) to illustrate the ragas, modern scholars have not yet been able to reconstruct them with assurance.

The basic difficulty scholars face lies in determining the intervals used in each of the ragas. In the ancient system, the *jāti*s were something like the ancient Greek and medieval church modes in that each was derived from a parent scale by altering the ground note and the tessitura (range). In modern Indian music, however, the ragas are all transposed to a common ground note. This change may well be connected with the introduction of the drone and the evolution of the long-necked-lute family on which the drone is usually played. In the old system, with the changing ground note, it would have been necessary to retune drone instruments from one raga to another, which would have been a cumbersome and impractical operation to carry out during a recital. It may have been this factor that provided the impetus for the change to the standard-ground-note system. There is no conclusive evidence to show just when this change might have taken place, and it is not clear whether the *Bṛhaddeśī* and the *Saṅgītaratnākara* are using the old ground-note system or one similar to that used in modern times.

THE ISLĀMIC PERIOD

Impact on musical genres and aesthetics. The Muslim conquest of India can be said to begin in the 12th century, although Sind (now in Pakistan) had been conquered by the Arabs as early as the 8th century. Muslim writers such as al-Jāḥiẓ and al-Masʿūdī had already commented favourably on Indian music in the 9th and 10th centuries, and the Muslims in India seem to have been very much attracted by it.

In the beginning of the 14th century the great poet Amīr Khosrow, who was considered to be extremely proficient in both Persian and Indian music, wrote that Indian music was superior to the music of any other country. Further, it is stated that, after the Muslim conquest of the Deccan under Malik Kāfūr (*c.* 1310), a large number of Hindu musicians were taken with the royal armies and settled

in the North. Although orthodox Islām considered music illegal, the acceptance of the Ṣūfī doctrines, in which music was an accepted means to the realization of God, enabled Muslim rulers and noblemen to extend their patronage to this art. At the courts of the Mughal emperors Akbar, Jahāngīr, and Shāh Jahān, music flourished on a grand scale. Apart from Indian musicians, there were also musicians from Persia, Afghanistan, and Kashmir in the employ of these rulers; nevertheless, it appears that it was Indian music that was most favoured. Famous Indian musicians, such as Svāmī Haridās and Tānsēn, are legendary performers and innovators of this period. After the example set by Amīr Khosrow, Muslim musicians took an active interest in the performance of Indian music and added to the repertoire by inventing new ragas, *tāla*s, and musical forms, as well as new instruments.

The Muslim patronage of music was largely effective in the north of India and has had a profound influence on North Indian music. Perhaps the main result of this influence was to de-emphasize the importance of the words of the songs, which were mostly based on Hindu devotional themes. In addition, the songs had been generally composed in Sanskrit, a language that had ceased to be a medium of communication except among scholars and priests. Sanskrit songs were gradually replaced by compositions in the various dialects of Hindi, Braj Bhasa, Bhojpuri, and Dakhani, as well as in Urdu and Persian; nevertheless, the problems of communication, in terms of both language and subject matter, were not easily reconciled. A new approach to religion was, in any case, sweeping through India at about this time. This emphasized devotion (*bhakti*) as a primary means to achieving union with God, bypassing the traditional Hindu beliefs of the transmigration of the soul from body to body in the lengthy process of purification before it could achieve the Godhead. The Islāmic Ṣūfī movement was based on an approach similar to that of the *bhakti* movements and also gained many converts in India. A manifestation of these devotional cults was the growth of a new form of mystic-devotional poetry composed by wandering mendicants who had dedicated their lives to the realization of God. Many of these mendicants have been sanctified and are referred to as poet-saints or singer-saints, since their poems were invariably set to music. A number of devotional sects sprang up all over the country, some Muslim, some Hindu, and others merging elements from both. These sects emphasized the individual's personal relationship with God. In their poetry, man's love for God was often represented as a woman's love for man and, specifically, the love of the milkmaid Rādhā for Krishna, a popular incarnation of the Hindu god Vishnu. In the environment of the royal courts, there was a less idealistic interpretation of the word love, and much of the poetry, as well as the miniature painting, of the period depicts the states of experience of the lover and the beloved.

Influence of religious movements

This attitude is also reflected in the musical literature of the period. From early times, both *jāti*s and ragas in their connection with dramatic performance were described as evoking specific sentiments (*rasa*) and being suitable for accompanying particular dramatic events. It was this connotational aspect, rather than the technical one, that gained precedence in this period. The most popular method of classification was in terms of ragas (masculine) and their wives, called *rāgiṇī*s, which was extended to include *putra*s, their sons, and *bhāryā*s, the wives of the sons. The ragas were personified and associated with particular scenes, some of which were taken from Hindu mythology, while others represented aspects of the relationship between two lovers. The climax of this personification is found in the *rāgamāla* paintings, usually in a series of 36, which depict the ragas and *rāgiṇī*s in their emotive settings.

Theoretical developments. From the middle of the 16th century, a new method of describing ragas is found in musical literature. It was also at about this time that the distinction between North and South Indian music became clearly evident. In the literature, ragas are described in terms of scales having a common ground note. These scales were called *mela* in the South and *mela* or *thāṭa* in the North.

Emergence of modern theoretical concepts

It was in the South that a complete theoretical system of *mela*s was introduced, in the *Caturdaṇḍiprakāśika* ("The Illuminator of the Four Pillars of Music"), a text written in the middle of the 17th century. This system was based on the permutations of the tones and semitones, which had by this time been reduced to a basic 12 in the octave. The octave was divided into two tetrachords, or four-note sequences, C–F and G–c, and six possible tetrachord species were arranged in an order showing their relationship with each other. It will be noted in the sequence of tetrachords shown below that each lower tetrachord has an analogous upper tetrachord and that the outer notes of each are constant, whereas the inner notes change their pitch.

1.	C	D♭	E♭♭	F	and	G	A♭	B♭♭	c
2.	C	D♭	E♭	F		G	A♭	B♭	c
3.	C	D♭	E	F		G	A♭	B	c
4.	C	D	E♭	F		G	A	B♭	c
5.	C	D	E	F		G	A	B	c
6.	C	D♯	E	F		G	A♯	B	c

The list could have extended further, except that apparently no pitch distinction was made between the enharmonic pairs D–E♭♭, D♯–E♭, A–B♭♭, and A♯–B♭. (Enharmonic notes have different pitch names but sound either the same pitch or, in some tuning systems, have very slight differences in pitch.)

By utilizing all possible combinations of a lower with an upper tetrachord, 36 *mela*s, or raga scales, were derived; a further 36 were formed by using F♯ in place of the F in the lower tetrachord. The *mela*s were named in such a way that the first two syllables of the name, when applied in a code, gave the number of that *mela* in the sequence. The musician, given the number, could easily reconstruct the scale of the *mela*. The names of the *mela*s were often derived from prominent ragas in those *mela*s, with a two-syllable prefix that supplied the code numbers; for instance, the name of the *mela Dhīra-śaṅkarābharaṇa* is derived from the raga *Śaṅkarābharaṇa*, the two syllables *dhīra* giving the code number 29, which indicates a scale similar to the Western major scale, or C mode. The *Caturdaṇḍiprakāśika* acknowledges the theoretical nature of its analytical system and mentions clearly that only 19 of the possible 72 *mela*s were in use at the time that the text was written.

Although North Indian texts also describe ragas in terms of *mela*s or *thāṭa*s, there is no attempt to arrange them systematically. In the *Rāgataraṅgiṇi* ("The River of Rāga"), probably of the 16th century, 12 *mela*s are mentioned:

bhairavī	C	D	E♭	F	G	A	B♭	c
toṛī	C	D♭	E♭	F	G	A♭	B♭	c
gaurī	C	D♭	E	F	G	A♭	B	c
karṇāta	C	D	E	F	G	A	B♭	c
kedāra	C	D	E	F	G	A	B	c
imana	C	D	E	F♯	G	A	B	c
sāraṅga	C	D	E♯	F♯	G	A♯	B	c
megha	C	D	E	F	G	A♯	B	c
dhanāśrī	C	D♭	E	F♯	G	A♭	B	c
pūravā	C	D	E	F♯	G	A⁺	B	c
mukhārī	C	D	E♭	F	G	A♭	B♭	c
dīpaka	no description							

Although it appears from the description of *sāraṅga* and *megha mela*s that enharmonic intervals were used, there is good reason to believe that the E♯ and A♯ in the two *mela*s really represent their chromatic counterparts, F and B♭, and that F and F♯ (and B and B♭) do not appear in sequence. The A⁺ in the *mela pūravā* is said to be raised by one *śruti*. The description of the ragas in these *mela*s shows that the North Indian system was by this time also based on 12 semitones.

THE MODERN PERIOD

With the collapse of the Mughal Empire in the 18th century and the emergence of the British as a dominant power in India, the subcontinent was divided into many princely states. Music continued to be patronized by the rulers, although the courts were never again to achieve their former opulence.

Musically, there has been a continuous evolution from the Islāmic period to the present, and both North and

Influence of theory on composition

South Indian classical music have continued to expand. South Indian music has clearly been influenced more by theory than has the North. The 72-*mela* system continues to be the basis of classifying the ragas in South India, but it has had more than a classificatory significance. Many new ragas have been composed in the past few centuries, some of them inspired by the theoretical scales of the *mela* system. As a result, there are now ragas in all of the 72 *mela*s.

In North Indian music, theory has had little influence on performance practice. This can be ascribed to the language problem, an especially significant influence on the many Muslim musicians in North India, who were not able to cope with the Sanskrit musical literature. Thus, there had been no attempt to systematize the music, and there was a considerable gap between performance and theory until the present century. Vishnu Narayana Bhatkande, one of the leading Indian musicologists of this century, contributed a great deal toward diminishing the gap. Being both a scholar and a performer, he devoted much effort to collecting and notating representative versions of a number of ragas from musicians belonging to different family traditions, or *gharānā*s. Based on this collection, he concluded that most of the ragas of North Indian music can be grouped into the following scales, called *thāṭa*s (compare the South Indian *mela*s shown above):

kalyāṇa	C	D	E	F♯	G	A	B	c
bilāvala	C	D	E	F	G	A	B	c
khamāja	C	D	E	F	G	A	B♭	c
bhairava	C	D♭	E	F	G	A♭	B	c
pūrvī	C	D♭	E	F♯	G	A♭	B	c
mārvā	C	D♭	E	F♯	G	A	B	c
kāfī	C	D	E♭	F	G	A	B♭	c
āsāvarī	C	D	E♭	F	G	A♭	B♭	c
bhairavī	C	D♭	E♭	F	G	A♭	B♭	c
toṛī	C	D♭	E♭	F♯	G	A♭	B	c

The *thāṭa*s do not cover all the ragas used in North Indian music, but there is reason to believe that most of the ragas having scales other than the above are relatively modern innovations. New ragas are constantly being created, and some North Indian musicians are using the vast potential of the South Indian *mela* system as their source of inspiration.

Scale classifications as opposed to raga

Mela and *thāṭa* are theoretical devices for the classification of ragas. Ragas have scalar elements, such as specified ascending and descending movements, that might or might not employ adjacent steps. They may also employ oblique or zigzag movements. Ragas can be heptatonic, hexatonic, or pentatonic and may also have accidentals (sharpened or flattened notes) that occur only in specific melodic contexts. A further distinction between scale and raga is found in the varying emphasis placed on different notes in a raga. Ragas, furthermore, also have melodic elements, such as certain recurrent nuclear motives (brief melodic fragments) that enable the raga to be identified more easily. One scale type can be the basis for perhaps 20 or 30 ragas, in which case it is the nonscalar elements that provide the distinguishing features of each raga in the group.

Rhythmic organization. *South India.* Just as the system of classifying raga is better organized in South Indian music, so too is the system of classifying *tāla,* or time measure. The main group is composed of 35 *tāla*s, called the *sūlādi-tāla*s. Each *tāla* is composed of one, two, or three different units: short, medium, and long. The medium unit is twice the duration of the short; the long unit is, however, a variable and may be three, four, five, seven, or nine times the duration of the short. There are seven basic *tāla* patterns, and, because the long unit of these *tāla*s can be of five different durations, the total number of *tāla*s in this system is 35. The basic *tāla* patterns are:

dhruva-tāla—long, medium, long, long
maṭhya-tāla—long, medium, long
rūpaka-tāla—medium, long
jhampā-tāla—long, short, medium
tripuṭa-tāla—long, medium, medium
āṭa-tāla—long, long, medium, medium
eka-tāla—only a single long.

The total duration of each pattern is controlled by the duration of the variable long; thus, if the long unit is five times the short, a *tāla* pattern such as *dhruva-tāla* will be 5 + 2 + 5 + 5, or 17 units. Several of these *tāla*s have the same total duration but are distinguished from each other by their internal subdivisions. In the course of a performance, the vocalist, as well as the audience, may mark the time by clapping, hand waving, and finger counting.

In addition to the *sūlādi-tāla*s, there are four *cāpu-tāla*s that are used in South Indian classical music. Said to derive from folk music, they consist of two sections of unequal length, 1 + 2, 2 + 3, 3 + 4, and 4 + 5. Of these, the 3 + 4 combination is the most prominent. On rare occasions a performer may use one of the "classical" *tāla*s referred to in Sanskrit texts. These generally involve long time cycles composed of as many as 100 short units. The most frequently heard time measures, however, are *ādi-tāla,* a modified eight-beat version of *tripuṭa-tāla* (4 + 2 + 2); *miśra-cāpu-tāla* (3 + 4); and *rūpaka-tāla* (4 + 2). The difficult and long *tāla*s are used primarily as a tour de force. Each *tāla* may be performed in either slow, medium, or quick tempo; there is no gradual acceleration as in North Indian music.

North India. In North Indian music the *tāla*s are fewer and not organized in any systematic manner. As in South Indian music, the two main factors are the duration of the time cycle and the subdivisions within the cycle. Each of these subdivisions is marked by a clap or a wave, with the greatest emphasis falling on beat 1 of the cycle, which is called *sam.* North Indian *tāla*s have a further feature, the *khālī* ("empty"), a conscious negation of stress occurring at one or more points in each *tāla* where one would expect a beat. It often falls at the halfway point in the time cycle and is marked by a wave of the hand. There is nothing comparable to the *khālī* in the South Indian system. A further distinguishing feature found only in North Indian *tāla*s is the emphasis placed on the characteristic drum pattern of each *tāla,* called *ṭhekā.* Two *tāla*s might have the same duration and subdivisions but might, nevertheless, be differentiated from each other by different characteristic drum patterns. In addition, the *tāla*s are also associated with different forms of song and even particular tempi. The usual North Indian *tāla*s range from six to 16 time units in duration. The most popular are *tīn-tāla* (4 + 4 + 4 + 4), *eka-tāla* (2 + 2 + 2 + 2 + 2 + 2), *jhap-tāla* (2 + 3 + 2 + 3), *kaharavā* (4 + 4), *rūpaka-tāla* (3 + 2 + 2), and *dādrā* (3 + 3). *Tīn-tāla* should not be confused with Western $\frac{4}{4}$, or common time, for the time cycle repeats only after 16 units and is more like four bars of common time.

Characteristic North Indian rhythmic features

Musical forms and instruments. *South India.* Both raga and *tāla* provide bases for composition and improvisation in Indian classical music. A performance usually begins with an improvised section, called *ālāpa,* played in free time without accompaniment of drums. It may have various sections and might on occasion last half an hour or longer. It is followed by a composed piece in the same raga, set in a particular *tāla.* In South Indian music all composed pieces are primarily for the voice and have lyrics. In North India, however, there are also some purely instrumental compositions, called *gat* and *dhun.* The emphasis on the composition varies in the different forms of song and, to some extent, in the interpretation of the performer. In South Indian music the composed piece is generally emphasized more than in the North. Much of the South Indian repertoire of compositions stems from three composers, Tyagaraja, Muthuswami Dikshitar, and Syama Sastri, contemporaries who lived in the second half of the 18th and the beginning of the 19th centuries. The devotional songs that they composed, called *kṛti,* are a delicate blend of text, melody, and rhythm and are the most popular items of a South Indian concert. The composed elements in these songs sometimes include sections such as *niraval,* melodic variations with the same text, and *svara-kalpana,* passages using the Indian equivalent of the sol-fa syllables, which are otherwise improvised.

The longest item in the South Indian concert, called *rāgam-tānam-pallavi,* is, on the other hand, mostly improvised. It begins with a long *ālāpa,* called *rāgam* in

Interaction of composition and improvisation

this context, presumably because this elaborate, gradually developing *ālāpa* is intended to display the raga being performed in as complete a manner as possible, without the limitations imposed by a fixed time measure. This is followed by another improvised section, *tānam,* in which the singer uses meaningless words to produce more or less regular rhythms, but still without reference to time measure. This section, too, is without drum accompaniment. The final section, *pallavi,* is a composition of words and melody set in a particular *tāla,* usually a long or complex one. The *pallavi* may have been composed by the performer himself and be unfamiliar to his accompanists, usually a violinist who echoes the singer's phrases and a drummer who plays the mridanga, a double-ended drum. The statement of the composition is followed by elaborate rhythmic and melodic variations that the accompanists are expected to follow. It is customary to have a drum solo at the end of the *pallavi,* and the performance concludes with a brief restatement of the *pallavi.*

Other forms used in South Indian classical music derive largely from the musical repertoire of *bhārata-nāṭyam,* the classical South Indian dance. The *varṇam,* a completely composed piece, serves mainly as a warming up and is performed at the beginning of a concert. *Pada* and *jāvali* are two kinds of love songs using the poetic imagery characteristic of the romantic-devotional movement mentioned earlier. *Tillānā* has a text composed mostly of meaningless syllables, which may include the onomatopoeic syllables used to represent the different drum sounds. This is a very rhythmic piece and is usually sung in fast tempo.

Melodic, drone, and rhythmic instruments

The ensemble used in present-day South Indian classical music consists of a singer or a main melody instrument, a secondary melody instrument, one or more rhythmic percussion instruments, and one or more drone instruments. The most commonly heard main melody instruments are the *vīṇā,* a long-necked, fretted, plucked lute with seven strings; the *veṇu,* a side-blown bamboo flute; the *nagaswaram,* a long, oboe-like, double-reed instrument with finger holes; the violin, imported from the West about 200 years ago, played while seated on the floor with the scroll resting on the player's left foot; and the *goṭṭuvādyam,* a long-necked lute without frets, played like the Hawaiian guitar, with a sliding stop in the left hand.

The violin is by far the most common secondary melody instrument in South India. It plays in unison where the passage is composed but imitates the voice or main melody instrument in the improvised passages. Of the rhythm instruments, the mridanga, a double-conical, two-headed drum, is the most common. Others include the *kañjīrā,* a tambourine; the *ghaṭam,* an earthenware pot without skin covering; the *morsing,* a metallic jew's harp; and the *tavil,* a slightly barrel-shaped, double-ended drum, which accompanies the *nagaswaram.* The most prominent drone instrument is the four-stringed tamboura, a long-necked lute without frets. It accompanies the voice and all melody instruments, except the *nagaswaram,* which is usually accompanied by the *oṭṭu,* a longer version of the *nagaswaram* but without finger holes. A hand-pumped harmonium drone, called *śruti* or *śruti* box, sometimes replaces the *oṭṭu* or the tamboura.

North India. The most common vocal form in North Indian classical music at the present time is the *khyāl,* a Muslim word meaning "imagination." The *khyāl* is contrasted with the *dhruvapada* (now known as *dhrupad*), which means "fixed words." The two forms existed side by side in the Islāmic period, and it is only in the last century or two that *khyāl* has achieved ascendancy. There are two types of *khyāl.* The first is sung in extremely slow tempo, with each syllable of the text having extensive melisma (prolongation of a syllable over many notes), so that the words are virtually unrecognizable. It is not usually preceded by a lengthy *ālāpa;* instead, *ālāpa*-like phrases are generally sung against the very slow time measure to the accompaniment of the drums. Also characteristic of the *khyāl* are the *sargam tānas,* passages using the Indian equivalent of the sol–fa syllables, and the *ā-kār tānas,* which are rapid runs sung to the syllable *aah.* The second type of *khyāl,* which may be as much as eight times faster than the slow and is generally set in a different *tāla,* follows the slow. Its composed portion is usually quite short, and the main features of the improvisation are the *ā-kār tānas.* Occasionally, a composition called *tarānā,* made up of meaningless syllables, may replace the fast-tempo *khyāl.*

The *ṭhumrī* is another North Indian vocal form and is based on the romantic-devotional literature inspired by the *bhakti* movement. The text is usually derived from the Rādha-Krishna theme and is of primary importance. The words are strictly adhered to, and the singer attempts to interpret them with his melodic improvisations. It is quite usual for a singer to deviate momentarily from the raga in which the composition is set, by using accidentals and evoking other ragas that might be suggested by the words, but he always returns to the original raga.

Some of the North Indian musical forms are very like the South Indian. The vocal forms *dhrupad* and *dhamār* resemble the *rāgam-tānam-pallavi.* They begin with an elaborate *ālāpa* followed by the more rhythmic but unmeasured *non-tom* using meaningless syllables such as *te, re, na, nom,* and *tom.* Then follow the four composed sections of the *dhrupad* or *dhamār,* the latter being named after *dhamār-tāla* of 14 units (5 + 5 + 4) in which it is composed, the former name derived from *dhruvapada.* The song, usually in slow or medium tempo, is first sung as composed; then the performer introduces variations, the words often being distorted and serving merely as a vehicle for the melodic and rhythmic improvisations. Although the *dhrupad-dhamār* form has been out of favour for over a century, it is now apparently being revived.

Instrumental forms

Instrumental music has gained considerable prominence in North India in recent times. The most common instrumental form is the *gat,* which seems to have derived its elements from both *dhrupad* and *khyāl.* It is usually preceded by *ālāpa* and *jor,* which resemble the *ālāpa* and *non-tom* sections of the *dhrupad.* On plucked stringed instruments these two movements are often followed by *jhālā,* a fast section in which the rhythmic plucking of the drone strings is used to achieve a climax. The performer usually pauses before the composed *gat* is introduced. Like the *khyāl,* the *gat* can be in slow or fast tempo. The composition is generally short, and the emphasis is on the improvisations of the melody instrumentalist and the drummer, who for the most part alternate in their extemporizing. The final climax may once again be achieved by a *jhālā* section, in which the tempo is accelerated quite considerably. Other forms played on instruments are the *ṭhumrī,* basically an instrumental rendering of a vocal *ṭhumrī,* and *dhun,* which is derived from a folk tune and does not usually follow a conventional raga. One may also hear a piece called *rāga-māla* (literally, "a garland of ragas"), in which the musician modulates from one raga to another, finally concluding with a return to the original raga.

Musical instruments of North India

The most prominent melody instruments used in North Indian classical music are the sitar, a long-necked fretted lute; *surbahār,* a larger version of the sitar; the sarod, a plucked lute without frets and a shorter neck than that of the sitar; the *sāraṅgī,* a short-necked bowed lute; the bansuri, a side-blown bamboo flute with six or seven finger holes; the *sheh'nai,* a double-reed wind instrument similar to the oboe, but without keys; and the violin, played in the same manner as in South India. Secondary melody instruments are used only in vocal music, the two most common being the *sāraṅgī* and the keyboard harmonium, an import from the West. The violin and the *surmaṇḍal,* a plucked board zither, are also used in this context. In recent times, instrumental duets, in which the musicians improvise alternately, have grown in popularity. In these duets the musicians may imitate each other's phrases, temporarily creating something of the effect of a secondary melody instrument.

As with South Indian music, the drone is usually provided by a tamboura (Bengali *tanpura*) or a hand-pumped reed drone similar to the harmonium but without a keyboard, called *sur-peṭī* in North India. The *sheh'nai* is usually accompanied by one or more drone *shehnais,* called *sur.*

The rhythmic accompaniment is usually provided on the tabla, a pair of small drums played with the fingers. As

accompaniment to the somewhat archaic *dhrupad*, however, the pakhavāj, a double-conical drum, similar to the South Indian mridanga, is generally used. The *sheh'nai* in classical music is usually accompanied by a small pair of kettledrums, called *ḍukaṛ-ṭikaṛ*.

Interaction with Western music. It is in the sphere of musical instruments that the influence of Western music is most obvious. In addition to the violin and the harmonium, many other Western instruments are occasionally used. These include the clarinet, saxophone, trumpet, guitar, mandolin, and organ. Scholars have criticized the use of some of these instruments on the ground that their tuning, being based on the Western tempered scale (having 12 equal semitones), is not suitable for the performance of Indian music, and All-India Radio has forbidden the use of the harmonium in its programs. Most of the leading North Indian singers, however, have been using the harmonium as a secondary melody instrument for many years and have continued to do so in concerts and on recordings.

Apart from the area of musical instruments, Indian music appears to have absorbed very little of Western music. It is possible that some modern developments in classical music might have been inspired by Western music. These include the slightly increased use of chromaticism (using a succession of semitones) and some of the new drone tunings in which the major third is added (making for example, the drone on the first, third, and fifth notes of the scale, rather than on the first and fifth only). But the evidence is not conclusive, and it could equally be argued that these are natural developments within the system. Western technology has, of course, had a profound influence on Indian music. Sound-amplification devices have made concerts available to large audiences, and the intimate atmosphere in which the music was traditionally performed is now seldom encountered. The Indian musician has been obliged to adapt his music, once played before a select and musically educated group of listeners, to new circumstances involving a mass of people, many of whom are unable to appreciate the finer points of the music. The use of microphones during concerts has had a marked effect on voice production, and, since the voice no longer needs to project over distances, many modern singers now sing with a relaxed throat and produce a more mellow tone.

Impact outside of India

Since the mid-1950s, Indian classical music has been performed fairly regularly in the West. Initially, the audiences were composed mainly of South Asians, but gradually an increasing number of Westerners have been attending the concerts. Perhaps the music would not have reached beyond a very limited audience were it not for the interest shown by the American violinist Yehudi Menuhin, who sponsored a number of programs in the West, and the British popular-music group the Beatles, who attempted to incorporate the sound of the sitar and other elements of Indian culture into the world of Western popular music. At the same time, several North Indian instrumentalists, such as Ravi Shankar, Ali Akbar Khan, Vilayat Khan, Imrat Khan, and Nikhil Banerjee, were received with overwhelming enthusiasm by Western audiences. By the end of the 1960s the sitar and tabla were heard frequently in Western pop music, jazz, cinema, and television programs, as well as in radio and television advertisements.

Within three or four years, the mass Western involvement with Indian music was over. It is perhaps too early to assess the full impact of this period. It would seem that Indian music has not as yet had any significant influence on Western music. A few modern composers have attempted to incorporate elements of Indian music into their compositions, but their works remain as experiments. The fusing of Indian music and jazz would seem to have more possibilities, since improvisation is an important factor in both, but present attempts have not fulfilled this expectation. Most of these attempts seem to be premature and based on an inadequate understanding of one or the other musical system. (N.A.J.)

Dance and theatre

Theatre and dance in South Asia stem principally from Indian tradition. The principles of aesthetics and gesture language in the *Nāṭya-śāstra*, a 2,000-year-old Sanskrit treatise on dramaturgy, have been the mainstay of all the traditional dancers and actors in India. Even folk performers follow some of its conventions; *e.g.*, the *Kandyan* dancers of Ceylon (now Sri Lanka), who preserve some of the whirls and spins described in this ancient Indian text. Despite the influence of the different religious waves that swept the subcontinent through the centuries, the forms of South Asian dance and theatre were always able to preserve their ancient core.

Traditionally, dance and acting are inseparable. The classical South Asian dancer, equipped with a repertoire of gesture language, alternates between *nṛtta*, pure dance; *nṛtya*, interpretive dance; and *nāṭya*, dance with a dramatic element. (The Sanskrit word *naṭa* means a dancer-actor.) Traditional theatre throughout both South and Southeast Asia is a combination of music, dance, mime, stylized speech, and spectacle. The classical and folk actor must be a dancer, a singer, and a mime in one.

Influence on Southeast Asia

Between the 2nd century BC and the 8th century AD, South Indian kings sent overseas trade missions, priests, court dancers, and sometimes armies to Southeast Asia. During these years of cultural expansion, Indian dance forms, mythological lore, and the language of gesture flourished in Burma, Cambodia, Java, Sumatra, and Bali. Later, when India's economic and political power shrank, its cultural empire remained intact. Even when these Southeast Asian countries embraced Buddhism or Islām, they continued performing dance dramas with Hindu gods and goddesses, adding to these their own local myths, costumes, and masks. The two Hindu epics, the *Rāmāyaṇa* and the *Mahābhārata*, storehouses of dramatic personae of traditional dramas, have been absorbed by these countries as part of their own cultural heritage. Some dance forms and gesture vocabulary that died out in their land of birth have been preserved in Bali. For a discussion of the dance and theatre of Southeast Asia see the article SOUTHEAST ASIAN ARTS.

THE PERFORMING ARTS IN INDIA

The royal courts and temples of India traditionally have been the chief centres of the performing arts. In ancient times, Sanskrit dramas were staged at seasonal festivals or to celebrate special events. Some kings were themselves playwrights; the most notable of the playwright-kings was Śūdraka, the supposed 4th-century author of *Mṛcchakaṭika* (The Little Clay Cart). Other well-known royal dramatists include Harṣa, who wrote *Ratnāvālī* in the 7th century; Mahendravikramavarman, author of the 7th-century play *Bhagavad-Ajjukiya;* and Viśākhadatta, creator of the 9th-century drama *Mudrārākṣasa*.

In the 4th century BC, Kauṭilya, the chief minister of Emperor Candragupta, referred in his book on the art of government, the *Artha-śāstra*, to the low morals of players and advised the municipal authorities not to build houses in the midst of their villages for actors, acrobats, and mummers. But, in the glorious era of the Hindu kings during the first eight centuries after Christ, actors and dancers were given special places of distinction. This tradition continued in the princely courts of India even under British rule. *Kathākali* dance-drama, for instance, was created by the Raja of Kottarakkara, ruler of one of the states of South India in the 17th century. The powerful peshwas of the Marāthā kingdom in the 18th century patronized the *tamasha* folk theatre. Nawab Wajid Ali Shah (flourished mid-19th-century) was an expert *kathak* dancer and producer of Krishnalore plays in which his palace maids danced as the *gopīs* (milkmaids who were devotees of Krishna). Maharajas of Travancore and Mysore competed with each other for the excellence of their dance troupes. In the 20th century, the Maharaja of Banaras (Vārānasi) carried on this tradition by being patron and producer of the spectacular *rāmlīlā*, a 31-day cycle play on Rāma's life that he witnessed every night while sitting on his royal elephant. On special nights the spectators numbered more than 30,000.

Royal patronage

Dance is a part of all Hindu rituals. Farmers dance for a plentiful harvest, hunters for a rich bag, fishermen for a good catch. Seasonal festivals, religious fairs, mar-

riages, and births are celebrated by community dancing. A warrior dances before the image of his goddess and receives her blessings before he leaves for battle. A temple girl dances to please her god. The gods dance in joy, in anger, in triumph. The world itself was created by the Cosmic Dance of Lord Śiva, who is called Naṭarāja, the king of dancers, and worshipped by actors and dancers as their patron.

Religious festivals

Religious festivals are still the most important occasions for dance and theatrical activity. The *rāmlīlā kṛṣṇalīlā* and *rāslīlā* in North India (Uttar Pradesh, Delhi, Rājasthān, Haryana, and Punjab), the *chhau* masked dance-drama in Saraikela region in Bihār, and the *bhagavatha mela* in Melatur village in Tamil Nadu are performed annually to celebrate the glory of their particular deities. During the Daśaharā festival every village in North India enacts for a fortnight the story of Rāma's life, with songs, dances and pageants. The *jātrā* in West Bengal is a year-round dramatic activity, but the number of troupes swells to many thousands in Calcutta during the Pūjā festival. The hill and tribal people dance all night to celebrate their community festivals and weddings rich in masks, pageants, and carnivals. In far-flung areas of South Asia, people may not have seen a drama, but there will be hardly a person who has not witnessed or taken part in a community dance.

Audience participation

In folk theatre, traditional dance, classical music, and poetical symposia (especially the Urdu *mushā'irah*), performances are held in the open air or in a well-lit canopied courtyard so that the players can see the spectators and be motivated by their reactions.

For the usually all-night folk dramas, people come with their children, straw mats, and snacks, making themselves at home. At these performances there is a constant inflow and outflow of spectators. Some go to sleep, asking their neighbours to awaken them for favourite scenes. Stalls selling betel leaves, peanuts, and spicy fried things, adorned with flowers and incense and lighted by oil lamps, surround the open-air arena. The clown, an essential character in every folk play, comments on the audience and contemporary events. Zealous spectators offer donations and gifts in appreciation of their favourite actor or dancer, who receives them in the middle of the performance and thanks the donor by singing or dancing a particular piece of his choice. The audience thus constantly throws sparks to the performer, who throws them back. People laugh, weep, sigh, or suddenly fall silent during a moving scene.

In both folk and classical forms of drama, the performer may lengthen or shorten his piece according to audience response. During a *kathak* dance, the drummer, in order to test the perfection of the dancer, disguises the main beat of his drum by slurs and offbeats, a secret he shares with the audience and announces by a loud thump that is synchronized with the dancer's stamping of the foot. At this point in the dance the spectators shout, swaying their heads in admiration. They show their approval and disapproval through delighted groans or sullen headshakes as the performance goes on. In the *rāslīlā*, the audience joins in singing the refrain and marks the beat by hand clapping. At a climactic point the people rock and sway, rhythmically clapping and singing. These practices bind the performers, chanters, and spectators together in a sense of aesthetic pleasure.

Instrumental music and singing

Instrumental music and singing are integral parts of Indian dance and theatre. Musicians, chanters, and drummers sit on the stage in view, a tradition observed throughout almost all of Asia. They watch the dancer and play on their instruments following his movements, whereas in the West the movements of a ballerina are timed and controlled by the already-written music. An Indian dancer is constantly reacting to the accompanying musician, and vice versa. He may signal the chanters and drummers and even instruct them during the performance without spoiling its aesthetic effect.

In some classical dance forms, such as *kuchipudi*, the dancer sings in voiceless whispers as she dances. In *bhārata-nāṭyam* the dance movements are like sculpted music in space, and the accompanying musician is invariably a dance guru (teacher). In *kathak* the rhythmic syllables beaten out by the dancer with her feet are vocalized by the singer and then chirped out by the drummer. No folk dancing is complete without the use of drum and vocal singing. Women's folk singing such as the *giddha* in the Punjab and the men's *kīrtan* in West Bengal takes the form of dance when the rhythm becomes fast.

In folk theatre this relationship is even more apparent. *Rāslīlā* dance sequences are interspersed with the singing as a decorative frill, to accentuate emotional appeal, or to mark the climax of a song. The *yakṣagāna* hero gives a brisk dance number to announce his entry. In many folk forms of opera (*bhavai, terukkūttu,* and *nautanki*), the characters sing and dance at the same time or alternate. Ballad singers from the states of Orissa and Andhra Pradesh dramatize their singing by strong facial gestures and rhythmic ankle bells and execute dance phrases between the narrative singing. On the other hand, no one can imagine a dancer who is not at the same time a musician. This double aesthetic discipline enriches both of these arts, and the Indian audience is conditioned to this tradition.

INDIAN DANCE

Dance in India can be organized into three categories: classical, folk, and modern. Classical dance forms are among the best preserved and oldest practiced in the 20th century. The royal courts, the temples, and the guru to pupil teaching tradition have kept this art alive and unchanged. Folk dancing has remained in rural areas as an expression of the daily work and rituals of village communities. Modern Indian dance, a product of the 20th century, is a creative mixture of the first two forms, with freely improvised movements and rhythms to express the new themes and impulses of contemporary India.

The popularity of dance in 20th-century India can be judged from the fact that there is hardly any Indian motion picture that does not have half a dozen dances in it. In the typical "boy meets girl" film the heroine dances everywhere and anywhere. A film company may not have a script writer (in some cases the financier writes the story himself), but it must have a dance director. To provide ample dance opportunities, motion pictures have been made on the lives of poets, courtesans, and temple dancers and on mythological themes. For these the services of expert dancers are sought.

In the 20th century, classical dance has left the temples and royal courts and is now presented regularly on the stage in large cities. Rich industrialists, international hotels, and the wealthy families of the upper class are the chief patrons. It is not uncommon to have a classical dance recital by a major performer at a business dinner or for the annual function of a club. Some universities have dance as a regular subject in their curricula. Women learn it as a social grace, and young girls learn a few classical dances for greater eligibility in marriage. Folk dancing has also become more common as a contemporary cultural event in the cities. Most colleges have their folk-dance troupes, and even the police of the Punjab have their folk-dance groups to perform the *bhangra*. Folk dance, cut off from its rural settings, has lost much of its original vigour and beauty, but that is the inevitable result of cross-fertilization of regional cultures through folk-troupe exchanges at an interstate level.

Classical dance. *The dance-drama.* India has evolved through its classical and folk traditions a type of dance drama that is a form of total theatre. The actor dances out the story through a complex gesture language, a form that, in its universal appeal, cuts across the multilanguage barrier of the subcontinent. Some of the classical dance-drama forms (*e.g., kathākali, kuchipudi, bhagavatha mela*) enact well-known stories derived from Hindu mythology. The 20th-century dancers Uday Shankar and Shanti Bardhan have created ballets that were inspired by such traditional dance-dramas. Contemporary Indian directors and writers are re-examining traditional dance forms and are using these in their current works for greater psychological appeal and deeper artistic impact. Millions in villages are still entertained by dance-dramas. In spite of the popu-

larity of straight prose plays in the cities, the appeal of dance-drama is unquestionably deeper and more satisfying to the rural Indian, whose aesthetics is still rooted in tradition.

The *Nāṭya-śāstra*

The chief source of classical dance is Bharata Muni's *Nāṭya-śāstra* (1st century BC to 1st century AD), a comprehensive treatise on the origin and function of *nāṭya* (dramatic art that is also dance), on types of plays, gesture language, acting, miming, theatre architecture, production, makeup, costumes, masks, and various *bhāvas* ("emotions") and *rasas* ("sentiments"). No other book of ancient times contains such an exhaustive study of dramaturgy.

Techniques and types of classical dance. According to the *Nāṭya-śāstra,* the dancer-actor communicates the meaning of a play through four kinds of *abhinaya* (histrionic representations): *angika,* transmitting emotion through the stylized movements of parts of the body; *vācika,* speech, song, pitch of vowels, and intonation; *āhārya,* costumes and makeup; and *sāttvika,* the entire psychological resources of the dancer-actor.

The actor is equipped with a complicated repertoire of stylized gestures. Conventionalized movements are prescribed for every part of the body, the eyes and hands being the most important. There are 13 movements of the head, seven of the eyebrows, six for the nose, six for the cheek, seven for the chin, nine for the neck, five for the breasts, and 36 for the eyes. There are 32 movements of feet, 16 on the ground and 16 in the air. Various positions of the feet (strutting, mincing, tromping, splaying, beating, etc.) are carefully worked out. There are 24 single-hand gestures (*asaṃyuta-hasta*) and 13 for combined hands (*saṃyuta-hasta*). One gesture (*hasta*) may mean more than 30 different things quite unrelated to each other. The *patāka* gesture of the hand, for example, in which all the fingers are extended and held close together with the thumb bent, can represent heat, rain, a crowd of men, the night, a forest, a horse, or a flight of birds. The *patāka* hand with the third finger bent (*tripatāka*) can mean a crown, a tree, marriage, fire, a door, or a king. In *karkaṭa* ("crab"), one of the combined hand gestures, the fingers of the hands are interlocked, and this may indicate a honeycomb, yawning after sleep, or a conch shell. Of course, for each of these different meanings, a *hasta* is given a different body posture or action.

The male or female classical dancer portraying a story in a solo performance simultaneously plays two or three principal characters by alternating facial expressions, gestures, and moods. Krishna, his jealous wife Satyabhāmā, and his gentle wife Rukmiṇī, for example, may be played by one person.

Bhāva and *rasa*

The aesthetic pleasure of Hindu dance and theatre is determined by how successful the artist is in expressing a particular emotion (*bhāva*) and evoking the *rasa.* Literally *rasa* means "taste" or "flavour" and is that exalted sentiment or mood that the spectator experiences after witnessing a performance. The critics do not generally concern themselves so much about plot construction or technical perfection of a poem or play as about the *rasa* of a particular work. There are nine *rasa:* erotic, comic, pathetic, furious, heroic, terrible, odious, marvelous, and spiritually peaceful. There are nine corresponding *bhāvas:* love, laughter, pathos, anger, energy, fear, disgust, wonder, and quietude.

Four distinct schools of classical Indian dance—*bhārata-nāṭya, kathākali, kathak,* and *manipuri*—exist in the 20th century, along with two types of temperament—*tāṇḍava,* representing the fearful male energy of Śiva, and *lāsya,* representing the lyrical grace of Śiva's wife Pārvatī. *Bhārata-nāṭya,* which takes its name from Bharata's *Nāṭya-śāstra,* has the *lāsya* character, and its home is Tamil Nadu, in South India. *Kathākali,* a pantomimic dance-drama in the *tāṇḍava* mood with towering headgear and elaborate facial makeup, originated in Kerala. *Kathak* is a mixture of *lāsya* and *tāṇḍava* characterized by intricate footwork and mathematical precision of rhythmic patterns; it flourishes in the north. *Manipuri,* with its swaying and gliding movements, is *lāsya,* and it has been preserved in Manipur state in the Assam Hills. In 1958 the Sangeet Natak Akademi (National Academy of Music, Dance and Drama) in New Delhi bestowed classical status on two other schools of dance—*kuchipudi,* from Andhra Pradesh, and *oṛissī,* from Orissa. These two styles overlap the *bhārata-nāṭya* school and therefore are not as distinctly different in temperament and style as other forms.

The bhārata-nāṭya school. Bhārata-nāṭya (also called *dasi attam*) has survived to the present through the *devadāsīs,* temple dancing girls who devoted their lives to their gods through this medium. Muslim invasions from the north destroyed the powerful Hindu kingdoms in the south but could not disrupt their arts, which took shelter in the temples. After the 16th century, the Muslims overpowered the south completely until the British came, thus giving a setback to Hindu dance. Slowly the institution of *devadāsī* fell into disrepute, and temple dancing girls became synonymous with prostitutes. In the latter half of the 19th century in Tanjore, Chinniyah, Punniah, Vadivelu, and Shivanandam, four talented dancers who were brothers, revived the original purity of *dasi attam* by studying and following the ancient texts and temple friezes, with missing links supplied by the socially spurned *devadāsīs.* Their popularized form of *dasi attam* was called *bhārata-nāṭya.*

A performance of *bhārata-nāṭya* lasts for about two hours and consists of six parts, beginning with *allarippu* (Telegu language, "to decorate with flowers"), a devotional prologue that shows off the elegance and grace of the dancer. The second part is *jātisvaram,* a brilliant blaze of *jātis* ("dance phrases") with *svaras* ("musical sounds"). This is followed by *shabdam,* the singing words that prepare the dancer to interpret through *abhinaya* (gesture language) interspersed with pure dance. The fourth part is *varṇam,* a combination of expressive and pure dance. Then follow the *padams,* songs in Telegu, Tamil, or Kanarese that the dancer dramatizes by facial expressions and hand gestures. The accompanying singer chants the line again and again, and the dancer enacts the clashing and contrasting meanings. Her virtuosity consists of exhausting all possible shades of suggestion. The performance ends with *tillānā,* a pure dance accompanied by meaningless musical syllables chanted to punctuate the rhythm. The dancer explodes into leaps and jumps forward and backward, from right and left, in a state of ecstasy. *Tillānā* ends with three clangs of the cymbals while the dancer executes a triple blaze of *jātis,* thumping her feet with a jingling flourish of ankle bells.

Bhārata-nāṭya has attained world recognition as one of the most exquisite forms of classical dance. Its aspirants go to Tamil Nadu to learn from gurus who still live in villages. Because of its *lāsya* character, performing artists have always been women. But their teachers have invariably been old men who chant the lines to tiny cymbals, controlling the complex rhythm without dancing themselves.

The major 20th-century performers associated with the *bhārata-nāṭya* school of dance are T. Balasaraswathi, especially known for her *abhinaya* (expressive interpretation) of *padams*; Rukmini Devi, who popularized *bhārata-nāṭya* among the upper classes in the 1930s; Yamini Krishnamurthi; and Shanta Rao. Two of the most important gurus were Minakshisundaram Pillai, who injected vigour into *bhārata-nāṭya* by his choreography, and his son-in-law, Chokkalingam Pillai.

The kathākali school. Kathākali (*kathā,* "story"; *kali,* "performance") originated in the 17th century in Kerala, the lush tropical coastal strip of South India washed by the Arabian Sea. It was devised by the Raja of Kottarakkara, who, angry over the refusal of a neighbouring prince to allow his dancers to perform a Sanskrit dance-drama in his court, decided to create his own dance troupe using Malayalam, the spoken language of the people. This school has its own *hastas,* based on a regional text influenced by the *Nāṭya-śāstra* and later treatises. It also has marked elements of energetic ritualistic dances. The makeup has its roots in the grotesque pre-Hindu Dravidian demon masks. Themes are taken mainly from the *Rāmāyaṇa,* the *Śiva-Purāṇa,* the *Bhāgavata-Purāṇa,* the *Mahābhārata,* and other religious texts. The superhuman characters represent primal forces of good and evil at war. Because of its terrifying vigour, men play all the roles.

Characters and costumes

Most *kathākali* characters (except those of women, Brahmins, and sages) wear towering headgear and billowing skirts and have their fingers fitted with long silver nails to accentuate hand gestures. The principal characters are classified into seven types. (1) *Pacca* ("green") is the noble hero whose face is painted bright green and framed in a white bow-shaped sweep from ears to chin. Heroes such as Rāma, Lakṣmaṇa, Krishna, Arjuna, and Yudhiṣṭhira fall into this category. (2) *Katti* ("knife"), haughty and arrogant but learned and of exalted character, has a fiery upcurled moustache with silver piping and a white mushroom knob at the tip of his nose. Two walrus tusks protrude from the corners of his mouth, his headgear is opulent, and his skirt is full. Duryodhana, Rāvaṇa, and Kichaka belong to this type. (3) *Chokannatadi* ("red beard"), power-drunk and vicious, is painted jet black from the nostrils upward. On both cheeks semicircular strips of white paper run from the upper lip to the eyes. He has black lips, white warts on nose and forehead, two long curved teeth, spiky silver claws, and a blood-red beard. (4) *Velupputadi* ("white beard") represents Hanuman, son of the wind god. The upper half of his face is black and the lower red, marked by a tracery of curling white lines. The lips are black, the nose is green, black squares frame the eyes, and two red spots decorate the forehead. A feathery gray beard, a large furry coat, and bell-shaped headgear give the illusion of a monkey. (5) *Karupputadi* ("black beard") is a hunter or forest dweller. His face is coal black with crisscross lines drawn around the eyes. A white flower sits on his nose, and peacock feathers closely woven into a cylinder rise above his head. He carries a bow, quiver, and sword. (6) *Kari* ("black") is intended to be disgusting and gruesome. Witches and ogresses, who fall into this category, have black faces marked with queer patterns in white and huge, bulging breasts. (7) *Minnukku* ("softly shaded") represents sages, Brahmins, and women. The men wear white or orange dhotis. Women have their faces painted light yellow and sprinkled with mica, and their heads are covered by saris.

Under a flower-decked canopy on a square, ground-level stage a tall brass worship lamp brimming with coconut oil burns brightly. The musicians and dancers bow before it before they start performing. Drummers standing in one corner pound the *cenda*, a barrel-shaped drum with a piercing, clattering sound suited for battle scenes, and continue throughout the performance, almost without respite.

Two men hold a 12-foot by six-foot (four-metre by two-metre) embroidered hand curtain from behind which the principal characters make their entrances. They dance, grab the trembling curtain, and give vivid facial expressions with fearful glances and grunts. This "peering over the curtain," called *tiranokku,* is a close-up that offers an actor full scope to display his art. At a climactic moment the curtain is whisked away and the character enters in full splendour. The performance lasts all night, the singers singing the text that the dancers act out in an elaborate gesture language.

Well-known performers of *kathākali* include Guru Chandu Panikkar, Guru Kunju Kurup, Ramunni Nair, and Kalamandalam Krishna Nair. The dancers Guru Gopi Nath and Krishnan Kutty have both emphasized simplification of the use of towering headgear and thick-crusted, elaborate makeup, so that the art may be more commonly understood.

The kathak school. *Kathak,* born of the marriage of Hindu and Muslim cultures, flourished in North India under Mughal influence. *Kathak* dancers retain their 17th-century costumes but are steeped in Rādhā and Krishna love lore. Krishna, playing his flute in the Vṛndāvana woods on the bank of the Yamuna River, is surrounded by the *gopīs* ("milkmaids"). Their play is the eternal game of the god and his devotees, the hide-and-seek of man and woman. This spiritual relationship is deeply passionate, with erotic love-play. Slowly the dance degenerated and found shelter in bawdy houses, where nautch girls practiced the art to make themselves more tantalizing. In the beginning of the 20th century it was reclaimed and revived, however, mainly through the efforts of Kalkaprasad Maharaj, whose three sons Achchan, Lachchu, and Shambhu, perfected the art.

Because of its mixed *lāsya* and *tāṇḍava* temperament, *kathak* is popular with both females and males. In *bhāratanāṭya,* footwork is synchronized with hand gestures and eye movements, but *kathak* has no such rigid technique. It takes its movements from life, stylizes them, and adds complex rhythmic patterns. The mathematical precision in doubling and quadrupling the beat with quick transfers and shifts makes the onlookers dizzy.

Kathak performers

A female *kathak* dancer generally wears a brocade blouse, a long, wide, shimmering silk skirt, a transparent tissue scarf of gold threads, and a heavy cluster of ankle bells. A musician, generally the guru, sits beside the drummer on the floor and vocalizes the complicated syllables of the drum that the dancer beats out with her feet. *Kathak's* basic dance posture and some of the steps can be traced to the *rāslīlā* of Braj Bhoomi. The musical refrain, which is called *lehra,* provides the base on which the drummer and the dancer execute a rich tapestry of rhythmic patterns. Beats are called *mātrās* and the footwork *tatkar.* Important elements of the dance are *chakkars, torahs,* and *tihais. Chakkar* denotes whirling with great speed and stopping for a fraction of time after each whirl within the prescribed beat while at the same time maintaining the beauty of the form. *Torah* is a composition consisting of rhythmic syllables. *Tihai* is the repetition of a phrase of rhythmic syllables used to adorn the concluding part of a *torah.* There are two styles of *kathak:* Jaipur *gharana* and Lucknow *gharana.* While the Lucknow *gharana* excels in *bhāva,* the Jaipur *gharana* specializes in brilliance of footwork.

In the 20th century the major performers of *kathak* include Shambhu Maharaj, who specialized in *bhavapradarśan* ("display of emotion"), and Sunder Prasad, who concentrated on the *tala* and *layakari* aspects of the dance. Birju Maharaj, Gopi Krishan, Sitara Devi, and Damayanti Joshi all have important reputations in India as well as abroad.

The manipuri school. *Manipuri* has survived in the sheltered valley of Manipur in the Assam Hills. It remained aloof not only from foreign influences but also from the main Indian trends. Its isolation was broken only in the 1920s, when Rabindranath Tagore visited the valley and invited a leading guru of the area, Atomba Singh, to teach at his school in Santiniketan. The supple movements of *manipuri* dance were suitable for Tagore's lyrical dramas, and he therefore employed them in his plays and introduced the dance as a part of the curriculum at his institution.

The *manipuri* dancer wears a large, stiff skirt that is glittering with round mirror pieces and a shimmering gauze veil. Her hair is done up in a high rolled crown that is adorned with chains of white blossoms, and her luminous cheeks and forehead are decorated with dots of sandalwood paste.

Style of the *manipuri* dance

Known for its femininity, *manipuri* is marked by a slow, swooning rhythm. The dancer, with her hips thrust back and head tilted on one side, turns and sways and glides as if in a dream. The immobility of her face, like that of a mask, is in sharp contrast with the other three schools of dance, in which the face and eyes are a major source of expression.

The *manipuri* drummer, his naked torso in a white dhoti with a red border tucked up above his knees, dances while he plays on the drum. He slaps and thumps; the drum rumbles and howls and chuckles. Drunk with its rhythm, the drummer dances in wild, frenzied leaps. His energetic and electric movements are a masculine counterpart to the slow, undulating patterns woven by the female dancer.

Chief 20th-century exponents of *manipuri* include Atomba Singh, who preserved the tradition of *rās* dancing, and Amubi Singh.

The kuchipudi school. *Kuchipudi* dance-dramas owe their origin to the small village of Kuchipudi (Kuchelapuram) in Andhra Pradesh. Their form was originated in the 17th century by Sidhyendra Yogi, creator of the superb dance-drama *Bhama Kalapam,* which is the story of charming Satyabhāma, jealous wife of Lord Krishna. Sidhyendra Yogi taught the art to Brahmin boys of Kuchipudi and gave a performance with them in 1675 for the Nawab of Golconda, who was so pleased that he granted Kuchipudi to the Brahmin Bhavathas for the preservation of this art. Even in the 20th century every Brahmin of Kuchipudi is expected to perform at least once in his life the role of Satyabhāma as an offering to Lord Krishna.

The *kuchipudi* dance begins with worship rituals. A male dancer moves about sprinkling holy water, and then incense is burned. *Indra-dhvaja* (the flagstaff of the god Indra) is planted on the stage to guard the performance against outside interference. Women sing and dance with worship lamps, followed by the worship of Gaṇeśa, the elephant god, who is traditionally petitioned for success before all enterprises. The *bhagavatha* (stage manager-singer) sings invocations to the goddesses Sarasvatī (Learning), Lakṣmī (Wealth), and Paraśakti (Parent Energy), in between chanting drum syllables.

Two men hold up the traditional coloured curtain. A long gold-embroidered braid is hung on the curtain as a challenge to anyone among the spectators who dares to act and dance. If anyone should take up this braid, the hero playing the female character Satyabhāma will cut off "her" hair. The principal characters are introduced from behind the curtain after each one has done a brisk dance, and at that time the *bhagavatha* sings out the background and function of each. All roles are traditionally played by men (but in recent times by women also), and all the four elements of *abhinaya* are used—dance, song, costume, and psychological resources. Thus, *kuchipudi* differs from other classical dances in which the performers do not sing.

Among the major *kuchipudi* dancers of the 20th century are Guru Chinta Krishnamurthi, Vedantam Satyanarayana, and Yamini Krishnamurthi.

Odissi. *Odissi,* practiced in Orissa, claims to be over 2,000 years old and the true inheritor of the *Nāṭya-śāstra* tradition. It originated and was initially developed in the temples and later flourished in the courts as well. Many of the 108 basic dance units (*karaṇas*) mentioned in the *Nāṭya-śāstra* can be found only in *odissi,* and many of its dance poses are sculpted on the exterior of the temples of Bhubaneswar, Konārak, and Purī. Kelu Charan Mahapatra and Indrani Rehman are the principal 20th-century figures associated with *odissi.*

Bhagavatha mela, mohini attam, and *kuṟavañci*

semiclassical dance forms are *bhagavatha mela, mohini attam,* and *kuravañci.* Performed at the annual Narasimha Jayanti festival in Melatur village in Tamil Nadu, the *bhagavatha mela* uses classical gesture language with densely textured Karnatak music. Its repertoire was enriched by the musician-poet Venkatarama Sastri (1759–1847), who composed important dance-dramas in the Telugu language. *Mohini attam* is based on the legend of the Hindu mythological seductress Mohinī, who tempted Śiva. It is patterned on *bhārata-nāṭya* with elements of *kathākali.* It uses Malayalam songs with Karnatak music. *Kuṟavañci* is a dance-drama of lyrical beauty prevalent in Tamil Nadu. It is performed by four to eight women, with a gypsy fortune-teller as initiator of the story of a lady pining for her lover. Formally, it is a mixture of the folk and classical types of Indian dance.

Folk dance. Indian folk dances have an inexhaustible variety of forms and rhythms. They differ according to region, occupation, and caste. The half-naked Adivasis (aboriginal tribes) of central and eastern India (Murias, Bhils, Gonds, Juangs, and Santāls) are the most uninhibited in their dancing. There is hardly a national fair or festival where these dances are not performed. The most impressive occasion occurs every January 26 on Republic Day, when dancers from all parts of India come to New Delhi to dance in the vast arena of the National Stadium and along a five-mile parade route.

Types of folk dances

It is difficult to categorize Indian folk dances, but generally they fall into four groups: social (concerned with such labours as tilling, sowing, fishing, and hunting); religious; ritualistic (to propitiate an angry goddess or demon with magical rites); masked (a type that appears in all the above categories).

The *kolyacha* is among the better known examples of social folk dance. A fisherman's dance indigenous to the Konkan coast of western central India, the *kolyacha* is an enactment of the rowing of a boat. Women wave handkerchiefs to their male partners, who move with sliding steps. For wedding parties young Kolis dance in the streets carrying household utensils for the newlywed couple, who join the dance at its climax.

The national social folk dance of Rājasthān is the *ghoomar,* danced by women in long full skirts and colourful *chuneris* (squares of cloth draping head and shoulders and tucked in front at the waist). Especially spectacular are the *kacchi ghori* dancers of this region. Equipped with shields and long swords, the upper part of their bodies each arrayed in the traditional attire of a bridegroom and the lower part concealed by a brilliant-coloured papier-mâché horse built up on a bamboo frame, they enact jousting contests at marriages and festivals. Bawaris, by tradition a criminal tribe, generally are expert in this form of folk dance.

In the Punjab, the most electrifying social folk dance is the male harvest dance, *bhangra,* which is also popular in the Punjab province of Pakistan. This dance is always punctuated by a song. At the end of every line the drum thunders. The last line is taken up by all the dancers in a chorus. In ecstasy they spring, bellow, shout, and gallop in a circle, madly wiggling their shoulders and hips. Any man of any age can join.

The Lambadi Gypsy women of Andhra Pradesh wear mirror-speckled headdresses and skirts and cover their arms with broad, white bone bracelets. They dance in slow, swaying movements, with men acting as singers and drummers. Their social dance is imbued with impassioned grace and lyricism and is less wild than that of Gypsies in other parts of the world.

The bison-horn dance of the Muria tribe in Madhya Pradesh is performed by both men and women, who traditionally have lived on equal terms. The men wear a horned headdress with a tall tuft of feathers and a fringe of cowry shells dangling over their faces. A drum shaped like a log is slung around their necks. The women, their heads surmounted by broad, solid-brass chaplets and their breasts covered with heavy metal necklaces, carry sticks in their right hands like drum majorettes. Fifty to 100 men and women dance at a time. The male "bisons" attack and fight each other, spearing up leaves with their horns and chasing the female dancers in a dynamic interpretation of nature's mating season.

The Juang tribe in Orissa performs bird and animal

dances with vivid miming and powerful muscular agility.

Religious folk dance

Some major examples of religious folk dances are the *dindi* and *kala* dances of Mahārāshtra, which are expressions of religious ecstasy. The dancers revolve in a circle, beating short sticks (*dindis*) to keep time with the chorus leader and a drummer in the middle. As the rhythm accelerates, the dancers form into two rows, stamp their right feet, bow, and advance with their left feet, making geometric formations. The *kala* dance features a pot symbolizing fecundity. A group of dancers forms a double-tiered circle with other dancers on their shoulders. On top of this tier a man breaks the pot and splashes curds over the naked torsos of the dancers. After this ceremonial opening, the dancers twirl sticks and swords in a feverish battle dance.

Garabā, meaning a votive pot, is the best known religious dance of Gujarāt. It is danced by a group of 50 to 100 women every year for nine nights in honour of the goddess Ambā Mātā, known in other parts of India as Durgā or Kālī. The women move in a circle bending, turning, clapping their hands, and sometimes snapping their fingers. Songs in praise of the goddess accompany this dance.

Of the endless variety of ritualistic folk dances, many have magical significance and are connected with ancient cults. The *karakam* dance of Tamil Nadu state, mainly performed on the annual festival in front of the image of Māriyammai (goddess of pestilence), is to deter her from unleashing an epidemic. Tumbling and leaping, the dancer retains on his head without touching it a pot of uncooked rice surmounted by a tall bamboo frame. People ascribe this feat to the spirit of the deity, which, it is believed, enters his body. The Therayattam festival in Kerala is held to propitiate the gods and demons recognized by the pantheon of the Malayalis. The dancers, arrayed in awe-inspiring costumes and hideous masks, enact weird rituals before the village shrine. A devotee makes an offering of a cock. The dancer grabs it, chops off its head in one stroke, gives a blessing, and hands the bloody gift back to the devotee. This ceremony is punctuated by a prolonged and ponderous dance.

Masked folk dances

The greatest number of masked folk dances are found in Arunachal Pradesh (formerly North East Frontier Agency) union territory of India, where the influence of Tibetan dance may be seen. The yak dance is performed in the Ladākh section of Kashmir and in the southern fringes of the Himalayas near Assam. The dancer impersonating a yak dances with a man mounted on his back. In *sada topo tsen* men wear gorgeous silks, brocades, and long tunics with wide flapping sleeves. Skulls arranged as a diadem are a prominent feature of their grotesquely grinning wooden masks representing spirits of the other world. The dancers rely on powerful, rather slow, twirling movements with hops. The *chhau*, a unique form of masked dance, is preserved by the royal family of the former state of Saraikela in Bihār. The dancer impersonates a god, animal, bird, hunter, rainbow, night, or flower. He acts out a short theme and performs a series of vignettes at the annual Chaitra Parva festival in April. *Chhau* masks have predominantly human features slightly modified to suggest what they are portraying. With serene expressions painted in simple, flat colours, they differ radically from the elaborate facial makeup of *kathākali* or the exaggerated ghoulishness of the Nō and Kandyan masks. His face being expressionless, the *chhau* dancer's body communicates the total emotional and psychological tensions of a character. His feet have a gesture language; his toes are agile, functional, and expressive, like those of an animal. The dancer is mute; no song is sung. Only instrumental music accompanies him. In another form of *chhau*, practiced in the Mayūrbhanj district of Orissa, the actors do not wear masks, but through deliberately stiff and immobile faces they give the illusion of a mask. The style of their dance is vigorous and acrobatic.

Modern Indian dance. While in the West the theatrical elements of spoken words, music, and dance developed independently and evolved in the forms of drama, opera, and ballet, Indian theatrical tradition continued to combine the three in its dramas. Indian films still follow this rule (the heroine suddenly bursts into a song or dances for the hero), which offends Western sensibility, but in fact they are following their own classical and folk tradition. Recently, dance in the form of ballet with complex choreography in the Western sense has emerged as a distinct form.

Modern ballet

Modern Indian ballet started with Uday Shankar, who went to England to study the plastic arts and was chosen by the Russian ballerina Anna Pavlova to be her partner in the ballet *Radha and Krishna*. Young Shankar returned to India fired with enthusiasm. After studying the essentials of the four major styles of classical dance, he created new ballets with complex choreography and music, mixing the sounds from wooden clappers and metal cymbals with those of traditional instruments. He used classical and folk rhythms. Employing Western stage techniques, he presented his ballets with a skill and polish previously unknown to Indian audiences. These ballets included *Shiva-Parvati* and *Lanka Dahan* ("The Burning of Lanka"), in which he used wooden masks from Ceylon. In *Rhythm of Life* (1938) and in *Labour and Machinery* (1939), he employed contemporary political and social themes. He established a culture centre at Almora in 1939 and during its four years' existence created a whole generation of modern dancers.

Shanti Bardhan, a junior colleague of Uday Shankar, produced some of the most imaginative dance-dramas of the modern period. After founding the Little Ballet Troupe in Andheri, Bombay, in 1952 he produced *Ramayana*, in which the actors moved and danced like puppets.

Mohan Khokar

"Ramayana," puppet-style modern dance-drama originally produced and choreographed by Shanti Bardhan, *c.* 1952.

His posthumous production *Panchatantra (The Winning of Friends)* is based on an ancient fable of four friends (Mouse, Turtle, Deer, and Crow), in which he used masks and the mimed movements of animals and birds.

Narendra Sharma and Sachin Shankar, both pupils of Uday Shankar, have continued his tradition. Other important figures who have shaped modern Indian dance include Menaka, Ram Gopal, and Mrinalini Sarabhai, who has experimented with conveying modern themes through the *bhārata-nāṭya* and *kathākali* styles.

Dance-training centres. Dance training in small academies and local *kala kendras* ("art centres") is available all over contemporary India. Most universities have introduced dance as a subject in their curricula. The gurus still impart specialized training to pupils who go to live with them in villages and learn the art over a number of years. But there are many state-run or public-financed training centres organized in the 20th century that attract students from all over the world. Among the most important of these are Kerala Kalamandalam (Kerala Institute of Arts), near Shoranūr; Kalakshetra at Adyar, Tamil Nadu; Kathak Kendra, a dance branch of the Bharatiya Kala Kendra in New Delhi; Triveni Kala Sangam (Centre of Music, Dance, and Painting), at New Delhi; Darpana Academy in Ahmadābād, Gujarāt; Visva-Bharati (founded by Rabindranath Tagore), at Santiniketan, West Bengal;

and the Jawaharlal Nehru Manipuri Dance Academy, at Imphāl.

INDIAN THEATRE

Classical theatre. Classical Sanskrit theatre flourished during the first nine centuries of the Christian era. Aphorisms on acting appear in the writings of Pāṇini, the Sanskrit grammarian of the 5th century BC, and references to actors, dancers, mummers, theatrical companies, and academies are found in Kauṭilya's book on statesmanship, the *Artha-śāstra* (4th century BC). But classical structure, form, and style of acting and production with aesthetic rules were consolidated in Bharata Muni's treatise on dramaturgy, *Nāṭya-śāstra.* Bharata defines drama as a

Bharata Muni's rules

> mimicry of the actions and conduct of people, rich in various emotions, depicting different situations. This relates to actions of men good, bad and indifferent and gives courage, amusement, happiness, and advice to all of them.

Bharata classified drama into ten types. The two most important are *nāṭaka* ("heroic"), which deals with the exalted themes of gods and kings and draws from history or mythology (Kālidāsa's *Śakuntalā* and Bhavabhūti's *Uttararāmacarita* fall into this caterory), and *prakaraṇa* ("social"), in which the dramatist invents a plot dealing with ordinary human beings, such as a courtesan or a woman of low morals (Śūdraka's *Mṛcchakaṭika,* "The Little Clay Cart," belongs to this type). Plays range from one to ten acts. There are many types of one-act plays, including *bhaṇa* ("monologue"), in which a single character carries on a dialogue with an invisible one, and *prahasana* ("farce"), which is classified into two categories: superior and inferior, both dealing with courtesans and crooks. King Mahendravikramavarman's 7th-century-AD *Bhagavad-Ajjukiya* ("The Harlot and the Monk") and *Mattavilāsa* ("Drunken Revelry") are examples of *prahasana.*

Types of classical theatre

There are three structural types of classical theatre: oblong, square, and triangular, each further divided into large, medium, and small sizes. According to the *Nāṭya-śāstra,* the playhouse was "like a mountain cave" with two floors at different levels, small windows so that outside noise and wind would not interfere with the acoustics, and a backstage for actors to do makeup, costumes, and offstage noise effects. Bharata disapproved of a large playhouse and recommended the medium-size structure meant for court productions.

The ancient Hindus insisted on a small playhouse, because dramas were acted in a highly stylized gesture language with subtle movements of eyes and hands. Hindu theatre differed from its Greek counterpart in temperament and method of production. The three unities rigidly followed by the Greeks were totally unknown to Sanskrit dramatists. Less time was consumed by a Greek program of three tragedies and a farce than by a single Sanskrit drama, with its subsidiary plots and wide variety of characters and moods. The Greeks laid emphasis on plot and speech, the Hindus on the four types of acting and visual demonstration. People were audiences to the Greeks and spectators to the Hindus. The aesthetic rules also differed. Aristotle's theory of catharsis bears no resemblance to Bharata's theory of *rasa.* The Greek conception of tragedy is totally absent in Sanskrit dramas, as is the aesthetic principle that prohibits any death or defeat of the hero on stage.

Kinds of Hindu production

There were two types of Hindu productions: the *lokadharmī,* or realistic theatre, with natural presentation of human behaviour and properties catering to the popular taste, and the *nāṭyadharmī,* or stylized drama, which, using gesture language and symbols, was considered more artistic. In *Śakuntalā* the king enters riding an imaginary chariot, and Śakuntalā plucks flowers that are not there; in "The Little Clay Cart" the thief breaks through a nonexistent wall, and Maitreya passes through Vasantasena's seven courtyards by miming.

A classical play traditionally opened with the *nāndī,* a benediction of eight to 12 lines of verse in praise of the gods, after which the *sūtra-dhāra* (stage manager) entered with his wife and described the place and occasion of the action. The last sentence of his prologue served as a bridge leading to the action of the play. In *Śakuntalā* he refers to the bewitching song of his wife, which has made him forget his surroundings as the pursuit of a deer has made the king forget his state affairs. At this point the king enters, riding his hunting chariot, and the spectators are plunged into action of the play.

The *vidūṣaka* (clown) is a noble, good-hearted, blundering fool, the trusted friend of the hero. A bald-headed glutton, comic in speech and manners, he is the darling of the spectators. With the decline of Sanskrit drama the folk theatre in various regional languages inherited the conventions of the opening prayer song, the *sūtra-dhāra,* and the *vidūṣaka.*

The only surviving Sanskrit drama is *kudiyattam,* still performed by the Cakkayars of Kerala. Some principles of the *Nāṭya-śāstra* are evident in their presentations.

The earliest available classical dramas are 13 plays edited in 1912 by Pandit Ganapati Sastri, who dug out their manuscripts in Trivandrum, the capital of Kerala state. These, ascribed to Bhāsa (1st century BC–1st century AD), include the one-act *Ūrubhaṅga* ("The Broken Thigh"), a tragedy that is a departure from Sanskrit convention, and the six-act *Svapnavāsavadatta* ("The Dream of Vāsavadattā").

The most acclaimed dramatist is Kālidāsa. Other important playwrights succeeding him include Harṣa, Mahendravikramavarman, Bhavabhūtī, and Viśakhādatta. An exception is King Śūdraka, whose work is perhaps the most theatrical in the entire Sanskrit range.

"The Little Clay Cart"

The title of "The Little Clay Cart" represents a departure from Sanskrit tradition, in which a *prakaraṇa* was generally named after its hero and heroine. *Mālavikāgnimitra,* for example, is the love story of Princess Mālavikā and King Agnimitra, *Vikramorvaśī* is the tale of King Purūravas and the heavenly nymph Urvaśī, and *Mālatī-Mādhava* is the love drama of Mālatī and Mādhava. Śūdraka, as if to mock tradition, chose an insignificant homely incident—the hero's son playing with a toy cart—and elevated this to the title.

"The Little Clay Cart" has a wide range of characters. The plot does not progress in a straight line but zigzags along a winding path. During its 10 acts the hero does not appear in four of them, the heroine is absent from three, and the lustful villain disappears after the first act until the eighth. Each act is an almost independent play. The device used to link the acts is that of ending them with subtitles that sum up their particular themes or plots.

"The Little Clay Cart" has been successful in the West, whereas Indian audiences, still fed on poetic-flavoured characters and romances of an ethereal type, have favoured *Śakuntalā.* Western audiences find "The Little Clay Cart" more in their own tradition of realism and individualized characterization. Its "lisping villain," gamblers, and rogues have something in common with Shakespeare's comic characters and Molière's crooks. "The Little Clay Cart" is better theatre, whereas *Śakuntalā* is better poetry.

Folk theatre. After the decline of Sanskrit drama, folk theatre developed in various regional languages from the 14th through the 19th centuries. Some conventions and stock characters of classical drama (stage preliminaries, the opening prayer song, the *sūtra-dhāra,* and the *vidūṣaka*) were adopted into folk theatre, which lavishly employs music, dance, drumming, exaggerated makeup, masks, and a singing chorus. Thematically it deals with mythological heroes, medieval romances, and social and political events, and it is a rich store of customs, beliefs, legends, and rituals. It is a "total theatre," invading all the senses of the spectators.

The most crystalized forms are the *jātrā* of Bengal, the *nautanki, rāmlīlā,* and *rāslīlā* of North India, the *bhavai* of Gujarāt, the *tamāshā* of Mahārāshtra, the *terukkūttu* of Tamil Nadu, and the *yakṣagāna* of Kanara.

Places and kinds of folk theatre

Folk theatre is performed in the open on a variety of arena stages; round, square, rectangular, multiple-set. The *bhavai,* enacted on a ground-level circle, and the *jātrā,* on a 16-foot (five-metre) square platform, have gangways that run through the surrounding audience and connect the stage to the dressing room. Actors enter and exit through these gangways, which serve a function similar to the *hanamichi* of the Japanese Kabuki theatre. In the *rāmlīlā,*

the action sometimes occurs simultaneously at various levels on a multiple set. Actors in *nautanki* and *bhavai* sit on the stage in full view instead of exiting and sing or play an instrument as a part of the chorus. In the *rāmlīlā*, the actor playing Rāvaṇa removes his ten-headed mask when he is not acting and continues sitting on his throne, but for the spectators he is theatrically absent. Asides, soliloquies, and monologues abound. Scenes melt into one another, and the action continues in spite of change of locale.

In most folk forms the art of the actor is hereditary. He learns by watching his elders throughout childhood. He starts with drumming, then dancing, plays female roles, and then major roles.

All roles are played by men except that of the *tamāshā* woman, who is always a dancer-singer-actress. Recently, women have started playing female roles in the *jātrā* but have failed to achieve the artistic stature of their professional male counterparts.

In the *rāmlīlā* and *rāslīlā*, the principal characters—Rāma and Krishna—are always played by boys under 14, because tradition decreed they must be pure and innocent.

Mohan Khokar

Rāsīlā folk drama of northern India, watercolour, late 19th century. In the collection of Mohan Khokar, New Delhi. 1.3 × 1.3 m.

They are considered representatives of the gods and are worshipped on these occasions. In the *rāmlīlā* the *vyas* ("director"), present on the stage throughout the performance, prompts and directs the characters loudly enough for the audience to hear. This is not regarded as disturbing because it is an accepted part of the tradition. Adult roles such as Rāvaṇa and Hanuman are sometimes played by the same individual throughout his life.

Non-religious folk dance

Of the nonreligious forms, the *jātrā* and the *tamāshā* are most important. The *jātrā*, also popular in Orissa and eastern Bihār, originated in Bengal in the 15th century as a result of the *bhakti* movement, in which devotees of Krishna went singing and dancing in processions and in their frenzied singing sometimes went into acting trances. This singing with dramatic elements gradually came to be known as *jātrā*, which means "to go in a procession." In the 19th century the *jātrā* became secularized when the repertoire swelled with love stories and social and political themes. Until the beginning of the 20th century, the dialogue was primarily sung. The length has been cut from all night to four hours. The *jātrā* performance consists of action-packed dialogue with only about six songs. The singing chorus is represented by a single character, the *vivek* ("conscience"), who can appear at any moment in the play. He comments on the action, philosophizes, warns of impending dangers, and plays the double of everybody. Through his songs he externalizes the inner feelings of the characters and reveals the inner meaning of their outer actions.

The *tamāshā* (a Persian word meaning "fun," "play," or "spectacle") originated at the beginning of the 18th century in Mahārāshtra as an entertainment for the camping Mughal armies. This theatrical form was created by singing girls and dancers imported from North India and the local acrobats and tumblers of the lower-caste Dombari and Kolhati communities with their traditional manner of singing. It flourished in the courts of Marāthā rulers of the 18th and 19th centuries and attained its artistic apogee during the reign of Bājī Rāo II (1796–1818). Its uninhibited *lavani*-style singing and powerful drumming and dancing give it an erotic flavor. The most famous *tamāshā* poet and performer was Ram Joshi (1762–1812) of Sholāpur, an upper class Brahmin who married the courtesan Bayabai. Another famous singer-poet was Patthe Bapu Rao (1868–1941), a Brahmin who married a beautiful low-caste dancer, Pawala. They were the biggest *tamāshā* stars during the first quarter of the 20th century. The *tamāshā* actress, commonly called the *nautchi* (meaning "nautch girl," or "prostitute") is the life and soul of the performance. Because of their bawdy elements, women never see *tamāshā* plays, nor do respectable men.

In the 20th century, *jātrā* and *tamāshā* both have become highly organized and are commercially run. Troupes are in heavy demand and work for nine months. Over 700 *tamāshā* troupes with 2,000 dancer-actresses tour the rural areas, providing a living for about 40,000 people. The *jātrā* is the most successful commercially. Its star actors draw more than any other professional actor in the theatrical centre of Calcutta.

Puppet theatre of North India

Popular in North India are the *putliwalas* ("puppeteers") of Rājasthān, who operate marionettes made of wood and bright-coloured cloth. The puppet plays deal with kings, lovers, bandits, and princesses of the Mughal period. Generally, the puppeteer and his nephew or son operate the strings from behind, while the puppeteer's wife sits on her haunches in front of the miniature stage playing the drums and commenting on the action. The puppeteer chirps, whimpers, and squeals in animal–bird voices and creates battles and tragic moments, expresses pathos, anger, and laughter. In Andhra Pradesh the puppets, called *tholu bommalata* ("the dance of leather dolls"), are fashioned of translucent, coloured leather. These are projected on a small screen, like colour photographic transparencies. Animals, birds, gods, and demons dominate the screen. The puppeteer manipulates them from behind with two sticks. Strong lamps are arranged so that the size, position, and angle of the puppets change with the distance of the light. They are similar to the *wayang kulit* puppets of Indonesia but are much smaller and quicker moving.

In the absence of a powerful Indian city theatre (with the exception of a few in Calcutta, Bombay, and Tamil Nadu), folk theatre has kept the rural audiences entertained for centuries and has played an important part in the growth of modern theatres in different languages. The 19th-century dramatist Bharatendu Harishchandra, who was responsible for the birth of Hindi drama, used folk conventions—the opening prayer song, tableaux, comic interludes, duets, stylized speech—and combined these with Western theatrical forms in vogue at that time. Parsi companies adapted the popular folk techniques for their extravaganzas and were a major influence until the 1930s. Rabindranath Tagore, rejecting the heavy sets and realistic decor of the commercial companies, created a lyrical theatre of the imagination. Much influenced by the *baul* singers and folk actors of Bengal, he introduced the Singing Bairagi and the Wandering Poet (similar to the *vivek* of the *jātrā*) in his dramas. In the late 20th century, folk theatre has been viewed as a form that can add colour and vitality to contemporary theatre.

Modern theatre. Modern Indian theatre first developed in Bengal at the end of the 18th century as a result of Western influence. The other regional theatres more or less followed Bengal's pattern, and within the next 100 years they took the same meandering path, though they never achieved the same robust growth.

British influence on Bengali theatre

The British conquered Bengal in 1757 and influenced local arts by their educational and political systems. Their clubs performed Shakespeare, Molière, and Restoration comedies, introducing Western dramatic structure and the

proscenium stage to the Indian intelligentsia. With the help of Golak Nath Dass, a local linguist, Gerasim Lebedev, a Russian bandmaster in a British military unit, produced the first Bengali play, *Chhadmabes* ("The Disguise"), in 1795 on a Western-style stage with Bengali players of both sexes. Subsequently, Bengali playwrights began synthesizing Western styles with their own folk and Sanskrit heritage. With growing national consciousness, theatre became a platform for social reform and propaganda against British rule. Among the most important playwrights were Michael Madhu Sudan (1824–73), Dina Bandhu Mitra (1843–87), Girish Chandra Ghosh (1844–1912), and D.L. Roy (1863–1913).

The success of Dina Bandhu Mitra's *Nildarpan* ("Mirror of the Indigo"), dealing with the tyranny of the British indigo planters over the rural Bengali farm labourers, paved the way for professional theatre. The actor-director-writer Girish Chandra Ghosh founded in 1872 the National Theatre, the first Bengali professional company, and took *Nildarpan* on tour, giving performances in the North Indian cities of Delhi and Lucknow. The instigatory speeches and lurid scenes of British brutality resulted in the banning of this production. To overcome censorship difficulties, playwrights turned to historical and mythological themes with veiled symbolism that was clearly understood by Indian audiences. The heroes and villains of these plays came to represent the Indian freedom fighter against the British oppressor. Girish's historical tragedies *Mir Qasim* (1906), *Chhatrapati* (1907), and *Sirajuddaulah* (1909) bring out the tragic grandeur of heroes who fail because of some inner weakness or betrayal of their colleagues. D.L. Roy emphasized the same aspect of nationalism in his historical dramas *Mebarapatan* (The Fall of Mebar), *Shahjahan* (1910), and *Chandragupta* (1911).

Girish introduced professional efficiency and showmanship. His style of acting was flamboyant, with fiery grace. Actors such as Amar Datta and Dani Babu carried his style into the early 1920s. The acting and production methods of the Star, the Minerva, and the Manmohan Theatres (all professional) were modelled on Girish's pioneer work.

The beginning of realism

The first elements of realism were introduced in the 1920s by Sisir Kumar Bhaduri, Naresh Mitra, Ahindra Chowdhuri, and Durga Das Banerji, together with the actresses Probha Devi and Kanka Vati. In his Srirangam Theatre (closed in 1954), Sisir performed two most memorable roles: the again Mughal emperor Aurangzeb and the shrewd Hindu philosopher-politician Cānakya. Sisir's style has been refined by actor-director Sombhu Mitra and his actress wife Tripti, who worked in the Left-wing People's Theatre movement in the 1940s. With other actors they founded the Bahurupee group in 1949 and produced many Tagore plays including *Rakta Karabi* ("Red Oleanders") and *Bisarjan* ("Sacrifice"), so far unattempted by any professional company.

Rabindranath Tagore (1861–1941), steeped in Hindu classics and indigenous folk forms but responsive to European techniques of production, evolved a dramatic form quite different from those of his contemporaries. He directed and acted in his plays along with his cousins, nephews, and students. These productions were staged mostly at his school, Santiniketan, in Bengal as a nonprofessional and experimental theatre. The Calcutta elite and foreign visitors were attracted to these performances.

A painter, musician, actor, and poet, Tagore combined these talents in his productions. He used music and dance as essential elements in his latter years and created the novel opera-dance form in which a chorus sat on the stage and sang while the players acted out their roles in dance and stylized movements. Sometimes Tagore himself sat on a stool acting as the *sūtra-dhāra* and chanted to the accompaniment of music and drum as the dancing players became visual moving pictures.

In northern and western India, theatre developed in the latter half of the 19th century. The Bombay Parsi companies, using Hindi and Urdu, toured all over India. Their spectacular showmanship, based on a dramatic structure of five acts with songs, dances, comic scenes, and declamatory acting, was copied by regional theatres. The Maharashtrian theatre, founded in 1843 by Visnudas Bhave, a singer-composer-wood-carver in the court of the Raja of Sāngli, was developed by powerful dramatists such as Khadilkar and Gadkari, who emphasized Marāthā nationalism. The acting style in Maharashtrian theatre remained melodramatic, passionately arousing audiences to laughter or tears.

In the south, the popularity of dance-dramas has not allowed theatrical realism to flourish. Tamil commercial companies with their song and dance extravaganzas have dominated Andhra Pradesh, Kerala, and Mysore. The most outstanding Tamil company since the independence of India in 1947 has been the T.K.S. Brothers of Madras, famous for trick scenes and gorgeous settings. Also famous is the actor-producer-proprietor Rajamanickam, who specializes in mythological plays with an all-male cast, using horses, chariots, processions, replicas of temples, and even elephants.

Urdu and Hindi drama

Urdu and Hindi drama began with the production of *Indrasabha* by Nawab Wajid Ali Shah in 1855 and was developed by the Parsi theatrical companies until the 1930s.

Parsi theatre was an amalgam of European techniques and local classical forms, folk dramas, farces, and pageants. Mythical titans thundered on the stage. Devils soared in the air, daggers flew, thrones moved, and heroes jumped from high palace walls. Vampire pits, the painted back cloth of a generalized scene, and mechanical devices to operate flying figures were direct copies of the 19th-century Lyceum melodramas and Drury Lane spectacles in London.

The star film actor Prithvi Raj Kapoor founded Prithvi Theatres in Bombay in 1944 and brought robust realism to Hindi drama, then closed down in 1960 with a sense of completion after many tours throughout India. Prithvi's sons, nephews, and old associates worked in his large company, which became a training centre for many actors who later joined the films. Among these was the outstanding stage actress Zohra Sehgal, a former dance partner of Uday Shankar in the 1930s who had tremendous emotional depth and range, rare in actresses on the Hindi stage. Out of Prithvi's eight productions, in which he always played the lead, the best was *Pathan* (1946), which ran for 558 nights. It deals with the friendship between a tribal Muslim khān and a Hindu dewan and is set in the rugged frontier from which Prithvi came. This tragedy of two archtypes in which the khān sacrifices his son to save the life of his friend's son had intensity of action, smoldering passion, and unity of mood and achieved the highest quality of realism on the Hindi stage to this day.

Among the actors who molded regional-language theatres are Shri Narayan Rao Rajhans (popularly known as the Bala Gandharva of the Mahārāshtra stage), Jayashankar Bhojak Sundari of Gujarāt, and Sthanam Narasimhrao of Andhra. All three specialized in female roles and were star attractions during the first quarter of the 20th century.

In the last half of the 20th century, two outstanding actor-directors are Ebrahim Alkazi, director of the National School of Drama in New Delhi, and Utpal Dutt, who founded the Calcutta Little Theatre Group in 1947, which originally performed plays in English and in 1954 changed to productions in Bengali. Dutt is an actor fully committed to the revolutionary ideology of the Chinese Communist leader Mao Tse-tung. He acts on open-air stages in rural areas of Bengal, where he exerts a strong artistic and political influence.

Since Lebedev in 1795 there has been a continuous stream of Western-trained actors and producers who have been revitalizing regional-language theatrical groups. Nawab Wajid Ali Shah had visiting French opera composers in his mid-19th-century court. Tagore did his first opera, *Valmiki Pratibha* ("The Genius of Vālmīkī"), in 1881, after returning from England, where he became familiar with Western harmonies. Prithvi Raj Kapoor, E. Alkazi, and Utpal Dutt all had their earlier training in English productions. Norah Richards, an Irish-born actress who came to the Punjab in 1911, produced in 1914 the first Punjabi play, *Dulhan* ("The Bride"), written by her pupil I.C. Nanda. For 50 years she promoted rural drama and inspired actors and producers, including Prithvi Raj Kapoor.

India's genius still lies in its dance-dramas, which have

a unique form based on centuries of unbroken tradition. There are very few professional theatre companies in the whole of India, but thousands of amateur productions are staged every year by organized groups. Out of this intense experimental activity, the Indians hope a contemporary national theatre will emerge, influenced by Western techniques but distinctly Indian in flavour.

Centres for training

Many centres for theatrical training have been established in the 20th century. Among the most important are the National School of Drama and the Asian Theatre Institute in New Delhi, Sangeet Natak Akademi (National Academy of Music, Dance, and Drama) in New Delhi, and the National Institute for the Performing Arts in Bombay. Bharatiya Natya Sangh, the union of all Indian theatre groups, was founded in 1949 and is centered in New Delhi. Affiliated with UNESCO's branch of the International Theatre Institute, it organizes drama festivals and seminars, as well as serving as a centre for information.

SRI LANKA (CEYLON)

The ritualistic dances of Sri Lanka have attained world fame for their weird mystical beauty. Literary drama has not flourished, because the monks of predominantly Buddhist Sri Lanka shunned theatre. Dramatic activity found expression in exorcism ceremonies and masked dramas that employed mime, song, dance, acrobatics, and bits of prose dialogue. Heavily influenced by India, Sri Lanka's Kandyan dance and *kōlam* plays have South Indian origins. But over the centuries these have been transformed and now have a distinctly Sri Lankan character.

It is difficult to divide Sri Lankan performing arts into dance and drama, because a *kōlam* play uses dance and song, and the devil dance has bits of improvised prose dialogue.

Dance. *Devil dance.* The Buddhists of Sri Lanka still believe in supernatural beings and the healing power of magical rites. Their devil dancing is the expression, however, of pre-Buddhist beliefs.

The devil dance is performed to cure a person gripped by disease, insanity, or bad luck believed to be caused by some malignant spirit and to propitiate demons and deities to bring good fortune. The dancers belong to a lower-caste community and are professional. During their performance the patient lies to one side. Several palm-leaf shrines are constructed outside his house, each dedicated to a particular demon to lure him into the arena. The role of the Vesamuni, king of all demons, is played by the chief exorcist.

Three types of supernatural beings have to be appeased: demons, deities, and others that are half demon, half deity. The most terrible is Riri Yakka (Demon of Blood), who inhabits cremation grounds and graveyards and rides a pig. His belly is smeared with blood, and he has a monkey's face and four clawed hands that hold a parrot, a sword, a rooster, and a human head.

Costumes of the devil dancers

The dancers, all men, each wear around their heads a red cloth fringed with long ribbons of palm leaves hanging down like female hair, a strip of cloth around their chests, 22 yards (20 metres) of thin white cloth wound so skillfully around their hips that it never comes loose during an entire night of violent activity, and clusters of bells fitted around their calves to make a deafening jingle. Their appearance is half female, half male.

The dance is punctuated by little pieces of mimes and magical actions, with naked-chested drummers pounding to the accompaniment of a chorus of singers. The climax is reached when the dancers, holding flaming torches in both hands, whirl and spin, forming circles of fire around themselves. The flames lick their bodies, but they remain unsinged. The dancers leap and dive through the air in seeming defiance of gravity. In this surcharged atmosphere they pause to put on masks representing various demons. These have terrifying expressions. They romp and stomp in circles, describing their identity and purpose of visiting. The particular demon associated with the malady enters the patient's body. The chief exorcist questions, threatens, torutures, beseeches, and offers bribes to appease the demon until it finally leaves and its victim is healed.

The *sanni yakku* dance, exorcising the disease demon, has a series of humorous impersonations. One is of the demon as a beautiful woman, then as a pregnant woman, and finally as a mother. The exorcists ask questions about her pregnancy, and she lists all the respectable men of the village.

Out of many devil-dance ceremonies, most picturesque and important are the *kohomba kankariya* (or "ritual of the god Kohomba"), performed to ensure prosperity and to get rid of pestilence, and the *bali,* danced to propitiate the heavenly beings.

Kandyan dance. The *kandyan* dance, shorn of occult ceremonies, is highly sophisticated and refined. It flourished under the Kandyan kings from the 16th through the 19th centuries, and today it is considered the national dance of Sri Lanka. It has four distinct varieties: The *pantheru, naiyadi, udekki,* and *ves* (the most artistic and renowned). Its energetic movements and postures are reminiscent of India's *kathākali.* Besides the above four styles, there are 18 *vannamas* (dance enactments) including the *gajaga vannama,* depicting the elephant; the *hanuma vannama,* the monkey; and the *mayura vannama,* the peacock. These beautiful animal movements and abstract impersonations have been distilled and perfected over several hundred years.

The *vannamas*

Hindu mythological themes were originally the subjects of *kandyan* dances, the most popular being Rāma's crossing over to Laṅkā with the help of his monkey general and his reunion with Sītā. Gradually, stories of kings and legendary heroes and mimes of birds and forest beasts were introduced. The Kandyan kings elevated the dance to such beauty and skill that the Buddhists began admitting it into their temple courtyards as a tribute to the glory of their religion. It became a part of the annual August Perahera festival, in which a procession of gilded elephants, palanquins, saffron-robed monks, drummers, and chanters move majestically to the Temple of the Tooth in Kandy, where Buddha's tooth is enshrined. The *kandyan* dancers are a glittering attraction as they perform en route to the temple.

Ewing Krainin—Stockpile

Kandyan dancers and drummers from Sri Lanka.

A *kandyan* dancer wears a pagoda-like conical silver headpiece with glistening forehead fringe and huge earpieces, many-stranded bead necklaces of silver and ivory across his naked torso, beaten-silver epaulets on his biceps, and hollow silver anklets filled with silver beads to make them rattle. He spins with sudden leaps and reaches violent climaxes of geometric patterns. The sudden right and left turns of his head make the onlookers dizzy. When telling a story, he sings descriptive passages and enacts them with spurts of dancing.

Masked drama. Out of the four folk-drama forms—*kōlam, sokari, nadagam,* and *pasu*—the most highly de-

veloped and significant is the *kōlam*, in which actors wear brightly painted and intricately carved wooden masks.

The *kōlam*

The word *kōlam* is of Tamil origin and means "costume," "impersonation," or "guise." The performance consists of the masked representation of many isolated characters, such as kings, demons, deities, hunters, animals and birds, the washerman, the police constable, a pregnant woman—a British Museum manuscript concerning the *kōlam* lists 53 such characters. The most terrifying masks are of the demons, with twisted faces, protruding tusks, and cavelike nostrils for snorting fury. The *nāga* demon has a long, flaming, red tongue and dozens of cobras writhing around his head. Some old masks have only one large bulging eye, with a cobra hissing out from one nostril. The design of these masks lies between the strongly stylized tribal masks of Africa and the highly polished, sophisticated masks of the Japanese Nō Theatre. Five basic colours are used—red, blue, yellow, green, and black, the last two for lower rank characters. Exaggerated comicality, distortions, bulges, nightmarish whimsy, bright colours, and artful carving of the masks have been significant factors in keeping this form of drama alive.

The *kōlam* is performed once a year for seven to ten nights, starting at night after dinner and lasting through the early hours of the morning. The performance is generally held in the open courtyard of a house, to the accompaniment of two drummers, an instrumentalist, and a singing chorus with leader. After songs in praise of Lord Buddha and others (including the patron of the show), the *sabhapati* (master of ceremonies) describes the origin of *kōlam*—how an Indian king's pregnant wife expressed a desire to see a masked dance-drama and how a troupe was invited from a distant court. The *sabhapati* then introduces the masked characters as they enter and describes their various vocations and backgrounds.

Out of many, two plays are especially famous: the *Sandakinduru Katava* and the *Gothayimbala Katava*. The former deals with the legendary idyllic love between a half-human, half-bird couple singing and dancing in a forest. The King of Banaras comes hunting and, attracted by the beautiful Kinduri, kills her husband and makes advances to her. Rejected, he is ready to kill her when Lord Buddha appears and brings her husband back to life. In the *Gothayimbala Katava* the beautiful wife of the warrior Gothayimbala bathing in a pond attracts the attention of a demon, who falls in love with her. The enraged husband comes and chops off the demon's head, which, because of its magical power, reunites itself with the body every time it is cut off. Finally, the forest deity comes and rescues the warrior.

The recorded history of *kōlam* is not very old. There is only one known early eye witness account of *kōlam*, that of John Callaway, who in 1829 published 185 verses of a play with a description of the performance and some sketches of the masks and a brief introduction concerning the masquerade. According to Callaway, the dancers did not sing. The chanters described the characters in the third person and sometimes exclaimed to draw the attention of the audience to a particular action. The earliest *kōlam* text is preserved in the Colombo National Museum on palm leaves; another is in the British Museum inscribed on paper. The oldest printed text, edited in 1895 by A.G. Perera, is in the Colombo National Museum Library.

Masks are made of the light woods kaduru (Strychnos nux vomica) and ruk-attana (*Alstonia scholaris*) and after 50 years start decaying; consequently, the earlier masks are no longer in existence.

There has been an important revival of interest in drama in Sri Lanka since independence. E.R. Sarachchandara, a scholar of traditional Ceylonese theatre, has been responsible for a major breakthrough in revitalizing and adapting for the modern stage traditional dramatic forms such as the *kōlam*. Several new playwrights have become prominent in the mid-20th century. Foremost among them is Henry Jayasena. A producer-writer-actor, Jayasena has written and staged plays in Sinhalese and translations of foreign plays. But modern theatre is still very weak.

DANCE AND THEATRE IN KASHMIR

The Vale of Kashmir, predominantly populated by Muslims, has remained aloof from the main cultural currents of India. The ancient caves and temples of Kashmir, however, reveal a strong link with Indian culture at the beginning of the Christian Era. At one time the classical dances of the south are believed to have been practiced. When Islām was introduced, in the 14th century, dancing and theatrical arts were suppressed, being contrary to a strict interpretation of the Qur'ān. These arts survived only in folk forms and were performed principally at marriage ceremonies. The popular *hafiza* dance performed by Kashmiri women at weddings and festivals to the accompaniment of *sufiana kalam* (devotional music of the Muslim mystics known as Ṣūfīs) was banned in the 1920s by the ruling maharaja, who felt this dance was becoming too sensual. It was replaced by the *bacha nagma*, performed by young boys dressed like women. A popular entertainment at parties and festivals, it is also customarily included in modern stage plays.

In contrast to its natural scenic richness, Kashmir is theatrically a pauper. Theatrical productions are generally amateurish, since there is no regular performing company or any tradition of civic theatre.

There is only the *bhand jashna* ("festival of clowns"), a 300- to 400-year-old genre of Kashmiri folk theatre. Performed in village squares, it satirizes social situations through dance, music and clowning.

Bhand jashna

The Kashmiri-language theatre was founded in 1947, when a new national consciousness, the aftermath of the independence of the Indian subcontinent from Britain, inspired playwrights and folk actors to dramatize topical events and create a "visual newspaper" for the people. Left-wing propaganda plays such as *Zamin Sanz* ("Who Owns the Land?") and *Jangbaaz* ("The Warmonger"), though mediocre, had topical interest. Notable among those who tried their hand at writing for the stage is the poet Nadim, author of two operas, *Bambur-yambarzal (The Bumblebee)* and *Himal Nagraj (The Beautiful Woman and the Snake Prince)*.

Since the 1960s, the Jammu and Kashmir Academy of Art, Culture, and Languages has been struggling to promote theatre in the Kashmiri and Dogri languages, but with little success. Its emphasis is on literary dramas and folk-dance festivals of regional appeal.

PAKISTAN

Muslim culture has frowned upon the performing arts, with the result that there is no Arabic or Persian classical theatre. The only possible sources of drama were the Persian passion plays dealing with the martyrdom of Ḥuysayn (grandson of Muḥammad) in the desert of Karbalā' in 680 AD, which have inspired some Urdu playwrights. Pakistan, a Muslim country, therefore either had to find a theatrical heritage in Urdu and Bengali theatre, which had been flourishing in India long before the partition, or look to the West. It did both. The Urdu-language theatre of Pakistan had started in the Lucknow court of Nawab Wajid Ali Shah in 1855 and was nurtured by both Muslim and Hindu artists. In Pakistan the *kathak* style is preferred because of its strong Muslim flavour and Mughal court associations. Cut off from Hinduism and its lore, Pakistani performers use these Indian classical dance styles to interpret the aspirations of a young nation, while their folk dances express the character of Pakistan's rural culture.

Folk dance. Pakistan's dances are virile and explosive. *Bhangra* and Khaṭak are the most popular. Khaṭak is a dance of the tribal Pathans, known for their hospitality and feuds in the rugged hills of the northwest. It originated in zealous preparations for raids and celebrations of victories. In the 20th century, any joyous event is the occasion for this community dance. The Pathans, dressed in baggy *salwars*, embroidered waistcoats, and skullcapped turbans, perform it holding a rifle in both hands. In a frenzy they spin and somersault, float and whirl, with sudden bursts of swordplay to the accompaniment of drums and pipes. Because of its popularity, Khaṭak is presented to visiting dignitaries and for this purpose has been refined into choreographed productions.

Khaṭak

Bhangra, folk dance of the Punjab region of Pakistan and India.
Lustig—FPG

Female dances

Important dances by women are the *sammi, kikli, giddha,* and *luddi.* Except for the *sammi,* which has a slow rhythm accompanied by a sad song because of its association with the tragic love legend of Princess Sammi and Prince Dhola, all the other forms are charged with energy and fast rhythms. The *kikli* is performed by teen-age girls in groups of two. The partners cross their arms, interlock their fingers, and, touching the toes of their feet, stretch backward and whirl. The *giddha* is danced in a circle, the participants keeping the rhythm by clapping their hands. Two women impulsively leave the circle, jump into the centre, and perform a hilarious mimetic dance enacting a *boli* (two-line song) and again join the circle to dance in a ring and allow another couple to take the centre. In the *luddi,* women click their fingers and clap their hands, moving in a circle by jumps and half-turns and accelerating their rhythm by stamping their feet.

Performing arts in the Punjab. The genius of Punjabis finds expression in love stories, lusty dancing, and humour. The *mirasis* (professional wits), *naqalias* (mummers), and *domanis* (female singer-actresses) are professional performers belonging to the lower classes. They exploit all the tricks of exaggeration, absurdity, malapropism, comic gags, and lewd references. In the performance of a *naqal* (comic sketch), two people constitute a troupe. The leader holds a leather folder and slaps his foolish partner, who leads his master to a hilarious situation through absurd replies. Expert in mime and clowning, these character types are distantly related to the Western court fool and the commedia dell'arte.

Theatre in Pakistan. Urdu theatre grew out of a spectacular production of *Indrasabha* ("The Heavenly Court of Indra"), an operatic drama written by the poet Agha Hasan Amanat and produced in 1855 in the palace courtyard of the last Nawab of Oudh, Wajid Ali Shah. The story deals with the love of a fairy and Prince Gulfam. The fairy takes her lover to heaven where the angry and jealous Indra hurls him down to earth. Finally, the fairy, through her songs and dances, wins the heart of Indra, and the two lovers are united. Wajid Ali Shah, an expert *kathak* dancer and author of many valuable treatises on stage techniques, composed some of the melodies and dances for his production and used folk conventions, gorgeous costumes, elaborate settings, and gold-inlaid masks. *Indrasabha* was a fantastic success; it was translated into almost all the regional languages, with many local variants. Its characters—Sabaz Pari (Green Fairy), Kala Deo (Black Devil), Lal Deo (Red Devil)—became a part of the theatrical vocabulary of the subcontinent.

Parsi theatre. During the second half of the 19th century, Urdu was the main spoken and written language of the northern half of the subcontinent and understood in almost all the principal cities. The Parsis (originally Zoroastrians from Iran who settled on the coast of Bombay), comprising a wealthy community with sharp business acumen, were the pioneers in establishing a commercial theatre, that lasted from 1873 to 1935 and influenced all the other regional theatres. Though located mainly in Bombay and Calcutta, the Parsi companies toured the subcontinent with huge staffs, sets, and an army of players.

The best known playwright of this period is Agha Hashr (1876–1935), a poet-dramatist of flamboyant imagination and superb craftsmanship. Among his famous plays are *Sita Banbas,* based on an incident from the *Rāmāyaṇa; Bilwa Mangal,* a social play on the life of a poet, whose blind passion for a prostitute results in remorse; and *Aankh ka Nasha* ("The Witchery of the Eyes"), about the treachery of a prostitute's love, with realistic dialogue of a brothel. Many of Hashr's plays were adapted from Shakespeare: *Sufayd Khūn* ("White Blood") was modelled on *King Lear,* and *Khūn-e Nāḥaq* ("The Innocent Murder") on *Hamlet.* His last play, *Rustam-o-Sohrab,* the tragic story of two legendary Persian heroes, Rustam and his son Sohrab, is a drama of passion and fatal irony.

Parsi productions

Productions by Parsi theatrical companies were large-budgeted affairs. Plays opened with the actors in full makeup and costume, their hands folded and eyes closed, singing a prayer song in praise of some deity, and generally ended in a tableau. Sometimes at curtain call the director rearranged the tableau in a split second and offered a variant. Actors were required to know singing, dancing, music, acrobatics, and fencing and to possess strong voices and good physical bearing. In improvised auditoriums with bad acoustics and packed with more than 2,000 people, actors' voices reached the farthest spectator. Plays began at 10 o'clock and lasted until dawn, moving from comedy to tragedy, from pathos to farce, from songs to the rattle of swords, all interspersed with moral lessons and rhyming epigrams. The droll humour and realism of the comic interludes remain unsurpassed in contemporary Urdu drama. Important playwrights of this period were Narain Prasad Betab, Mian Zarif, and Munshi Mohammed Dil of Lucknow. All took inspiration from Hindu mythology and Persian legends, transforming these tales into powerful dramas.

Imtiaz Ali Taj (1900–70) was a bridge between Agha Hashr and contemporary Pakistani playwrights. His *Anarkali* (1922), the tragic love story of a harem girl, Anarkali, and Crown Prince Salim (son of Akbar the Great), unfolds the love-hate relationship of a domineering emperor and his rebellious son. Brilliant in treatment and character analysis, this play has been staged hundreds of times by amateur groups and has entered the list of Urdu classics.

In the absence of a professional company, Urdu theatre has found it difficult to strike roots. After 1947 many Muslim actors and writers were absorbed by the Indian film industry in Bombay, and they found it difficult to adjust their great talent to amateur theatrical clubs. All the same, plays have been staged in Karāchi, Lahore, and Rāwalpindi. The best productions have been those dealing with topical themes—refugee problems, new adjustments, the corrupt bureaucracy, the Kashmir issue, and other sociopolitical issues. Agha Babar in Rāwalpindi produced *Burra Sahib* (1961: "The Big Boss"), an adaptation of Gogol's *Government Inspector,* setting it in Pakistan. *Tere Kuce se Jub Hum Nikle* ("Thrown Out of Your Lane"), by Naseer Shamshi, describes the pathetic condition of an aristocratic family in Delhi that is forced to leave home because of communal riots. In *Lal Qile se Lalukhet Tak* ("From the Red Fort to Lalukhet"), by Khwajah Moinuddin, the comedy arises out of the pitiable condition of the refugees who leave their well-settled existence in Delhi dreaming of prosperity, take a tedious journey, and arrive homeless in Karāchi to find shelter in thatched hovels. Ali Ahmed, an avant-garde actor-director in Karāchi, presents his plays with polished stagecraft and esoteric appeal.

Lahore remains the centre of amateur theatre based on the tradition of the late directors A.S. Bokhari and G.D.

Sondhi, both former principals of the Government College in Lahore. In 1942 G.D. Sondhi built the Open-Air Theatre, situated on a small artificial hillock in the Lawrence Gardens and perhaps the best in all of South Asia. It has remained the centre of dramatic contests and festivals and is a favourite of visiting dancers and actors.

The actor-playwright Rafi Peer, with his knowledge of Western theatre as a result of his training in Berlin in the 1930s, has helped to develop Pakistani theatre. Professional in approach, he has produced radio and stage plays and has been a critical colleague of A.S. Bokhari and Imtiaz in the revival of amateur theatre.

Radio and television plays. Plays are being written for radio and television that are readily adaptable for the stage, and vice versa. Saadat Hussan Mantoo (1912–55), the greatest writer of short stories and author of over 100 radio plays and features, is still the model for contemporary writers for plot construction, bitter realism, and whimsical dialogue. His collection of plays (1942–45), including *Mantoo ke Dramay* ("Mantoo's Plays"), *Ao* ("Come"), and *Teen Aurten* ("Three Women"), have flashes of the then-unborn Theatre of the Absurd.

More dramas are written in Urdu today than are staged. The turnover is large because of their generally amateurish character and short runs. There is no major professional centre for the training of actors, nor a school for stagecraft and production. Notwithstanding, the young directors and playwrights have been enthusiastic about establishing a permanent Urdu stage.

BANGLADESH

East Bengal continued the folk *jātrā* and used this form for themes concerning current political problems and historical events. A successful example of the latter is *Nawab Sirajuddaulah,* which deals with the fall of the last Muslim ruler of Bengal in 1757 through betrayal by his ambitious brother-in-law Mīr Jaʿfar, who joined the British. This *jātrā* is popular with both rural and urban audiences. Tales of Muslim kings and lovers from Persian legends also have been rendered into *jātrās.*

Contemporary theatre inherits the tradition of the prepartition Bengali stage. The poet-playwright Nazrul Islam followed the tradition of Tagore's verse plays and dance operas. Inspired by left-wing ideology, he wrote for the People's Theatre in East Bengal, championing the cause of the poor farmer. He has dealt with psychological problems and inner tensions in his *Shilpi* ("The Artist"), in which the artist is torn between love for his wife and for his art. Especially popular are historical themes of political significance, inspiring Muslims who for centuries were subjugated by the Hindus of East Bengal. Ebrahim Khan wrote *Kamal Pasha* (1926), a play about the Turkish liberator, a symbol of hope and reawakening, and *Anwar Pasha,* about the downfall of Anwar (Enver), who could not cope with the new historical forces.

Bangladesh has a solid acting tradition and a rich repertoire of Bengali plays. Its amateur stage has professional actors, and it retains the impassioned lyricism and power of the mainstream of Bengali tradition. (B.Ga.)

Visual arts

VISUAL ARTS OF THE INDIAN SUBCONTINENT

Indian art is the term commonly used to designate the art of the Indian subcontinent, which includes the present political divisions of India, Kashmir, Pakistan, and Bangladesh. Although a relationship between political history and the history of Indian art before the advent of Islām is at best problematical, a brief review will provide a broad context. The earliest urban culture of the subcontinent is represented by the Indus Valley civilization (*c.* 2500–1800 BC), which possessed several flourishing cities not only in the Indus Valley but also in Gujarāt and Rājasthān. The circumstances in which this culture came to an end are obscure. Although there is no clear proof of historical continuity, scholars have noticed several striking similarities between this early culture and features of later Indian civilization. The period immediately following the urban Indus Valley civilization is marked by a variety of essentially rural cultures. A second urbanization began to occur only around the 6th century BC, when flourishing cities started to reappear, particularly in the Gangetic Basin. The Buddha lived and preached in this period, which culminated in the great Maurya Empire, whose relatively few works are the earliest surviving remnants of monumental art. The Maurya dynast Aśoka (died 238 BC) is considered the greatest of Buddhist kings; and the majority of the monuments of the next 500 years appear to be dedicated to the Buddhist faith, though iconographical and other details suggest that the art also drew heavily on popular religion.

The Maurya Empire spread over almost all of what is modern India and Pakistan. Territories as extensive were never possessed by any other dynasty. With its fall, the empire broke up into a number of states ruled by many dynasties, some of which acquired considerable power and fame for varying periods of time. Among these, the Śuṅgas (*c.* 2nd–1st century BC) in the north and the longer-lived Sātavāhanas in the Deccan and the south are particularly noteworthy. Though these kings were Hindu by religion, Buddhist monuments form the great majority of surviving works.

Toward the end of the 1st century BC, northern India was subjected to a series of invasions by Scythian tribes, resulting finally in the establishment of the vast Kushān (Kuṣāṇa) empire, of which Mathurā was an important centre. The new rulers seemed to have followed Indian faiths, the great emperor Kaniṣka (*c.* AD 78) being a devout Buddhist. The schools of Gandhāra and Mathurā flourished during their rule, and, though much of the work is dedicated to the Buddhist religion, the foundations of later Hindu iconography were also laid in this period. While the Kushān dynasty was sovereign in the north, the Sātavāhanas continued to rule in the south. The bulk of the work at Amarāvatī was produced during their hegemony.

The Golden Age of India

Around the mid-4th century, the Gupta dynasty, of indigenous origin, rapidly expanded its power, uprooting the last remnants of foreign rule and succeeding in bringing almost all of northern India under its sway. In the Deccan there arose at the same time the equally powerful Vākāṭakas, with whom the Guptas appear to have had friendly relations. The period extending from the 4th through the 5th centuries is marked by the most flourishing artistic activities. In addition to the Buddhist monuments, there are the first strong indications of specifically Hindu patronage. Works of remarkable beauty and elegance were produced in this period, which is commonly called the Golden Age of India.

The disintegration of these two empires toward the close of the 5th and the 6th centuries ushered in what has been called the medieval period (*c.* 8th–12th centuries), marked by the appearance of a large number of states and dynasties, often at war with each other. Their rise to power and their decline was part of a constantly recurring process, for none of them was able to hold onto a position of even relative paramountcy for any extended period of time. In the north, the great dynasties were the Gurjara-Pratīhāras, whose empire at its greatest equalled that of the Guptas; the Pālas, who ruled chiefly over northeastern India; and various other dynasties, such as the Kalacuris, the Candelas, and the Paramāras of north central India, the Cāhamānas of Rājasthān, the Cālukyas of Gujarāt. In the Deccan, also, several dynasties rose and fell, the most powerful of which were the Cālukyas of Bādāmi, the Rāṣṭrakūṭas, and the Cālukyas of Kalyāṇī. They were often at war not only with their powerful neighbours to the north but also with the great Pallava and Cōḷa kingdoms of southern India. Most of the dynasties of medieval India were Hindu, though some Jaina and a very few Buddhist kings are also known. The various faiths, however, existed in comparative harmony; and Buddhist and Jaina monuments continued to be built, though most of the surviving works are Hindu.

Although the effects of constant struggle were not as devastating as one might expect, largely as a result of the institutionalization of war and its confinement to appropriate castes, the Hindu kingdoms fell easy prey to the Islāmic invasions, which began as early as the 8th century

AD but gathered strength only in the 11th century. By the end of the 12th century, almost all of northern India had been conquered. Islāmic advances in the south were checked for a while by the Vijayanagara dynasty, but with its collapse almost all of India fell under various degrees of Islāmic hegemony. Large Hindu kingdoms enjoying differing degrees of independence continued to exist chiefly in Rājasthān and portions of southern India, but overall political supremacy was vested with the Islāmic states. The Muslim powers were also divided into many kingdoms, despite attempts made by the sultanate of Delhi, and later by the Mughals, to achieve paramountcy over large portions of India. These attempts were successful only for short periods of time. Although the initial impact of Islām on Indian art was generally destructive, Islāmic influences entering India were gradually transformed in the new environment and eventually resulted in the flowering of an extremely rich and important aspect of the Indian genius.

Ascendency of the European powers

The ascendency of the European powers in the 18th century, culminating in the establishment of the British Empire, laid the foundation of modern India's contacts with the West. As a whole, the European advent was marked by a relative insensitivity to native art traditions, but rising nationalism attempted a conscious revival of Indian art toward the end of the 19th century. In modern times, the absorption of European influence is a more natural, freer process that affects artistic development in a vital and profound way.

General characteristics. *The unity of Indian art.* Indian art is spread over a subcontinent and has a long, very productive history; but it nevertheless shows a remarkable unity and consistency. Works produced in the several geographical and cultural regions possess decidedly individual characteristics but at the same time have sufficient elements in common to justify their being considered manifestations of a general style. The existence of this style is evidence of the essential cultural unity of the subcontinent and to the uninterrupted contact between the various geographical units, at least from the historical period onward. Developments in one area have been quickly reflected in the others. The regional idioms have contributed to the richness of Indian art, and the mutual influences exercised by them have been responsible for the multi-faceted development of that art throughout the course of its long life.

The style of Indian art is largely determined not by a dynasty but by conditions of time and space. It has, essentially, a geographical rather than a dynastic basis, which is to say that the evolution of regional schools appears to have been largely independent of any particular dynasty that happened to rule over a specific region. The style does not change because of the conquest of one area by another dynasty; rather the influences exercised by one area on another are usually through the agency of factors other than conquest. Instances in which dynastic patronage changed the nature of a style are very few and confined mostly to the Islāmic period. The political history of India is itself quite vague, and the areas in possession of a dynasty at various points in its history are even less susceptible to precise definition. For all these reasons, the classification of Indian art adopted here is not based on dynasties, for such a division has little meaning. Nevertheless, names of certain dynasties are used, for these have passed into common usage. When this is done, however, the name must be understood as little more than a convenient way of labelling a particular period.

The materials of Indian art. Indian art employs various materials, such as wood, brick, clay, stone, and metal. Most wooden monuments of the early period have perished but have been imitated in stone. Clay and brick were also abundantly used; but, particularly in later times, the favoured material seems to have been stone, in the dressing (facing and smoothing) and carving of which the Indian artist attained great excellence. The material may have influenced the form somewhat, but essentially Indian art tends to impose the form on the material. Thus, materials are generally regarded as interchangeable: wooden and clay forms are imitated in stone, and stone is imitated in bronze, and in turn stone sculpture assumes qualities appropriate to metal. It is as though the nature of the material presented a challenge that had to be met and overcome. At the same time, Indian art stresses the plasticity of forms; sculpture is generally characterized by emphatic mass and volume; architecture is often sculpture on a colossal scale; and the elements of painting, particularly of the early period, are modelled by line and colour.

Emphasis on the plasticity of forms

Indian and foreign art. Thanks to its geographical situation, the Indian subcontinent has been constantly fed by artistic traditions emanating from West and Central Asia. The Indian artist has shown a remarkable capacity for accepting these foreign influences naturally and assimilating and transforming them to accord with the nature of his own style. The process occurred frequently: in the Maurya period; in the two centuries after Christ, when the Kushān dynasty attained imperial supremacy in the north; and at a much later period, in the 16th century, when the Mughals patronized a new school of architecture and painting.

Just as India received influences, so it transmitted its own art abroad, particularly to Ceylon and the countries of Southeast Asia. Developments of great importance were therby precipitated in Ceylon, Burma, Thailand, Indonesia, and Indochina, where the reinterpretation of Indian influences resulted in the creation of works of great originality.

Indian art and religion. Indian art is religious inasmuch as it is largely dedicated to the service of one of several great religions. It may be didactic or edificatory as is the relief sculpture of the two centuries before and after Christ; or, by representing the divinity in symbolic form (whether architectural or figural), its purpose may be to induce contemplation and thereby put the worshipper in communication with the divine. Not all Indian art, however, is purely religious, and some of it is only nominally so. There were periods when humanistic currents flowed strongly under the guise of edificatory or contemplative imagery, the art inspired by and delighting in the life of this world.

Although Indian art is religious, there is no such thing as a sectarian Hindu or Buddhist art, for style is a function of time and place and not of religion. Thus it is not strictly correct to speak of Hindu or Buddhist art, but, rather, of Indian art that happens to render Hindu or Buddhist themes. For example, an image of Vishnu and an image of Buddha of the same period are stylistically the same, religion having little to do with the mode of artistic expression. Nor should this be surprising in view of the fact that the artists belonged to nondenominational guilds, ready to lend their services to any patron, whether Hindu, Buddhist, or Jaina.

Religion, symbolism, and abstraction

The religious nature of Indian art accounts to some extent for its essentially symbolic and abstract nature. It scrupulously avoids illusionistic effects, evoked by imitation of the physical and ephemeral world of the senses; instead, objects are made in imitation of ideal, divine prototypes, whose source is the inner world of the mind. This attitude may account for the relative absence of portraiture and for the fact that, even when it is attempted, the emphasis is on the ideal person behind the human lineaments rather than on the physical likeness.

The artist and patron. Works of art in India were produced by artists at the behest of a patron, who might commission an object to worship for spiritual or material ends, in fulfillment of a vow, for the discharge of virtues enjoined by scripture, or even for personal glory. Once the artist received his commission, he fashioned the work of art according to his skill, gained by apprenticeship, and the written canons of his art, which possessed a holy character. There were prescribed rules for proportionate measurement, iconography, and the like, often with a symbolic significance. This is not to say that the individual artist was invariably aware of the symbolic meaning of the prescribed standards, based as these were on complex metaphysical and theological considerations; but the symbolism nevertheless formed part of the fabric of his work, ready to add an extra dimension of meaning to the initiated and knowledgeable spectator.

In these conditions it is not surprising that the artist as

Early Indian architecture and sculpture

Stūpa III at Sānchi, Madhya Pradesh, sandstone, 1st century BC.

Detail of a sandstone relief sculpture from the *torana* of Stūpa I at Sānchi, Madhya Pradesh, 1st century BC.

Fragment of a soapstone disc from Kausāmbī, Uttar Pradesh, 3rd century BC. In the Municipal Museum, Allāhābād, Uttar Pradesh. Height 5.7 cm.

Abduction scene, terra-cotta relief from Kausāmbī, Uttar Pradesh, *c.* 2nd century BC. In the Municipal Museum, Allāhābād, Uttar Pradesh.

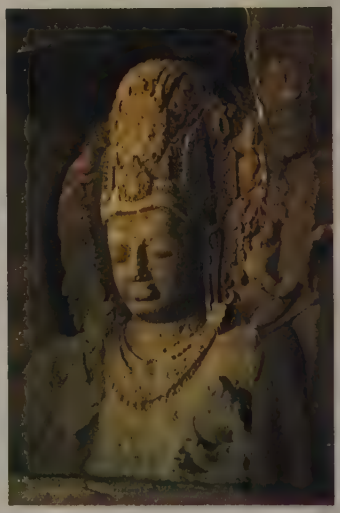
Plates 1–8 P. Chandra

Viṣṇu lying on the serpent Sesa; sandstone relief panel on the Viṣṇu temple at Deogarh, Uttar Pradesh, 5th century AD.

Indian art of the Golden Age: 5th to 6th centuries AD

(Below) The Pārvatī temple at Nācnā Kuthārā, Madhya Pradesh, sandstone, 5th century AD. (Left) Amorous couples and lotus scroll, detail of the doorframe of the Pārvatī temple.

Lotus scroll painted on the ceiling of Cave 2 at Ajanta, Mahārāshtra, 5th century AD.

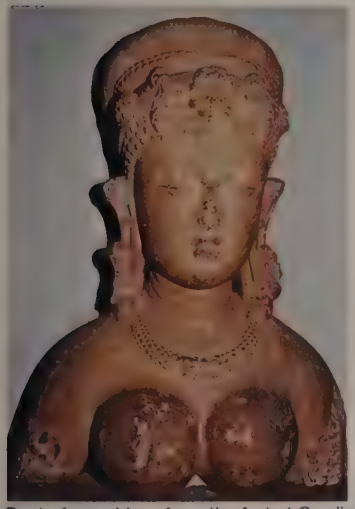


Śiva-Mahesamūrti, the main image in the cave Temple at Elephanta, Mahārāshtra, 6th century AD.

Medieval sculpture of North and South India

The hermitage by the Ganges, detail of a granite relief depicting the penance of Arjuna, from Mahābalipuram, Tamil Nadu, early 7th century AD.

The god Śiva, detail of a doorframe from Singhpur, Madhya Pradesh, sandstone, 10th century AD.



Bust of a goddess from the fort at Gwalior, Madhya Pradesh, *c.* 9th century AD. In the Gwalior Museum, Madhya Pradesh. Height 54 cm.

Śiva and his consort, bronze sculpture from Tiruvenkadu, Tamil Nadu, early 11th century AD. In the Thanjāvūr Museum and Art Gallery, Tamil Nadu. Height of male 106 cm., height of female 94 cm.

Seated Avalokiteśvara, gilt bronze sculpture from Nālandā, Bihār, 8th century AD. In the Nālandā Museum, Bihār. Height 28 cm.

Medieval temple architecture: styles of North and South India

Temple with *kutina* superstructure, the Tālapurīśvara at Panamalai, Tamil Nadu, early 8th century AD.

Temples, tank, and *gopura* of the Śiva temple at Cidambaram, Tamil Nadu, 12th–13th century AD.

Group of temples at Badoli, Rājasthān, 10th century AD.

Temple with *bhūmija* superstructure, the Udayaeśvara (or Nīlakaṇṭhhaeśvara) at Udayapur, Madhya Pradesh, *c.* AD 1059–82.

Temple with *latina* superstructure at Umrī, Madhya Pradesh, 9th century AD.

(Left) The Brhadīsvara temple at Thanjāvūr, Tamil Nadu, early 11th century AD. (Right) Detail of the temple wall.

The Keśava temple at Somnāthpur, Karnataka, *c.* AD 1268.

The monk Kālaka addressing the Sāhi king, detail from a folio from a *Kālakācāryakathā* manuscript, Western Indian style, late 13th century AD. In the Prince of Wales Museum of Western India, Bombay. Dimensions of miniature 7.6 × 7.6 cm.

Ladies in conversation, detail from a folio from a *Mahābhārata* manuscript, AD 1516. In the collection of the Asiatic Society of Bombay. Dimensions of miniature 10.2 × 10.2 cm.

A prince and his lady, Rajasthani style, Mālwa, mid-17th century AD. In a private collection.

Krsna and Rādhā, miniature from a series illustrating the *Gītagovinda*, Rajasthani style, Mewār, mid-17th century AD. In a private collection.

A hill chief smoking, Pahari style, Basohlī, late 17th century AD. In the National Museum of India, New Delhi.

The Mughal style and its influences

A queen on a hunting expedition, Pahari style, Kāngra, *c.* AD 1760. In the National Museum of India, New Delhi.

Court scene by Basāvan, folio from an illustrated manuscript of the *Anwār-e Suhayli*, Mughal style, AD 1596–97. In the Bharat Kala Bhavan, Vārānasi, Uttar Pradesh. 24.8 × 13.9 cm.

The feast of Nauroz at Jahāngīr's court, Mughal style, *c.* AD 1615. In the collection of the Reza Library, Rāmpur, Uttar Pradesh.

The musical mode Megha-Malāra, Rajasthani style, Būndi, late 17th century AD. In a private collection.

Copper bowl with hunting scene, Mughal, *c.* AD 1583. In the Prince of Wales Museum of Western India, Bombay.

The so-called Dīvān-e Khāss at Fatehpur Sīkri, red sandstone, *c.* AD 1585.

Mughal architecture and decorative arts

The tomb of Humāyūn at Delhi, red sandstone and marble, *c.* AD 1564.

Detail of a silk tapestry, Mughal, early 17th century AD. In the Prince of Wales Museum of Western India, Bombay.

Jade dish inlaid with semiprecious stones and gold, Mughal, mid-17th century AD. In the Prince of Wales Museum of Western India, Bombay.

a person is for the most part anonymous, very few names of artists having survived. It was the skill with which the work of art was made to conform to established ideals, rather than the artist who possessed the skill, that held the place of first importance.

The appreciation of Indian art. According to Indian aesthetic theory, a work of art possesses distinct "flavours" (*rasa*), the "tasting" of which constitutes the aesthetic experience. Because the work of art operates at various levels, granting to the spectator what he is capable of receiving by virtue of his intellectual and emotional preparation, the appreciation of the beauty of form and line is considered an appropriate activity of the educated and cultured man. The supreme aesthetic experience, however, is believed to be much deeper and cognate to the experience of the Godhead. From this point of view, the work of art is in a sense irrelevant and unnecessary for a person at a high level of spiritual progress; and for the devout layman its excellence is measured by its efficacy in promoting spiritual development.

Architecture. The favoured material of early Indian architecture appears to have been wood, but little has survived the rigours of the climate. Wooden forms, however, affected work in other mediums and were sometimes quite literally copied, as, for example, in early cave temples of western India. The principles of wooden construction also played an important part in determining the shape of Indian architecture and its various elements and components.

Effect of wooden forms on other mediums

Baked or sun-dried brick has a history as ancient as that of wood; among the earliest remains are buildings excavated at sites of the Indus Valley civilization. The use of brick is once again evident from about the 6th century BC, and its popularity was undiminished in subsequent centuries. Many brick monuments have been discovered, particularly in areas in which good clay was easily available, such as the Gangetic Basin. Although more durable than wood, few brick buildings from before the 5th century AD have survived in a good state of preservation.

Traditions of stone architecture appear to be more recent than wood or brick, the earliest examples of the use of dressed stone for building purposes not predating the 6th century BC. The Indian architect, however, soon gained great proficiency in its use, and, by the 7th century AD, the use of stone for monumental buildings of considerable size had become quite popular. The preference for stone can also be seen in Islāmic monuments of India, which contrast markedly with the brick and tile structures popular in neighbouring West Asia.

Most surviving examples of Indian architecture before the Islāmic period are of a religious nature, consisting mainly of Buddhist shrines, or *stūpa*s, and temples. Monastic residences give some idea of civil architecture, but, surprisingly, very few examples of palaces and secular dwellings have been found.

Indus Valley civilization (c. 2500–1800 BC). From excavated remains, it is clear that the Indus Valley civilization possessed a flourishing urban architecture. The major cities associated with the civilization, notably Mohenjodaro, Harappā, and Kalibangan, were laid out on a grid pattern and had provisions for an advanced drainage system. The residential buildings, which were serviceable enough, were mainly brick and consisted of an open patio flanked by rooms. For monumental architecture, the evidence is slight, the most important being a "sacred" tank (thought to be for ritual ablution) and associated structures. Corbel vaulting (arches supported by brackets projecting from the wall) was known, and, to a limited extent, timber was used together with brick; whatever architectural ornamentation existed must have been of brick or plaster.

The Maurya period (c. 321–185 BC). The state of Indian architecture in the period between the Indus Valley civilization and the rise of the Maurya Empire is largely unknown since most work was done in such perishable material as wood or brick. Excavations at Rājgīr, Kauśāmbī, and other sites, however, testify to the existence of fortified cities with *stūpa*s, monasteries, and temples of the type found at the later Maurya sites of Nagarī and Vidiśā; and there is evidence of the use of dressed stone in a palace excavated at Kauśāmbī. Considering the power of the Maurya Empire and the extensive territory it controlled, the architectural remains are remarkably few. The most important are *stūpa*s (later enlarged) such as a famous example of Sānchi; the ruins of a hall excavated at the site of Kumrāhar in Patna (ancient Pāṭaliputra), the capital city; and a series of rock-cut caves in the Barābar and Nāgārjunī hills near Gayā, which are interesting because they preserve in the more permanent rock some types of wooden buildings popular at that time.

The *stūpa*

The *stūpa*, the most typical monument of the Buddhist faith, consists essentially of a domical mound in which sacred relics are enshrined. Its origins are traced to mounds, or tumuli, raised over the buried remains of the dead that were found in India even before the rise of Buddhism: *Stūpa*s appear to have had a regular architectural form in the Maurya period: the mound was sometimes provided with a parasol surrounded by a miniature railing on the top, raised on a terrace, and the whole surrounded by a large railing consisting of posts, crossbars, and a coping (the capping on the top course), all secured by tenons and mortices in a technique appropriate to craftsmanship in wood. The essential feature of the *stūpa*, however, always remained the domical mound, the other elements being optional.

Along with *stūpa*s were erected roofless, or hypaethral, shrines enclosing a sacred object such as a tree or an altar. Temples of brick and timber with vaulted or domical roofs were also constructed, on plans that were generally elliptical, circular, quadrilateral, or apsidal (*i.e.*, having an apse, or semicircular plan, at the sanctum end). These structures have not survived, but some idea of their shape has been obtained from the excavated foundations and the few examples imitating wooden originals that were cut into the rock, notably the Sudāmā and the Lomas Ṛṣi caves in the Nāgārjunī and Barābar hills near Gayā. The latter has an intersesting entrance showing an edged barrel-vault roof (an arch shaped like a half cylinder) in profile supported on raked pillars, the ogee arch (an arch with curving sides, concave above and convex toward the top) so formed filled with a trellis to let in light and air. The interiors of most caves are highly polished and consist of two chambers: a shrine, elliptical or circular in plan with a domed roof (Sudāmā cave); and an adjacent antechamber, roughly rectangular and provided with a barrel vault. Remains of structural buildings have been excavated at Bairāt and Vidiśā, where wood and brick shrines with timber domes and vaults once existed. A temple (No. 40) at Sānchi was apsidal in plan and perhaps had a barrel-vault roof of timber.

A hall excavated at Kumrāhar in Patna had a high wooden platform of most excellent workmanship, on which stood eight rows of 10 columns each, which once supported a second story. Only one stone pillar has been recovered, and it is circular in shape and made of sandstone that has been polished to a high lustre. The capitals that topped them must have been similar to others found in neighbouring Lohanipur and almost certainly consisted of one or two pairs of addorsed (set back to back) animals, recalling Persepolitan examples. Indeed, there is much about Maurya architecture and sculpture to suggest Iranian influence, however substantially transformed in the Indian environment.

Early Indian architecture (2nd century BC–3rd century AD). Except for *stūpa*s, architectural remains from the 2nd century BC (downfall of the Maurya dynasty) to the 4th century AD (rise of the Gupta dynasty) continue to be rare, indicating that most of the work was done in brick and timber. Once again, examples cut into the rock and closely imitating wooden forms give a fairly accurate idea of at least some types of buildings in this period.

The *stūpa*s become progressively larger and more elaborate. The railings continue to imitate wooden construction and are often profusely carved, as at Bhārhut, Sānchi II, and Amarāvatī. These were also provided with elaborate gateways, consisting of posts supporting from one to three architraves, again imitating wooden forms and covered with sculpture (Bhārahut, Sānchi I, III). In the course of

time an attempt was made to give height to the *stūpas* by multiplying the terraces that supported the dome and by increasing the number of parasols on top. In Gandhāra and southeastern India, particularly, sculptured decoration was extended to the *stūpa* proper, so that terraces, drums, and domes—as well as railing—were decorated with figural and ornamental sculpture in bas-relief. *Stūpas* in Gandhāra were not provided with railings but, instead, had rows of small temples arranged on a rectangular plan.

West Indian cave temples

Cave temples of western India, cut into the scarp of the Western Ghāts and stretching from Gujarāt to southern Mahārāshtra, constitute the most extensive architectural remains of the period. Two main types of buildings can be distinguished, the temple proper (*caitya*) and the monastery (*vihāra, saṅghārāma*). The former is generally an apsidal hall with a central nave flanked by aisles. The apse is covered by a half dome; and two rows of pillars, which demarcate the nave, support a barrel-vault roof that covers the rest of the building. In the apsidal end is placed the object to be worshipped, generally a *stūpa*, the hall being meant for the gathered congregation. In front of the hall is a porch, separated from it by a screen wall provided with a door of considerable size, together with an arched opening on top clearly derived from wooden buildings of the Lomas Ṛṣi type and permitting air and dim light to filter into the interior. Other influences of wooden construction are equally striking, particularly in the vaulting ribs that cover the entire ceiling and that are sometimes actually of wood, as at Bhājā, where the pillars are also raked in imitation of the exigencies of wooden construction. The pillars are generally octagonal with a pot-shaped base and a capital of addorsed animals placed on a bell-shaped, or campaniform, lotus in the Maurya tradition. The most significent example is at Kārli, dating approximately to the closing years of the 1st century BC. The Bhājā *caitya* is certainly the earliest, and important examples are to be found at Beḍsā, Kondane, Pītalkhorā, Ajantā, and Nāsik. Toward the end of the period, a quadrilateral plan appears more and more frequently, as, for example, at Kuda and Sailarwāḍī.

In addition to the *caitya*, or temple proper, numerous monasteries (*vihāras*) are also cut into the rock. These are generally provided with a pillared porch and a screen wall pierced with doorways leading into the interior, which consists of a "courtyard" or congregation hall in the three walls of which are the monks' cells. The surviving rock-cut examples are all of one story, though the facade of the great monastery at Pitalkhorā simulates a building of several stories.

Monasteries carved into the rock are also known from Orissa (Udayagiri-Khandagiri), in eastern India. These are much humbler than their counterparts in western India, and consist of a row of cells that open out into a porch, the hall being absent. At Uparkot in Junāgadh, Gujarāt, is a remarkable series of rock-cut structures dating from the 3rd–4th century AD, which appear to be secular in character and in all probability served as royal pleasure houses.

The large number of representations of buildings found on relief sculpture from sites such as Bhārhut, Sānchi, Mathurā, and Amarāvatī are a rich source of information about early Indian architecture. They depict walled and moated cities with massive gates, elaborate multi-storied residences, pavilions with a variety of domes, together with the simple, thatched-roofed huts that remained the basis of most Indian architectural forms. A striking feature of this early Indian architecture is the consistent and profuse use of arched windows and doors, which are extremely important elements of the architectural decor.

The Gupta period (4th–6th centuries AD). Dating toward the close of the 4th and the beginning of the 5th century AD is a series of temples that marks the opening phase of an architecture that is no longer content with merely imitating wooden building but initiates a new movement, ultimately leading to the great and elaborate temples of the 8th century onward.

Two main temple types of the Gupta period

Two main temple types have been distinguished in the Gupta period. The first consists of a square, dark sanctum with a small, pillared porch in front, both covered with flat roofs. This type of temple answers the simplest needs of worship, a chamber to house the deity and a roof to shelter the devotee. Temple No. 17 at Sānchi is a classic example of this flat-roofed type. The plain walls are of ashlar masonry (made up of squared stone blocks), composed of sizable blocks, which are spanned by large slabs that constitute the ceiling. The pillars of the porch have a campaniform lotus capital, one of the last times this form appears in Indian architecture. Another temple of this type is the Kaṅkālī Devī shrine at Tigowā, which has more elaborate pillars, provided with the overflowing vase, or the vase-and-foliage (*ghaṭa-pallava*), capital that became the basic north Indian order.

It is the second type of temple that points the way to future developments. It also has a square sanctum, or cella, but instead of a flat roof there is a pyramidal superstructure (*śikhara*). Among the most interesting examples are a brick temple at Bhītargaon and the Vishnu temple at Deogarh, built entirely of stone. The pyramidal superstructure of each consists essentially of piled-up cornice moldings of diminishing size, which are decorated primarily with *candraśālā* (ogee arch) ornament derived from the arched windows and doors so frequently found in the centuries immediately before and after Christ. The sanctums of both temples are square in plan, with three sides provided with central offsets (vertical buttress-like projections) that extend from the base of the walls right up to the top of the *śikhara* (spire); the section of the central offset that extends across the wall is conceived in the form of a niche, in which is placed an image. The Deogarh temple is also noteworthy for the large terrace with four corner shrines (now ruined) on which it is placed, prefiguring the quincunx, or *pañcāyatana*, grouping (one structure in each corner and one in the middle) popular in the later period. The doorway surround, too, is very

P. Chandra

Carved sandstone doorframe of the Vishnu temple at Deogarh, Uttar Pradesh, India, 5th century AD.

elaborate, carved with several bands carrying floral and figural motifs. At the base of the surround are rows of worshippers, and in the crossette (projection at the corner) on top are images of graceful river goddesses.

The Pārvatī Devī temple at Nācnā Kuṭhārā, also of this period, is interesting for the covered circumambulatory provided around the sanctum and the large hall in front. When first discovered, the temple had an entire chamber above the sanctum (which subsequently collapsed). Though provided with a door, there seems to have been no access to it; thus, for all practical purposes it constituted a false story and, aside from a symbolic meaning,

served no other purpose than to emphasize the importance of the sanctum. The principle of gaining height not by the superimposition of ornamental cornice moldings with *candraśālā* decoration but by the multiplication of stories, each imitating the story below, also distinguished the later architectural style of southern India.

The great Mahābodhi temple at Buddh Gaya, commemorating the spot where the Buddha attained enlightenment, though burdened with later restorations, is essentially a temple of this period. It has a particularly majestic *śikhara*, decorated with ornamental niches and *candraśālās*, rising over a square sanctum to a great height.

Along with temples, *stūpas* continued to be built. These also aspired to height, which was achieved by multiplication and heightening of the supporting terraces and elongating the drum and dome. A good example of this new form is the Dhamekh *stūpa* at Sārnāth. Along more conventional lines, but quite elaborate, are the brick *stūpas* in Sind, notably a fine example at Mirpur Khās.

The rock-cut temple and monastery tradition also continued in this period, notably in western India, where the excavations—especially at Ajantā—acquire extreme richness and magnificence. The monasteries are characterized by the introduction of images into some of the cells, so that they partake of the nature of temples instead of being simple residences. Temples with an apsidal plan and barrel-vault roofs, however, soon went out of fashion, and are found very rarely in the subsequent period. The early 5th-century cave temples at Udayagiri, Madhya Pradesh, are similar to the simple flat-roofed temples with a hall and are not descended from ancient traditions as preserved in western India.

Period of the great stone temples

Medieval temple architecture. Architectural styles initiated during the 5th and 6th centuries found their fullest expression in the medieval period (particularly from the 9th to the 11th centuries), when great stone temples were built. Two main types can be broadly distinguished, one found generally in northern India, the other in southern India. To these can be added a third type, sharing features of both and found in Karnataka and the Deccan. These three types have been identified by some scholars with the *nāgara, drāviḍa,* and *vesara* classes referred to in some Sanskrit texts, though the actual meaning of these terms is far from clear. In spite of the havoc wrought by the destructive Islāmic invasions, particularly in the Indo-Gangetic Plains, an extremely large number of monuments have survived in almost every other part of India, particularly in the south, and these continue to be discovered and recorded to the present day.

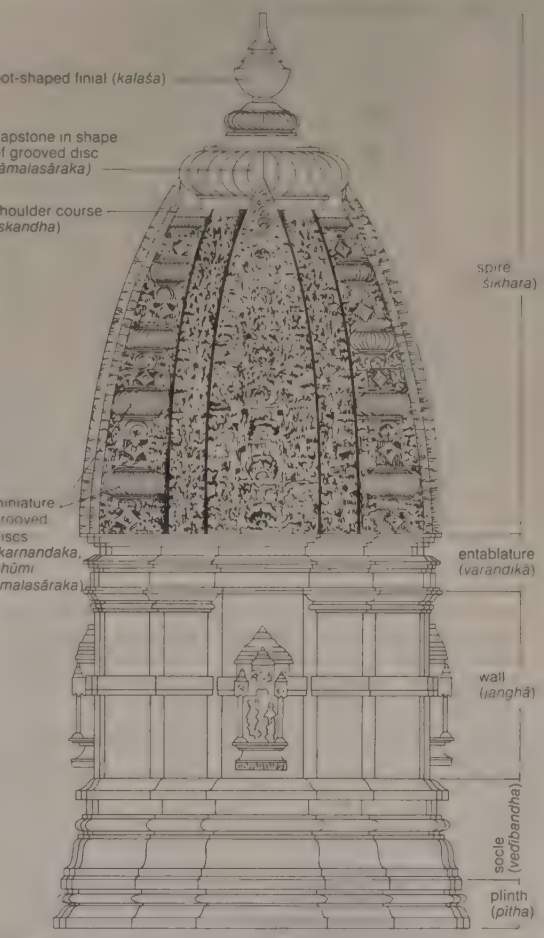
Medieval temple architecture: North Indian style. North Indian temples generally consist of a sanctum enshrining the main image, usually square in plan and shaped like a hollow cube, and one or more halls (called *maṇḍapas*), aligned along a horizontal axis. The sanctum may or may not have an ambulatory, but it is invariably dark, the only opening being the entrance door. The doorway surrounds are richly decorated with bands of figural, floral, and geometrical ornament and with river-goddess groups at the base. A vestibule (*antarāla*) connects the sanctum to the halls, which are of two broad types: the *gūḍhamaṇḍapas*, which are enclosed by walls, light and air let in through windows or doors; and open halls, which are provided with balustrades rather than walls and are consequently lighter and airier. The sanctum almost invariably, and the *maṇḍapas* generally, have *śikharas*; those on the sanctum, appropriately, are the most dominant in any grouping. Internally, the sanctum has a flat ceiling; the *śikhara* is solid theoretically, though hollow chambers to which there is no access must be left within its body to lessen the weight. The ceilings of the halls, supported by carved pillars, are coffered (decorated with sunken panels) and of extremely rich design.

The sanctum is often set on a raised base, or a plinth (*pīṭha*), above which is a foundation block, or socle (*vedībandha*), decorated with a distinct series of moldings; above the *vedībandha* rise the walls proper (*jaṅghā*), which are capped by a cornice or a series of cornice moldings (*varaṇḍikā*), above which rises the *śikhara.* One, three, and sometimes more projections extend all the way from the base of the temple up the walls to the top of the *śikhara.* The central offset (*bhadra*) is the largest and generally carries an image in a niche; the other projections (*rathas*), too, are often decorated with statuary.

The entire temple complex, including sanctum, halls, and attendant shrines, may be raised on a terrace (*jagatī*), which is sometimes of considerable height and size. The attendant shrines—generally four—are placed at the corners of the terrace, forming a *pañcāyatana,* or quincunx, arrangement that is fairly widespread. The temple complex may be surrounded by a wall with an arched doorway (*toraṇa*).

Śikhara types

The *śikhara* is the most distinctive part of the North Indian temple and provides the basis for the most useful and instructive classification. The two basic types are called *latina* and *phāmsanā.* Curvilinear in outline, the *latina*



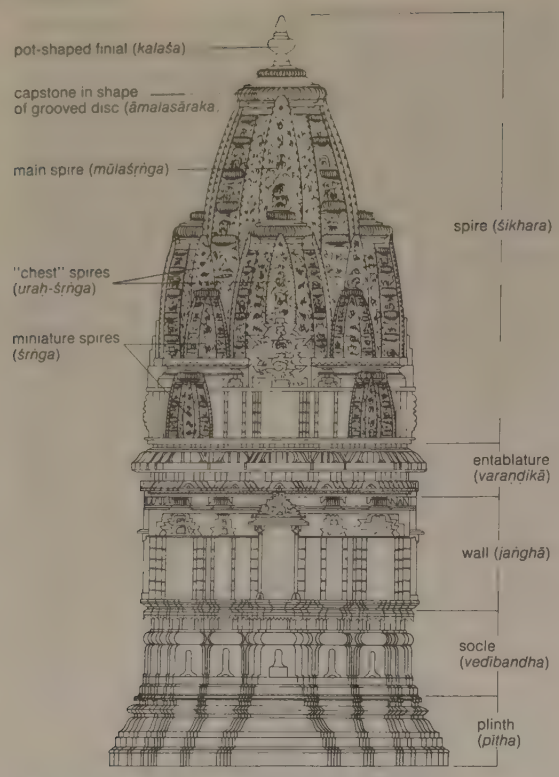
Elevation of a North Indian temple with the *latina* type of superstructure.

is composed of a series of superimposed horizontal roof slabs and has offsets called *latās.* The edges of the *śikhara* are interrupted at intervals with grooved discs, each one demarcating a "story." The surface of the entire *śikhara* is covered with a creeper-like tracery, or interlaced work, composed of diminutive ornamental *candraśālās.*

The *śikhara* is truncated at the top and capped by a shoulder course (*skandha*), above which is a circular necking (*grīvā*), carrying a large grooved disc called the *āmalasāraka.* On it rests a pot and a crowning finial (*kalaśa*).

Unlike the *latina,* the *phāmsanā śikhara* is rectilinear rather than curvilinear in outine, and it is lower in height. It is composed of horizontal slabs, like the *latina,* but is capped by a bell-shaped member called the *ghaṇṭā.* The surface of this type of *śikhara* may have projections, like the *latina śikhara,* and be adorned with a variety of architectural ornament.

From the 10th century onward, the *śekharī* type of spire, an elaboration of the *latina* type, became increasingly popular. In its developed form it consisted of a



Elevation of a North Indian temple with the *śekharī* type of superstructure.

central *latina* spire (*mūlaśṛṅga*) with one or more rows of half spires added on the sides (*uraḥ-śṛṅga*) and the base strung with miniature spires (*śṛṅgas*). The corners, too, are sometimes filled with quarter spires, the whole mass of carved masonry recalling a mountain with a cluster of subsidiary peaks.

The *latina* and *śekharī* spires are generally found on the sanctum, while the *phāmsanā* and its variants are usually confined to the *maṇḍapas*, or halls. The sanctum spires also have a large and prominent projection in front (*śukanāsā*), generally rising above the vestibule (*antarāla*). These projections are essentially large ogee arches of complex form, which often contain the image of the presiding deity.

A particularly rich and pleasing variety of North Indian *śikhara*, popular in Mālwa, western India, and northern Deccan, is the *bhūmija* type. It has a central projection on each of the four faces, the quadrants so formed filled with miniature spires in vertical and horizontal rows right up to the top.

The *bhūmija śikhara*

Although basically reflecting a homogeneous architectural style, temple architecture in northern India developed a number of distinct regional schools. A detailed elucidation of all has yet to be made, but among the most important are the styles of Orissa, central India, Rājasthān, and Gujarāt. The style of Kashmir is distinct from the rest of northern India in several respects, and hardly any examples of the great schools that flourished in modern Uttar Pradesh, Bihār, and Bengal are left standing. The North Indian style also extended for some time into the Karnataka (formerly Karṇāṭa) territory, situated in the southern Deccan, though the architecture of Tamil Nadu was relatively unaffected by it.

Medieval temple architecture: North Indian style of Orissa. The greatest centre of this school is the ancient city of Bhuvaneśvara, in which are concentrated almost 100 examples of the style, both great and small, ranging in date from the 7th to the 13th century. Among the earliest is the Paraśurāmeśvara temple (7th–8th century), with a heavy, stately *latina śikhara*, to which is attached a rectangular *gūḍhamaṇḍapa* with double sloping roofs. The walls are richly carved, but the interiors, as in almost all examples of the style, are left plain. The Mukteśvara temple (10th century), which has a hall with a *phāmsanā* roof, is the product of the most exquisite workmanship. The enclosing wall and the arched entrance, or *toraṇa*, are still present, giving a clear idea of a temple with all its parts fully preserved. The Brahmeśvara temple, which is dated on the basis of an inscription to the mid-10th century, is a *pañcāyatana*, with subsidiary shrines at all of the corners. The most magnificent building, however, is the great Liṅgarāja temple (11th century), an achievement of Orissan architecture in full flower. The *latina* spire soars to a considerable height (over 125 feet [40 metres]); the wall is divided into two horizontal rows, or registers, replete with statuary; and the

P Chandra

Mukteśvara temple at Bhubaneswar, Orissa, India, late 10th century AD.

attached hall is exquisitely and minutely carved. The most famous of all Orissan temples, however, is the colossal building at Konārak, dedicated to Sūrya, the sun god. The temple and its accompanying hall are conceived in the form of a great chariot drawn by horses. The *śikhara* over the sanctum has entirely collapsed; and all that survives are the ruins of the sanctum and the *gūḍhamaṇḍapa*, or enclosed hall, and also a separate dancing hall. Of these, the *gūḍhamaṇḍapa* is now the most conspicuous, its gigantic *phāmsanā śikhara* rising in three stages and adorned with colossal figures of musicians and dancers.

Because the Orissan style usually favours a *latina śikhara* over the sanctum, the *śekharī* spire of the Rājrānī temple (11th century) at Bhuvaneśvara (Bhubaneswar) is quite exceptional. Of particular interest as a late survival of early building traditions is the Vaitāl Deul (8th century), the sanctum of which is rectangular in plan, its *śikhara* imitating a pointed barrel vault. Besides Bhuvaneśvara, important groups of temples are to be found at Khiching and Mukhalingam.

Medieval temple architecture: North Indian style of central India. The area roughly covered by the modern state of Madhya Pradesh was the centre of several vigorous schools of architecture, of which at least four have been identified. The first flourished at Gwalior and adjacent areas (ancient Gopādrī); the second in modern Bundelkhand, known in ancient times as Jejākabhukti; the third in the eastern and southeastern parts in the ancient country of Ḍāhala, of which Tripurī, near modern Jabalpur, was the capital; and the fourth in the west, in an area bordering Gujarāt and Rājasthān in the fertile land of Mālava (Mālwa).

The Gwalior temples

The earliest examples in the Gwalior area are a group of small shrines at Naresar, a few miles from Gwalior proper; dating to the 8th century, the shrines have *latina* spires and sparsely ornamented walls. In the 9th century a series of magnificent temples was built, including the Mālā-de at Gyāraspur, the Śiva temples at Mahuā and Indore, and a temple dedicated to an unidentified mother goddess at Barwa-Sāgar. The period appears to have been one of experimentation, a variety of plans and spires having been tried. The Mālā-de temple is an early example of the *śekharī* type in its formative stages; the Indore temple has a star-shaped plan; and the Barwa-Sāgar example has a twin *latina* spire over a rectangular sanctum. The masonry work is of the finest quality and the architectural ornament is crisply carved. (The figural sculptures are few.) The temple at Umrī, with a *latina* spire, is small and exquisitely finished; but the largest and perhaps the finest temple is the Telī-kā-Mandir on Gwalior Fort, rectangular in plan and capped by a pointed barrel vault, recalling once again the survival of ancient roof forms. The walls are decorated with niches (empty at present) topped by tall pediments (triangular gable ornament).

The style of this region became increasingly elaborate from the 10th century, during the supremacy of the Kacchapaghāṭa dynasty. The many examples from this period are distinguished by a low plinth and rich sculptural decoration on the walls. Outstanding among them are the Kākan-maḍh at Suhāniā (1015–35) and the Sās-Bahū temple (completed 1093) in Gwalior Fort. The several temples at Surwāyā and Kadwāhā, though smaller in size, are distinguished for their extremely rich and elegant workmanship.

The style is best represented by a large group of temples at Khajurāho, the capital of the Candella dynasty, though examples are also to be found in Mahoba and at several other sites in the Jhānsi district of Uttar Pradesh, notably Chāndpur and Dudhai. All of the distinctive characteristics of the fully developed style can be seen in the Lakṣmaṇa temple at Khajurāho (dated 941), which is a *pañcāyatana* placed on a tall terrace enclosed by walls. The sanctum has an ambulatory and, facing it, a series of halls, including the *gūḍhamaṇḍapa*, a porch, and a small intermediate hall. Both the ambulatory and the *gūḍhamaṇḍapa* are provided with lateral, balconied arms, or transepts, which let in light and air. Each hall has its own pyramidal *śikhara*, all skillfully correlated to ascend gradually to the main *śekharī* spire over the sanctum. Extraordinary richness of carving, both in the interior and on the exterior,

The Lakṣmaṇa temple

Lakṣmaṇa temple at Khajurāho, Madhya Pradesh, India, *c.* AD 941.
P Chandra

where the walls carry as many as three rows of sculpture, and a skillful handling of the main spire to suggest ascent are distinguishing features of the style. The largest temple of the group, very similar to the Lakṣmaṇa, is the Kandāriyā Mahādeo; and among the most distinguished are the Viśvanātha and the Pārśvanātha temples. The Dūlādeo temple, which does not have an ambulatory, represents the closing phase of the group and probably belongs to the 12th century.

The earliest temples of the Ḍāhala area, dating from the 8th–9th century, are the simple shrines at Bāndhogarh, which consist of a sanctum with *latina* spire and porch. To the 10th century, when the local Kalacuri dynasty was rapidly gaining power, belong the remarkable Śiva temples at Chandrehe and Masaun, the former being circular in plan, with a *latina* spire covered with rich *candraśālā* tracery. The Golā Math at Maihar has the more conventional square sanctum, with a very elegant *latina śikhara*, the walls of which are adorned with two rows of figural sculpture. There must have existed at Gurgī a large number of temples, though all of them now are in total ruin. Judging from a colossal image of Śiva-Pārvatī and a huge entrance, which have somehow survived, the main temple must have been of very great size. Another important site is Amarkantak, where there are a large group of temples, the most important of which is the Karṇa. Although generally of the 11th century, they are quite simple, lacking the rich sculptural decoration so characteristic of the period. By contrast, the Virāṭeśvara temple at Sohāgpur, with an unusually tall and narrow *śekharī* spire, is covered with sculptural ornamentation as rich as that of Khajurāho.

The Mālava region, ruled largely by the Paramāra dynasty, appears to have been the first to develop the *bhūmija* type of *śikhara* (10th century). The finest and most representative group of these structures is at Un. Though, unfortunately, they are considerably damaged, judging from the remains, they must have been very elegant struc-

Temples of the Mālava area

tures. The best preserved and easily the finest *bhūmija* temple is the Udayeśvara (1059–82), situated at Udaipur in Madhya Pradesh. The *śikhara*, based on a stellate plan, is divided into quadrants by four *latās*, or offsets, each one of which has five rows of aediculae. The large hall has three entrance porches, one to the front and two to the sides, and walls that are richly carved. The whole complex, including seven subsidiary shrines, is placed on a broad, tall platform. The Siddheśvara temple at Nemāwar (early 12th century) is even larger than the Udayeśvara, though the proportions are not as well balanced and the quality of the carving is inferior. Structures in the *bhūmija* manner continued to be made in Mālava up to the 15th century; the Malvai temple at Alīrājpur is a good example of the late phase.

From Mālava, the *bhūmija* style spread to the neighbouring regions. To the north in Rājasthān, the Mahānāleśvara temple at Menāl (*c.* 11th century), the Sun temple at Jhālrapātan (11th century), the Śiva temple at Rāmgarh (12th century), and the Uṇḍeśvara temple (12th century) at Bījoliān are important examples. To the west, in Gujarāt, are temples at Limkheda and Sarnāl of the 11th and 12th centuries. The style was particularly favoured in Mahārāshtra, to the south. Among surviving examples, the most impressive is the Ambarnāth temple near Bombay (11th century); Balsāṇe and Sinnar also have pleasing temples. The style continued up to the 16th century, many examples having been found in north Deccan and Berār. The *bhūmija* style also spread to the east of Mālava; the Bhāṇḍ Dewal at Arang (11th century), for example, is a Ḍāhala adaptation.

Medieval temple architecture: North Indian style of Rājasthān. A group of temples at Osiān, dating to about the 8th century, represents adequately the opening phases of medieval temple architecture in Rājasthān. They stand on high terraces and consist of a sanctum, a hall, and a porch. The sanctum is generally square and has a *latina* spire. The walls, with one central and two subsidiary projections, are decorated with sculpture, often placed in niches with tall pediments. The halls are generally of the open variety, provided with balustrades rather than walls, so that the interiors are well lit. The surrounds of the doorway sanctum are quite elaborate, with four or five bands of decoration and the usual river-goddess groups at the base. The pillars, with *ghaṭa-pallava* (vase-and-foliage) capitals, are also decorated, richness of sculpture and architectural elaboration being a characteristic of this group of monuments. The Mahāvīra temple, which is the largest, belongs to the 8th century, though renovated in later times, when the *toraṇa* (gateway) and the *śikhara* were added. Other important temples are Harihara Nos. 1, 2, and 3 and two temples dedicated to Vishnu. The ruined Harshat Mātā temple at Ābānerī, of a slightly later date (*c.* 800), was erected on three stepped terraces of great size and is remarkable for the exquisite quality of the carving. Some of the finest temples of the style date from the 10th century, the most important of which are the Ghaṭeśvara temple at Bāḍolī and the Ambikā Mātā temple at Jagat. The simple but beautiful Bāḍolī temple consists of a sanctum with a *latina* superstructure and an open hall with six pillars and two pilasters (columns that project a third of their width or less from the wall) supporting a *phāmsanā* spire. Only the central projections of the sanctum walls are decorated with niches containing sculpture. A large open hall was built in front of the temple at a later date. The Ambikā-Mātā temple at Jagat, of the mid-10th century, is exceptionally fine. It consists of a sanctum, a *gūḍhamaṇḍapa*, or enclosed hall, and a parapeted porch with projecting eaves. The walls of the sanctum and the hall are covered with fine sculpture, the superstructures being of the *śekharī* and the *phāmsanā* types.

Growing resemblance between styles of Rājasthān and Gujarāt

Temples, too numerous to mention, dating from the 10th and—to an even greater extent—the 11th century onward, are found throughout Rājasthān. The styles of Rājasthān and neighbouring Gujarāt during these centuries grew closer and closer together until the differences between them were gradually obliterated. This coalescence resulted in the emergence of a composite style found throughout Gujarāt and Rājasthān. Temples situated in the two areas are discussed separately here, but this is for the sake of convenience and does not signify any real stylistic difference.

The temples at Kirāḍu in Rājasthān, dating from the late 10th and 11th centuries, are early examples of the style shared by Rājasthān and Gujarāt. The Someśvara temple (*c.* 1020) is the most important and clearly shows the movement toward increasing elaboration and ornamentation. Each of the constituent parts became more complex; the moldings of the plinth, for example, are multiplied to include bands of elephants, horses, and soldiers. The walls are covered with sculpture, and the spire is of the rich *śekharī* type. Situated in Rājasthān, but again in the composite style, are the extraordinarily sumptuous temples known as the Vimala Vasahī (1031) and the Lūṇa Vasahī (1230) at Mt. Ābū. The Vimala Vasahī consists of a sanctum, a *gūḍhamaṇḍapa*, and a magnificent assembly hall added in mid-12th century. The plain, uncarved exterior walls of the rectangular enclosure of the temple have on the inside rows of cells containing images of divinities. The interiors are very richly carved, the coffered ceilings loaded with a wealth of detail. The Lūṇa Vasahī is even more elaborate, though the quality of the work had begun to decline perceptibly.

Traditional architecture continued even after the Islāmic invasions, particularly during the reign of Rāṇā Kumbhā of Mewār (*c.* 1430–69). During this period, the tall nine-storied Kīrttistambha and other temples at Chitor and also the great Chaumukha temple at Ranakpur (1438) were built.

Medieval temple architecture: North Indian style of Gujarāt. Gujarāt was the home of one of the richest regional styles of northern India. A temple at Gop (*c.* 600), with a tall terrace and a cylindrical sanctum with high walls capped by a *phāmsanā* roof, and other temples in Saurāshṭra show the formative phases of the style. Its distinctive features are clear in an interesting group of temples from Roḍā (*c.* 8th century). The sanctum is square in plan and has *latina* spires that are weighty and majestic. The walls are relatively plain, with niches, housing images, provided only on the central projection. The masonry work is exceptionally good, a characteristic of Gujarāt architecture throughout its history. The Rāṇakdevī temple at Wadhwān, of the early 10th century, is also characterized by plain walls and a *latina* spire, while the Śiva temple at Kerākoṭ has a *śekharī* spire and also a *gūḍhamaṇḍapa*. The great Sun Temple at Modhera, datable to the early years of the 11th century, represents a fully developed Gujarāt style of great magnificence. The temple consists of a sanctum (now in ruins), a *gūḍhamaṇḍapa*, an open hall of extraordinary richness, and an arched entrance in front of which was the great tank. The Navalakhā temple at Sejakpur continued this tradition. The Rudramāla at Siddhapur, the most magnificent temple of the 12th century, is now in a much ruined condition, with only the *toraṇa* (gateway) and some subsidiary structures remaining. Successively damaged and rebuilt, the Somanātha at Prabhāsa Patan was the most famous temple of Gujarāt, its best known structure dating from the time of Kumārapāla (mid-12th century). It has been now dismantled, but a great temple built at the site in recent years testifies to the survival of ancient traditions in modern Gujarāt.

The temple at Gop

The hills of Satrunjaya and Girnār house veritable temple cities. Most of the shrines, which are of late date, are picturesque but otherwise of little significance. With the Islāmic conquest, the Gujarāt architect adapted his considerable skills to meet the needs of a patron of different religion and quickly produced a totally successful Indian version of Islāmic architecture.

Medieval temple architecture: North Indian style of Karnataka. The North Indian style was largely confined to India above the Vindhyas, though for a short period it also flourished in a region of southern India known as Karnataka from ancient times and now largely part of Karnataka (formerly Mysore) state. Here, temples of the northern and the southern styles are found next to each other, notably at Aihole and Pattadkal. The earliest appears to be the Lāḍh Khān at Aihole, closely related

to the 5th-century temple at Nāchnā Kutharā in northern India. The northern style was also cultivated at Pattadkal, where the most important examples are the Kāśīviśvanātha, the Galaganātha, and the Pāpanātha. Ālampur, now in Andhra Pradesh, has eight temples of the northern style with *latina* spires. These belong to the late 7th and early 8th centuries and are the finest and among the last examples of the northern style in southern India.

Distinct architectural style of Kashmir

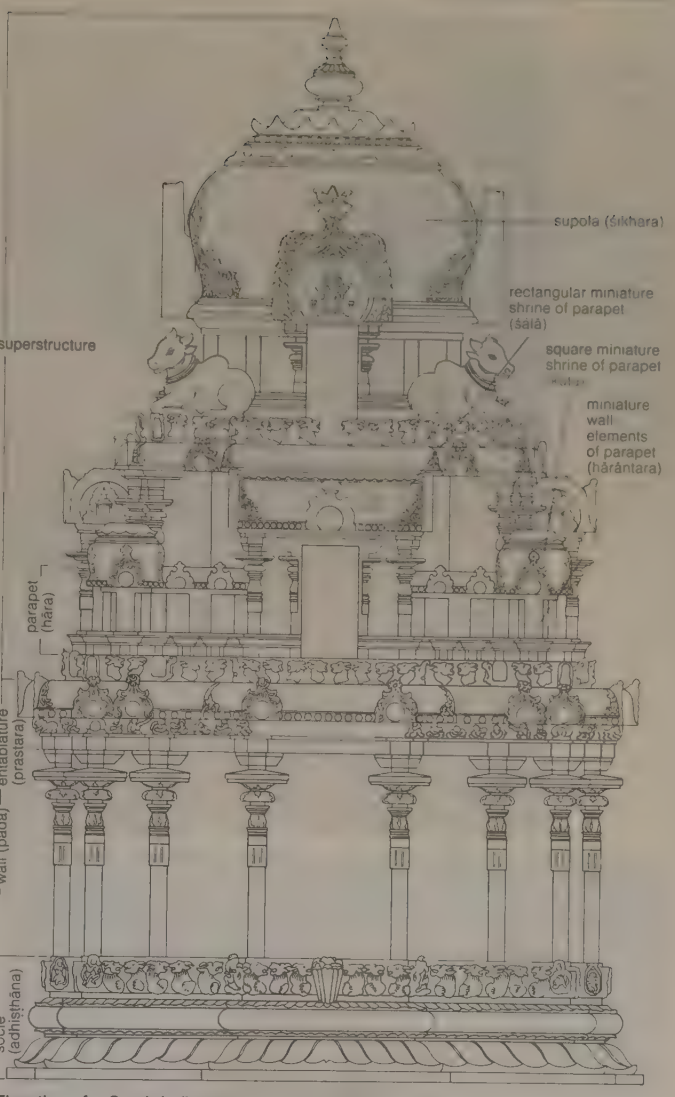
Medieval temple architecture: North Indian style of Kashmir. The architectural style of the Kashmir region is quite distinct: unlike other regions, in which the sanctum usually has a *latina* or *śekharī* spire, the roof of the Kashmir sanctum is of the *phāmsanā* type, with eaves raised in two stages. The greatest example to survive is the ruined Sun Temple at Mārtaṇḍ (mid-8th century), which, though its *śikhara* is missing, gives a good idea of the characteristic features of the style. The temple is placed in a rectangular court enclosed by a series of columns. Access to the court is through an imposing entrance hall, the walls of which have doorways with gabled pediments and a trefoil (shaped like a trifoliate leaf) recess. The Avantisvāmī temple of the mid-9th century, now quite ruined, must have been similar, though much more richly ornamented. The style continued up to the 12th century; the Rilhaṇeśvara temple at Pāndreṇthan is a comparatively well-preserved example of this period.

Medieval temple architecture: South Indian style. The home of the South Indian style, sometimes called the drāviḍa style, appears to be the modern state of Tamil Nadu; examples, however, are found all over southern India, particularly in the adjoining regions of Karnataka and Andhradeśa, now largely covered by the states of Karnataka and Andhra Pradesh. Both Andhradeśa and Karnataka developed variants, particularly Karnataka, which evolved a distinct manner, basically South Indian but with features of North Indian origin. The Karnatic style extended northward into Mahārāshtra, where the Kailāsa temple at Ellora is the most famous example.

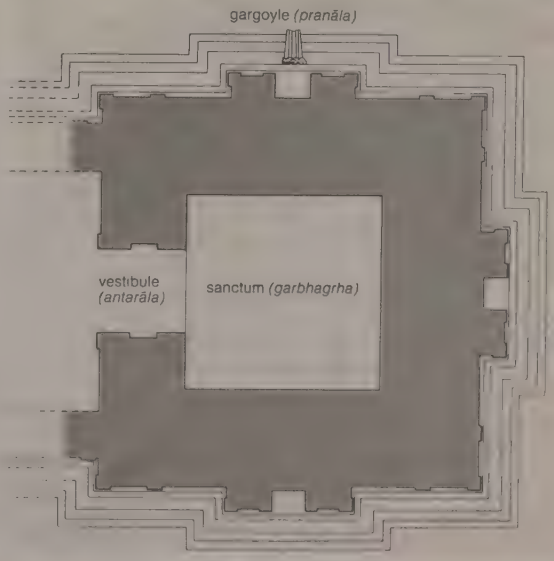
A typical South Indian temple consists of a hall and a square sanctum that has a superstructure of the *kūṭina* type. Pyramidal in form, the *kūṭina* spire consists of stepped stories, each of which simulates the main story and is conceived as having its own "wall" enclosed by a parapet. The parapet itself is composed of miniature shrines strung together: square ones (called *kūṭa*s) at the corners and rectangular ones with barrel-vault roofs (called *śālā*s) in the centre, the space between them connected by miniature wall elements called *hārāntara*s. (Conspicuous in the early temples, these stepped stories of the superstructure with their parapets became more and more ornamental, so that in the course of time they evolved into more or less decorative bands around the pyramidal superstructure.) On top of the stepped structure is a necking that supports a solid dome, or cupola (instead of the North Indian grooved disc), which in turn is crowned by a pot and finial. The walls of the sanctum rise above a series of moldings, constituting the foundation block, or socle (*adhiṣṭhāna*), that differ from North Indian temples; and the surface of the walls does not have the prominent offsets seen in North Indian temples but is instead divided by pilasters. In the Karnatic version, particularly from the late 10th century onward (sometimes called the *vesara* style), this arrangement of the superstructure is loaded with decoration, thus considerably obscuring the component elements. At the same time, these elements—particularly the central offset with its subsidiaries that carry *candraśālā* motifs—are so manipulated that they tend to form distinct vertical bands, in this respect closely recalling the *śikhara*s of northern India.

The design of the hall-temple roofed by a barrel vault, popular in the centuries before and after Christ, was adopted in southern India for the great entrance buildings, or *gopura*s, that give access to the sacred enclosures in which the temples stand. Relatively small and inconspicuous in the early examples, they had, by the mid-12th century, outstripped the main temple in size.

Medieval temple architecture: South Indian style of Tamil Nadu (7th–18th century). The early phase, which, broadly speaking, coincided with the political supremacy of the Pallava dynasty (*c.* 650–893), is best represented by the important monuments at Mahābalipuram. Besides a fine group of small cave temples (early 7th century), among the earliest examples of their type in southern India, there are



Elevation of a South Indian temple with the *kūṭina* type of superstructure.



Plan of the sanctum of a South Indian temple.

The Shore Temple

here several monolithic temples carved out of the rock, the largest of which is the massive three-storied Dharmarājaratha (*c.* 650). The finest temple at this site and of this period is an elegant complex of three shrines called the Shore Temple (*c.* 700), not cut out of rock but built of stone. The Tālapuriśvara temple at Panamalai is another excellent example. The capital city of Kānchipuram also possesses some fine temples—for example, the Kailāsanātha (dating a little later than the Shore Temple), with its stately superstructure and subsidiary shrines attached to the walls. The enclosure wall has a series of small shrines on all sides and a small *gopura*. Another splendid temple at Kānchipuram is the Vaikuṇtha Perumāl (mid-8th century), which has an interesting arrangement of three sanctums, one above the other, encased within the body of the superstructure.

The 9th century marked a fresh movement in the South Indian style, revealed in several small, simple, but most elegant temples set up during the ascendancy of the Cōḷa and other contemporary dynasties. Most important of a large number of unpretentious and beautiful shrines that dot the Tamil countryside are the Vijayālaya Cōḷīśvara temple at Nārttāmalai (mid-9th century), with its circular sanctum, spherical cupola, and massive, plain walls; the twin shrines called Agastyīśvara and Cōḷīśvara, at Kīḻaiyūr (late 9th century); and the splendid group of two temples (originally three) known as the Mūvarkovil, at Koḍumbāḷūr (*c.* 875).

These simple beginnings led rapidly (in about a century) to the mightiest of all temples in the South Indian style, the Bṛhadīśvara, or Rājarājeśvara, temple, built at the Cōḷa capital of Thanjāvūr. A royal dedication of Rājarāja I, the temple was begun around 1003 and completed about seven years later. The main walls are raised in two stories, above which the superstructure rises to a height of 190 feet (60 metres). It has 16 stories, each of which consists of a wall with a parapet of shrines carved in relatively low relief. The great temple at Gaṅgaikoṇḍacōḷapuram, built (1030–40) by the Cōḷa king Rājendra I, is somewhat smaller than the Bṛhadīśvara; but the constituent elements of its superstructure, whose outline is concave, are carved in bolder relief, giving the whole a rather emphatic plasticity. The Airāvateśvara (1146–73) and Kampahareśvara (1178–1223) temples at Dārāsuram and Tribhuvanam follow the tradition of the 11th century but are smaller and considerably more ornate. They bring to a close a great phase of South Indian architecture extending from the 11th to the 13th century.

P Chandra

Mūvarkovil at Koḍumbāḷūr, Tamil Nadu, India, *c.* AD 875.

From the middle of the 12th century onward, the *gopuras*, or entrance buildings, to temple enclosures began to be greatly emphasized. They are extremely large and elaborately decorated with sculpture, quite dominating the architectural ensemble. Their construction is similar to that of the main temple except that they are rectangular in plan and capped by a barrel vault rather than a cupola, and only the base is of stone, the superstructure being made of brick and plaster. Among the finest examples are the Sundara Pāndya *gopura* (13th century) of the Jambukeśvara temple at Tiruchchirāppalli and the *gopuras* of a great Śiva temple at Chidambaram, built largely in the 12th–13th century. Even larger *gopuras*, if not of such fine quality, continued to be built up to the 17th century. Such great emphasis was placed on the construction of *gopuras* that enclosure walls, which were not really necessary, were especially built to justify their erection. In the course of time several walls and *gopuras* were successively built, each enclosing the other so that at the present day one often has to pass through a succession of walls with their *gopuras* before reaching the main shrine. A particularly interesting example is the Ranganātha temple at Srīrangam, which has seven enclosure walls and numerous *gopuras*, halls, and temples constructed in the course of several centuries. The *gopuras* of the Mīnākṣī temple at Madurai are also good representative examples of this period.

In addition to the *gopuras*, temples also continued to be built. Although they never achieved colossal size, they are often of very fine workmanship. The Subrahmaṇya temple of the 17th century, built in the compound of the Bṛhadīśvara temple at Thanjāvūr, indicates the vitality of architectural traditions even at this late date.

Rock-cut cave temples of South India

Medieval temple architecture: South Indian style of Karnataka. The early phase, as in Tamil Nadu, opens with the rock-cut cave temples. Of the elaborate and richly sculptured group at Bādāmi, one cave temple is dated 578, and two cave temples at Aihole are early 8th century. Among structural temples built during the rule of the Cālukyas of Bādāmi are examples in the North Indian style; but, because the Karnataka region was more receptive to southern influences, there are a large number of examples that are basically South Indian with only a few North Indian elements. The Durgā temple (*c.* 7th century) at Aihole is apsidal in plan, echoing early architectural traditions; the northern *latina śikhara* is in all probability a later addition. The Mālegitti Śivālaya temple at Bādāmi (early 8th century), consisting of a sanctum, a hall with a parapet of *śālās* and *kūṭas* (rectangular and square miniature shrines), and an open porch, is similar to examples in Tamil Nadu. The Virūpākṣa at Pattadkal (*c.* 733–746) is the most imposing and elaborate temple in the South Indian manner. It is placed within an enclosure, to which access is through a *gopura;* and the superstructure, consisting of four stories, has a projection in the front, a feature inspired by the prominent projections, or *śukanāsā,* of North Indian temples. Belonging to the 9th century is the triple shrine (the three sanctums sharing the same *maṇḍapa,* or hall) at Kambaḍahalli and the extremely refined and elaborately carved Bhoganandīśvara temple at Nandi. The Chāvuṇḍarāyabasti (*c.* 982–995) at Śravaṇa-Beḷgoḷa is also an impressive building, with an elegant superstructure of three stories.

With the 10th century, the Karnatic idiom begins to show an increasing individuality that culminates in the distinctive style of the 12th century and later. The Kalleśvara temple at Kukkanūr (late 10th century) and a large

Jaina temple at Lakkundi (*c.* 1050–1100) clearly demonstrate the transition. The superstructures, though basically of the South Indian type, have offsets and recesses that tend to emphasize a vertical, upward movement. The Lakkundi temple is also the first to be built of chloritic schist, which is the favoured material of the later period and which lends itself easily to elaborate sculptural ornamentation. With the Mahādevā temple at Ittagi (*c.* 1112) the transition is complete, the extremely rich and profuse decoration characteristic of this shrine being found in all work that follows. Dating from the reign of the Hoysaḷa dynasty (*c.* 1141) is a twin Hoysaḷeśvara temple at Halebīd, the capital city. The sanctums are stellate in form but lack their original superstructures. The pillars of the interior are lathe-turned in a variety of fanciful shapes. The exterior is almost totally covered with sculpture, the walls carrying the usual complement of images; the base, or socle, is decorated with several bands of ornamental motifs and a narrative relief. Among other temples that were constructed in this style, the most important are the Chenna Keśava temple at Belūr (1117), the Amṛteśvara temple at Amritpur (1196), and the Keśava temple at Somnāthpur (1268).

Strong traditions of cave architecture in Mahārāshtra

Medieval temple architecture: South Indian style of Mahārāshtra, Andhradeśa, and Kerala. The traditions of cave architecture are stronger in Mahārāshtra than in any other part of India; there, great shrines were cut out of rock right up to the 9th century AD and even later. Of those belonging to the early phase, the most remarkable is a temple at Elephanta (early 6th century); equally impressive are numerous temples at Ellora (6th–9th centuries). The Karnatic version of the South Indian style extended northward into Mahārāshtra, where the Kailāsa temple at Ellora, erected in the reign of the Rāṣṭrakūṭā Krishna I (8th century), is its most stupendous achievement. The entire temple is carved out of rock and is over 100 feet (30 metres) high. It is placed in a courtyard, the three sides of which are carved with cells filled with images; the front wall has an entrance *gopura*. The tall base, or plinth, is decorated with groups of large elephants and griffins, and the superstructure rises in four stories. Groups of important temples in the southern style are also found in the Andhra country, notably at Biccavolu, ranging in date from the 9th to the 11th centuries. The 13th-century temples at Palampet are the counterparts of the elaborate Karnatic style of the same period, but without its overpowering elaboration. The temples of Kerala represent an adaptation of the South Indian style to the great main fall of this region and are provided with heavy sloping roofs of stone that imitate timber originals required for draining away the water.

Islāmic architecture in India: period of the Delhi and provincial sultanates. Although the province of Sind was captured by the Arabs as early as 712, the earliest examples of Islāmic architecture to survive in the subcontinent date from the closing years of the 12th century; they are located at Delhi, the main seat of Muslim power throughout the centuries. The Qūwat-ul-Islām mosque (completed 1196), consisting of cloisters around a courtyard with the sanctuary to the west, was built from the remains of demolished temples. In 1198 an arched facade (*maqṣūrah*) was built in front to give the building an Islāmic aspect, but its rich floral decoration and corbelled (supported by brackets projecting from the wall) arches are Indian in character. The Quṭb Mīnār, a tall (288 feet high), fluted tower provided with balconies, stood outside this mosque. The Aṛhāi-dīn-

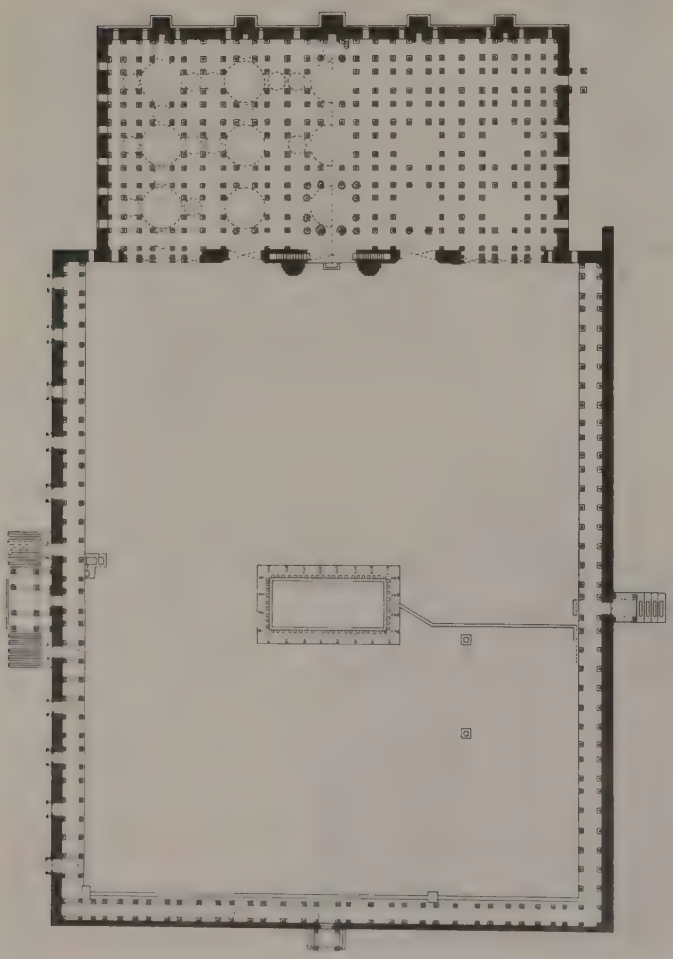
kā-jhompṛā mosque (*c.* 1119), built at Ajmer, was similar to the Delhi mosque, the *maqṣūrah* consisting of engrailed (sides ornamented with several arcs) corbel arches decorated with greater restraint than the Quṭb example. The earliest Islāmic tomb to survive is the Sultān Gharī, built in 1231, but the finest is the tomb of Iltutmish, who ruled from 1211 to 1236. The interior, covered with Arabic inscriptions, in its richness displays a strong Indian quality. The first use of the true arch in India is found in the ruined tomb of Balban (died 1287). From 1296 to 1316 ʿAlāʾ-ud-Dīn Khaljī attempted to expand the Qūwat-ul-Islām mosque, which already had been enlarged in 1230, to three times its size; but he was unable to complete the work. All that has survived of it is the Alai Darwāzah, a beautiful entrance.

14th-century style impoverished and austere

In contrast to this early phase, the style of the 14th century at Delhi, ushered in by the Tughluq dynasty, is impoverished and austere. The buildings, with a few exceptions, are made of coarse rubble masonry and overlaid with plaster. The tomb of Ghiyās-ud-Dīn Tughluq (*c.* 1320–25), placed in a little fortress, has sloping walls faced with panels of stone and marble. Also to be ascribed to his reign is the magnificent tomb of Shāh Rukn-e ʿĀlam at Multān in Pakistan, which is built of brick and faced with exquisite tile work. The Koṭla Fīrūz Shāh (1354–70), with its mosques, palaces, and tombs, is now in ruins but represents the major building activity of Fīrūz Shāh, who took a great interest in architecture. Many mosques and tombs of this period and of the 15th century are found in Delhi and its environs; the most notable of them are the Begampur and Khiṛkī mosques and an octagonal tomb of Khān-e Jahān Tilangānī. In the early 16th century, Shēr Shāh Sūr refined upon this style, the Qalʿah-e Kuhnah Masjid and his tomb at Sasarām (*c.* 1540) being the finest of a series of distinguished works that were created during his reign.



Plan of the Jāmiʿ Masjid, Ahmadābād, Gujarāt.

The provinces, which gradually became independent sultanates, did not lag behind in architectural activity. In West Bengal, at Pandua, is the immense Ādīna Masjid (1364–69), which utilized remains of Indian temples. In Jaunpur, Uttar Pradesh, are a group of elegant mosques, notably the Aṭalā Masjid (1377–1408) and the Jāmiʿ Masjid (*c.* 1458–79), characterized by *maqṣūrah*s that have the aspect of imposing gateways. The sultans of Mālwa built elegant structures at Māndu and at Chanderi in the middle of the 15th century. The sultanate of Gujarāt is notable for its great contribution to Islāmic architecture in India. The style, which is basically indigenous, reinterprets foreign influences with great resourcefulness and confidence, producing works notable for their integrity and unity. The city of Ahmadābād (Ahmedabad) is full of elegant buildings; the Jāmiʿ Masjid (*c.* 1424), for example, is a masterly exposition of the style. Fine examples dating from the second half of the 15th century are the small but exquisite mosques of Muḥāfiz Khān (1492) and Rānī Sabraʾi (1514) at Ahmadābād and the handsome Jāmiʿ Masjid at the city of Chāmpāner.

The Deccan was another great centre, but in contrast to Gujarāt it took little from the indigenous building traditions. Among the earliest works is the Jāmiʿ Masjid at Gulbarga (1367), with its extraordinary cloisters consisting of wide arches on low piers, producing a most solemn effect. The city of Bīdar possesses many remains, including a remarkable series of 12 tombs, the most elaborate of which is that of ʿAlā-ud-Dīn Aḥmad Bahmanī (died 1457), which has extremely fine decorations in coloured tile. Some of the finest examples of Islāmic architecture in the Deccan, however, are in Bijāpur. The most important buildings of this city are the great Jāmiʿ Masjid (begun in 1558) with its superb arched cloisters; the ornate Ibrāhīm Rawẓa; and the Gōl Gunbad (built by Muḥammad ʿĀdil Shāh), a tomb of exceptional size and grandeur, with one of the largest domes in existence.

The Hindu kingdoms that managed to retain varying degrees of independence during the period of Islāmic supremacy also produced important works. These structures naturally bore the imprint of what survived of traditional Indian architecture to a greater extent than did those monuments patronized by Muslims. Among the Hindu structures of this period are the extensive series of palaces, all in ruin, built by Rāṇā Kumbhā (*c.* 1430–69) at Chitor, and the superb Mān Mandir palace at Gwalior (1486–1516), a rich and magnificent work that exerted considerable influence on the development of Mughal architecture at Fatehpur Sīkrī.

Striking revival of Islāmic architecture

Islāmic architecture in India: Mughal style. The advent of the Mughal dynasty marks a striking revival of Islāmic architecture in northern India: Persian, Indian, and the various provincial styles were successfully fused to produce works of unusual refinement and quality. The tomb of Humāyūn, begun in 1564, inaugurates the new style. Built entirely of red sandstone and marble, it shows considerable Persian influence. The great fort at Āgra (1565–74) and the city of Fatehpur Sīkri (1569–74) represent the building activities of the emperor Akbar. The former has the massive so-called Delhi gate (1566) and lengthy and immense walls carefully designed and faced with dressed stone throughout. The most important achievements, however, are to be found at Fatehpur Sīkri; the Jāmiʿ Masjid (1571), with the colossal gateway known as the Buland Darwāza, for example, is one of the finest mosques of the Mughal period. Other notable buildings include the palace of Jodhā Bāī, which has a strongly indigenous aspect; the exquisitely carved Turkish Sultānā's house; the Pānch-Maḥal; the Dīvān-e ʿĀmm; and the so-called hall of private audience. Most of the buildings are of post and lintel construction, arches being used very sparingly. The tomb of the emperor, at Sikandarā, near Āgra, is of unique design, in the shape of a truncated square pyramid 340 feet (103 metres) on each side. It consists of five terraces, four of red sandstone and the uppermost of white marble. Begun about 1602, it was completed in 1613, during the reign of Akbar's son Jahāngīr. Architectural undertakings in this emperor's reign were not very ambitious, but there are fine buildings,

Tomb of 'Isā Khān at Delhi, 1547.
P Chandra

chiefly at Lahore. The tomb of his father-in-law I'timād-ud-Dawla, at Āgra, is small but of exquisite workmanship, built entirely of delicately inlaid marble. The reign of Shāh Jahān (1628–58) is as remarkable for its architectural achievements as was that of Akbar. He built the great Red Fort at Delhi (1639–48), with its dazzling hall of public audience, the flat roof of which rests on rows of columns and pointed, or cusped, arches, and the Jāmi' Masjid (1650–56), which is among the finest mosques in India. But it is the Tāj Mahal (*c.* 1632–*c.* 1649), built as a tomb for Queen Mumtāz Maḥal, that is the greatest masterpiece of his reign. All the resources of the empire were put into its construction. In addition to the mausoleum proper, the complex included a wide variety of accessory buildings of great beauty. The marble mausoleum rises up from a tall terrace (at the four corners of which are elegant towers, or minārs) and is crowned by a graceful dome.

P Chandra

Buildings at Fatehpur Sīkri, Uttar Pradesh, India, *c.* 1571.

Other notable buildings of the reign of Shāh Jahān include the Motī Masjid (*c.* 1648–55) and the Jāmi' Masjid at Āgra (1548–55).

Architectural monuments of the reign of Aurangzeb

Architectural monuments of the reign of Aurangzeb represent a distinct decline; the tomb of Rābī'ah Begam at Aurangābād, for example (1679), is a poor copy of the Tāj Mahal. The royal mosque at Lahore (1673–74) is of much better quality, retaining the grandeur and dignity of earlier work; and the Motī Masjid at Delhi (1659–60) possesses much of the early refinement and delicacy. The tomb of Ṣafdar Jang at Delhi (*c.* 1754) was among the last important works to be produced under the Mughal dynasty and had already lost the coherence and balance characteristic of mature Mughal architecture.

European traditions and the modern period. Buildings imitating contemporary styles of European architecture, often mixed with a strong provincial flavour, were known in India from at least the 16th century. Some of this work was of considerable merit, particularly the baroque architecture of the Portuguese colony of Goa, where splendid buildings were erected in the second half of the 16th century. Among the most famous of these structures to survive is the church of Bom Jesus, which was begun in 1594 and completed in 1605.

The 18th and 19th centuries witnessed the erection of several buildings deeply indebted to Neoclassic styles; these buildings were imitated by Indian patrons, particularly in areas under European rule or influence. Subsequently, attempts were made by the British, with varying degrees of success, to engraft the neo-Gothic and also the neo-Saracenic styles onto Indian architectural tradition. At the same time, buildings in the great Indian metropolises came under increasing European influence; the resulting hybrid styles gradually found their way into cities in the interior. In recent years an attempt has been made to grapple with the problems of climate and function, particularly in connection with urban development. The influence of the Swiss architect Le Corbusier, who worked on the great Chandigarh project, involving the construction of a new capital for Punjab, in the early 1950s, and that of other American and European masters has brought about a modern architectural movement of great vitality, which is in the process of adapting itself to local requirements and traditions.

Sculpture. On the Indian subcontinent, sculpture seems to have been the favoured medium of artistic expression. Even architecture and the little painting that has survived from the early periods partake of the nature of sculpture. Particularly is this true of rock-cut architecture, which is

Church of Bom Jesus at Velha Goa, India, 1594–1605.
P. Chandra

often little more than sculpture on a colossal scale. Structural buildings are also profusely adorned with sculpture that is often inseparable from it. The close relationship between architecture and sculpture has to be taken into account when considering individual works that, even if complete in themselves, are also fragments belonging to a larger context. Indian sculpture, particularly from the 10th century onward, thus cannot be studied in isolation but must be considered as part of a larger entity to the total effect of which it contributes and from which it in turn gains meaning.

The subject matter of Indian sculpture is almost invariably religious. This does not mean that it cannot be understood as a work of art apart from its religious significance; but, at the same time, an understanding of its motivation and intent enriches one's appreciation. Much of what is represented is the recounting of legend and myth, particularly in the two centuries before Christ, when narrative relief was much in vogue. The work at this time, didactic and edificatory in intent, generally expresses itself in forms that are surprisingly earthy and sensuous. The anthropomorphic representation of the Buddha is avoided, and the subsidiary gods and goddesses are very much creatures of this earth. The Buddha image formulated around the 1st century AD is not what one would expect of the meditative, compassionate, Master of the Law; he is presented rather as an energetic, earthy being radiating strength and power.

Buddhist influences

The foundations of traditional Hindu imagery were also laid about the same time that the Buddha image was first formulated: images with several arms, and sometimes heads, representing the Indian mind's attempt to define visually the infiniteness of divinity. In subsequent periods the image with many arms became a commonplace in Hindu, Buddhist, and Jaina iconography. Although the various pantheons expanded, they continued to share features of common derivation, expressing the belief that beyond the phenomenal multiplicity of forms lay the unity of the Godhead.

In addition to the major religions, there has always existed in India a substratum of folk beliefs and cults dedicated to the worship of powers that preside over the operation of the life processes of nature. These fertility cults, best expressed in the worship of the male and female divinities *yakṣas* and *yakṣīs*, played an important part in the development of Indian art. Among the perennial motifs that spring from the cults, those expressing life and

abundance—such as the lotus, the pot overflowing with vegetation, water, or the like, the tree, the amorous couple, and above all the *yakṣas* and *yakṣīs* themselves—are most significant. The images of these divinities, in particular, are the source of a great deal of artistic imagery and played a leading part in the development of iconographic types such as the images of the Buddha, the goddess Śrī, and other divinities. The maternal as the ideal of female beauty, which is manifested artistically in the emphasis on full breasts and wide hips, can be traced to the same beliefs. The very richness and exuberance of much Indian art is an expression of the view of life that equates beauty with abundance.

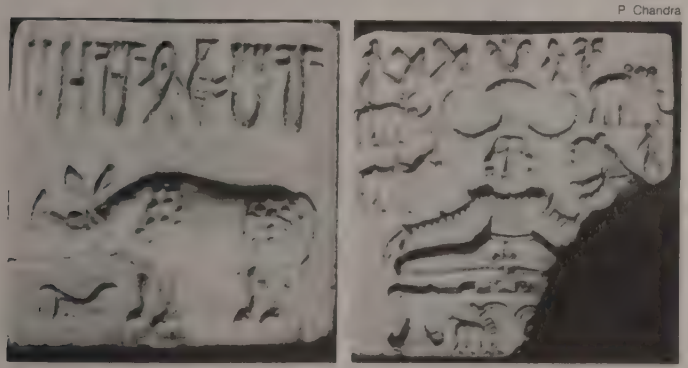
It is difficult to generalize about the style of a sculptural tradition that extended over a period of almost 5,000 years, but it is nevertheless clear that the distinguishing quality of Indian sculpture is its emphatic plasticity so obvious in Sānchi I and Mathurā sculpture from the 1st–3rd century AD. Forms are seen as swelling from within in response to the power of an inner life, the sculptor's function being to make these more manifest. At the same time a vision of form that is carved from without rather than modelled from within is also present, as for example at Bhārhut. The history of much of Indian sculpture, marked by periods of high achievement bursting with creativity followed by periods in which the potentialities so postulated are gradually worked out, is essentially the interaction of these two dominant tendencies.

Indus Valley civilization (c. 2500–1800 BC). Sculpture found in excavated cities consists of small pieces, generally terra-cotta objects, soapstone, or steatite, seals carved for the most part with animals, and a few statuettes of stone and bronze. The terra-cotta figurines are summarily modelled and provided with elaborate jewelry, which was fashioned separately and applied to the surface of the piece. Most of the work is simple, but a small group of human heads with horns are very sensitively modelled. Animal figures are common, particularly bulls, which are often carved with a sure understanding of their bulky, massive form. This plastic quality is also found in the humped bulls engraved on steatite seals, where the modelling is more refined and sensitive. A humpless beast, generally called a "unicorn," is another favourite animal, but it is frequently quite stylized. In addition to bisons, elephants, rhinoceroses, and tigers, seals are carved with images of apparent religious significance, often strongly pictographic.

Terra-cotta sculpture and seals

The terra-cotta sculpture and the seals both show two clear and distinct stylistic trends, one plastic and sensuous, the other linear and abstract. These appear during the same period and are also seen in the small group of stone and bronze sculptures that date from this period (National Museum, New Delhi). Of extraordinarily full and refined modelling is a fragmentary torso from Harappā, barely four inches (10 centimetres) high but of imposing monumentality; the same feeling for massive form is present in a lesser known bronze buffalo. A jaunty bronze dancing girl with head tilted upward (about 4½ inches [11 centimetres] high), from Mohenjo-daro, and a headless figure of a male dancer from Harappā, shoulders twisted in a circular movement, clearly demonstrate, in the attenuated and wiry tension of their forms, the second component of Indus Valley art. Of great interest is a famous bearded figure from Mohenjo-daro wearing a robe decorated with a pattern composed of trefoil motifs. The tight, compressed shape of the body and the expansive modelling of the head demonstrate that the two aspects of form revealed in Indus Valley art were not compartmentalized but interacted with each other. This can also be seen in the interplay of modelled form and textured surface frequently found in works produced by this civilization.

P. Chandra



Steatite seals of the Indus Valley civilization (c. 2300–c. 1750 BC). In the National Museum of India, New Delhi.

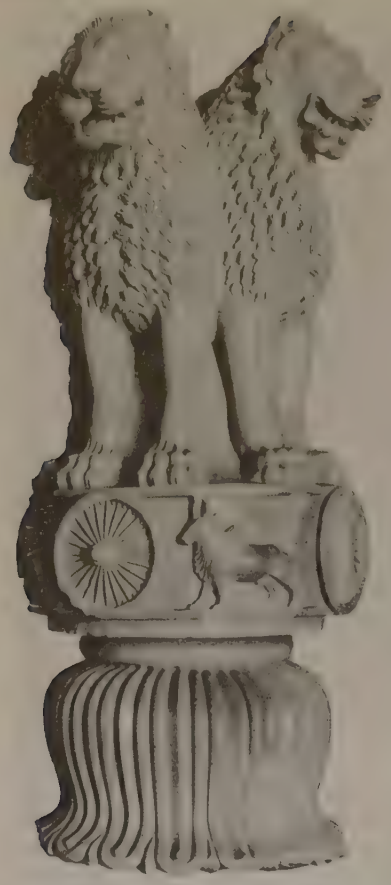
Maurya period (c. 3rd century BC). Little is known of Indian art in the period between the Indus Valley civilization and the reign of the Maurya emperor Aśoka. When sculpture again began to be found, it was remarkable for its maturity, seemingly fully formed at birth. The most famous examples are great circular stone pillars, products of Aśoka's imperial workshop, found over an area stretching from the neighbourhood of Delhi to Bihār. Made of fine-grained sandstone quarried at Chunār near Vārānasi (Benares), the monolithic shafts taper gently toward the top. They are without a base and, in the better preserved examples, are capped by campaniform lotus capitals supporting an animal emblem. The entire pillar was carefully burnished to a bright lustre commonly called the "Maurya polish." The most famous of these monuments is the lion capital at Sārnāth, consisting of the front half of four identical animals joined back to back. There is a naturalistic emphasis on build and musculature, and the modelling is hard, vigorous, and energetic, stressing physical strength and power. Very similar, if not at the same level of achievement, is the quadruple lion capital at Sānchi. Single lions are found at Vaiśālī (Bakhra), Rāmpurvā, and Lauriya Nandangarh. The Vaiśālī pillar is heavy and squat, and the animal lacks the verve of the other animals—features, according to some, designating it as an early work, executed before the Maurya style attained its maturity. By contrast, the Rāmpurvā lion, finished with painstaking and concise artistry, represents the style at its best. His smooth, muscled contours, wiry sinews, rippling, flamboyant mane, and alert stance reveal the work of a superior artist. An example at Lauriya Nandangarh is interesting because the pillar and the lion are both complete and in their original place, giving a clear idea of the column as it appeared to its contemporaries.

The Rāmpurvā lion

The lion was the animal most often represented, but figures of elephants and bulls are also known. At Dhauli in Orissa, the fore part of an elephant is carved out of rock on a terrace above a boulder that carries several of Aśoka's edicts. The modelling here is soft and gentle, and the plump, fleshy qualities of the young animal's body, seen as emerging from the rock, are suffused with warmth and natural vitality. Since the contrast with the rather formal, heraldic lions could not be more complete, the sculpture clearly testifies to the simultaneous existence of a style different from that of the lion capitals. The style might very well represent the indigenous tradition of plastic form that appears consistently in later art and also in some of the animal capitals made in the imperial atelier, notably the damaged elephant that once crowned the pillar at Saṅkisa and, above all, the splendid bull from Rāmpurvā. In this great work of art, the two opposing concepts of form merge in a work of harmonious power. The pronounced naturalism comes from the same source as do the lions, but the tense line and hard modelling yield to a form that wells from within and at the same time is given stability and strength by a vision imposed from without.

The sudden appearance of Maurya art with seemingly no tradition behind it has led to speculation that it was the creation of foreign artists, either Achaemenian or Hellenistic. Persian influence, particularly in the lotus capitals and the figures of lions can hardly be denied, but what is remarkable is the drastic reinterpretation of alien forms by Indian artists. This is a process that is repeatedly seen in the history of Indian art.

Besides the animal sculpture, some human figures, more or less life size, can also be assigned to the Maurya period, though scholarly opinion is by no means unanimous on the point. Among the most important are three images discovered at Patna (ancient Pāṭaliputra, the Maurya



Lion capital from Sārnāth, Uttar Pradesh, India, Chunār sandstone, mid-3rd century BC. Height 2.13 m.
P. Chandra

capital), two of which are representations of *yakṣa*s, the popular male divinities associated with cults of fertility, and the third, found at Dīdarganj (a section of Patna), a representation of a *yakṣī*, or female divinity. Stylistically the images are very similar. The standing *yakṣa*s (Indian Museum, Calcutta) are powerful creatures; the ponderous weight of their bodies, together with a certain refined appreciation of the soft flesh, is admirably rendered. The Dīdarganj *yakṣī* (Patna Museum), a masterpiece, displays the Indian ideal of female beauty, the heavy hips and full breasts strongly emphasizing the maternal aspect. In a nude torso discovered at Lopanipur, the sophisticated and sensitive treatment of the surfaces and the gentle blending planes that avoid all harsh accents produce a work of much refinement.

Small stone discs

Small stone discs (also called ring stones because several of them are perforated in the centre), found from Taxila to Patna, are clearly connected with the cult of a nude mother goddess. They represent Maurya sculpture on a smaller and more intimate scale but characterized by the same refined and exquisite workmanship. They are executed in bas-relief, which became the favourite form of sculpture in the subsequent period.

The terra-cotta art of the Maurya period is best represented by a substantial group of figurines, modelled for the most part, the clay sculptor performing work in his medium at the same level as the artist working in stone. Patna has yielded a large number of such works, but examples are found throughout the Gangetic Plain. The clothing and jewelry on the figurines are heavy and elaborate, the modelling, particularly of the head, is sensitive, and the expression is often one of great charm and refinement. There are also more archaic examples, distinguished by flat bodies, enormous hips, and modelled heads and breasts.

Indian sculpture in the 2nd and 1st centuries BC. The Maurya Empire collapsed in the early years of the 2nd century BC, and with it passed the art with which it was intimately related. The sculpture that is found throughout India from the middle of the 2nd century BC is startlingly different, but the process by which this change took place in a relatively short period of time is not fully understood. Several schools, sharing common features but nevertheless possessing distinct individual characteristics, are known to have existed. The history of the schools of northern India is somewhat obscure, largely due to the great destruction wrought in the Gangetic heartland; but there appears to have flourished there and in adjacent areas a school of great importance represented by the remains discovered at Bhārhut, Sānchi, Mathurā, and Buddh Gaya. Western India had its own school, as revealed in the sculptures decorating the cave temples, notably those of Bhājā, Pītalkhorā, and Kārli. In the southeast, the important school of Andhradeśa flourished in the Krishna River Valley at Amāravatī, Jaggayyapeta, and associated sites; and in eastern India, what is now the modern state of Orissa, made its contribution in the rock-cut sculptures at Udayagiri-Khandagiri. The distinctive schools, though spread over a subcontinent, were not isolated from each other. The contacts fostered by a flourishing trade and by the constant movement of pilgrims were always very close, and it was never long before developments in one part of India were echoed in another.

Judging from extant remains, artists of the earlier period (*c.* 3rd century BC) preferred figures carved in the round, relief sculpture being quantitatively quite insignificant. By contrast, it was sculpture in low relief that was favoured in the first two centuries before Christ; the earlier tradition was not quite forgotten, but figures carved in the round are relatively few. Although there is no stylistic difference, relief sculpture is here considered first according to the various regional schools, and sculpture in the round is treated separately.

Indian sculpture in the 2nd and 1st centuries BC: relief sculpture of northern and central India. Among the most important, and perhaps the earliest, remains in northern India are reliefs from the great *stūpa* at Bhārhut, dating approximately to the middle of the 2nd century BC. The work, suggesting a style imitating wooden sculpture, is characterized by essentially cubical forms, flat planes that meet at sharp angles, and very elaborate and precisely detailed ornamentation of surfaces. Most of the sculpture was confined to the railing of the *stūpa*. Some of the supporting posts bear large image of *yakṣa*s and *yakṣī*s of popular religion, now clearly pressed into the service of Buddhism, while most of the others are decorated with medallions in the centre and crescent-shaped motifs, or lunates, at the top and bottom, all filled with

Reliefs from the *stūpa* at Bhārhut

P. Chandra

lotus motifs. Some medallions contain amorous couples, the overflowing pot, the goddess Śrī standing on lotuses while being ceremonially bathed by elephants and other symbols of abundance; still others contain the earliest illustrations of events in the Buddha's life and of narratives of his former incarnations as related in the *Jātaka* tales (a collection of tales about the Buddha). Although compositions are crowded, great economy of expression is evident because the artist confines himself to the representation of essentials. Figures are often carved in horizontal rows, sometimes asymmetrically, adapting themselves awkwardly to the circular space of the medallion. Continuous narrative, in which events succeeding in time are shown in the same space, is often resorted to—the first occurrence of what was to become a favourite narrative technique. There is no attempt at establishing any interrelationship, psychological or compositional, between the various figures, each of which is strictly confined within its own space. The faces are masklike, without trace of emotion, lending a solemn and hieratic quality to their expression. Trapped between the background and a frontal plane beyond which they are not allowed to project, the figures are in a sense strictly two-dimensional, more so than in any other style of Indian sculpture. Often, however—particularly in the treatment of animals—the artist is more relaxed, giving glimpses of intimate observation and a natural rendering that anticipates the direction of future development. Like the posts, the top part, or coping, of the stone rail is also carved on both faces; on one of them is a continuous creeper bearing lotus flowers, leaves, and buds; on the other, again the winding stem of a creeper, but bearing other good things of life—such as clothes, jewelry, and fruits—and also scenes illustrating *Jātaka* stories.

Bhārhut is an extremely important monument inasmuch as it seems to mark a new beginning after the refined and naturalistic art of the Maurya Empire. The sophistication, in spite of the archaic, hieratic manner, would indicate that a considerable body of sculptural tradition, particularly in wood, preceded it; but of this no traces have survived. Be that as it may, Bhārhut states for the first time, and at some length, themes and motifs that would henceforth remain a part of Indian sculpture.

Stray finds of sculpture at Mathurā and other sites in modern Uttar Pradesh indicate that the Bhārhut style was spread over a large part of northern India, particularly the region roughly between that city and Vārānasi and Buddh Gaya in the east. A closely related style is also found at Sānchi in eastern Mālava, where a representative example is the sculpture of the railing of Stūpa II. Although the themes and motifs found at Bhārhut occur here, narrative representations are all but absent. The style is almost identical; the stiff and rigid contours are a little softer, but both the scale and richness of Bhārhut are missing.

Principal glory of Sānchi

It is the sculpture of the four gateways (*toraṇas*) of the Great Stūpa (Stūpa I) at Sānchi, however, that is the principal glory of that site, carrying the promise of the Bhārhut style to its fulfillment. The *toraṇas*, four in number, were attached to the plain railing around the middle of the 1st century BC. They consist of square posts with capitals supporting a triple architrave, or molded band, with voluted (turned in the shape of a spiral, scroll-shaped ornament) ends and a top crowned with Buddhist symbols. Bracket figures, in the form of *yakṣīs*, serve as additional supports. All parts of these gates, strongly reminiscent of wooden construction, are covered from top to bottom with the most exquisite sculpture. Subjects and motifs found at Bhārhut are also found here, the same profusely flowering lotus stem and associated motifs, the same compositions with figures basically arranged in horizontal rows, the same love for clear detail; but to all of these are added a truly voluminous sense of form, a smoother and more energetic movement, and a keen appreciation for the forms of nature, all of which endow the sculpture with a naïve and sensuous beauty unparalleled in Indian art.

Departures from the Bhārhut style are particularly striking in the narrative reliefs. Their greater depth, taken together with their crowded composition, results in the background, visible at Bhārhut, being submerged in shadow. The figures, in all their richness and abundance, flow out from the dark ground, secured in place by the frame of the panels. The Bhārhut angular silhouette and the rigid, severe outline of the body yields at Sānchi to a gently swelling plasticity, animated by a soft, breathing quality that molds the contours without strain or tension. There is a pronounced concern with the organization of composition, and the narration is often leisurely and discursive; the artist does not just tell the basic story but also lingers over the details, amplifying them to give a vivid picture of everyday life. The emotional monotone of Bhārhut survives in some Sānchi sculptures, but in others it is superseded by joyous faces and the emotional impact of vivid gesture and movement. Dejection is written large on the faces of the soldiers of Māra's army, who had tried to disturb the Buddha's meditation, as they stagger away from the scene of defeat, and the sensuousness of the amorous scenes is successfully evoked by the tender and intimate gestures of the couples. No longer transfixed in their own space, they turn to look at each other lovingly, responding to each other with a deeply felt understanding.

Long and elaborate bas-reliefs carved on the architraves of the *toraṇas* are the summit of the Sānchi sculptor's art. Among the finest are representations of the wars for the relics, the defeat of Māra, the *Viśvāntara Jātaka*, and the *Ṣaḍḍanta Jātaka*. The compositions are rich and crowded with figures, and are arranged with great skill. Particularly striking is the masterly handling of animals, notably the elephant, whose fleshy body and graceful movement are captured unerringly. Deer, water buffaloes, bulls, monkeys—all of the beasts and birds of the forests—are rendered with a sense of intimacy indicating the artist's sense of the fellowship of man and animal in the world of nature. The lush Indian landscape is often carved with ornamental trees, waterfalls, pools, mountains, and rivers. The Sānchi sculptor also shows a marked preference for architectural settings, filling his compositions with numerous buildings that often provide the spatial context for the action. Entire cities, with surrounding walls, elaborate gate houses, and palatial mansions, are depicted. Depth is achieved by rendering side views, and multiple perspective continues to be the rule.

Images of *yakṣīs*

The several large images of *yakṣīs* serving as brackets supporting the lowermost architraves of the *toraṇas* are unique achievements. Like the same goddesses at Bhārhut, they are shown in association with a tree to which they cling, but the style is remarkably different. The modelling shows a concern for the charms of the body, stressing the tactile nature of its flesh. The heavy jewelry and clothing that conceal the body are drastically reduced, revealing its nudity. The soft, melting sensuousness of the female form is so greatly emphasized that the belly and the folds of flesh at the waist are almost flabby, redeemed only by the smooth, firm breasts and the tender arms and limbs.

By comparison, reliefs adorning the railing around the Mahābodhi temple at Buddh Gaya (of about the same date or a little earlier) are in a somewhat impoverished idiom, lacking the rich proliferation both of Bhārhut and Sānchi. The posts have the usual medallions, lunates filled with lotuses, and reliefs depicting the familiar scenes of Buddhist myth and legend. The artistry of Buddh Gaya, however, is of a lower level of achievement than that at either Bhārhut or Sānchi: the relief is deeper than that at Bhārhut but shallower than that at the Great Stūpa of Sānchi; and crowded compositions are lacking, as are the clear and precise ornament and the rich floral motifs. The Buddh Gaya sculptor, however, though abbreviating even further the iconography of Bhārhut, breaks up, as does the Sānchi sculptor, the spatial isolation that so uncompromisingly separated each individual figure at that site.

The great school of Mathurā, also, seems to have come into existence about the 2nd century BC, though its period of greatest activity falls in the first two centuries after Christ. The city was repeatedly sacked in the course of the centuries, which may account for the paucity of materials, but enough has been discovered to reveal that the style, in its early stages, was very similar to that of Bhārhut, characterized by flat two-dimensional sculpture decorated with abundant and precise ornament. Several fragments

discovered at the site show the gradual stages by which this style evolved, leading to the sculpture of the Great Stūpa at Sānchi on the one hand and to Buddh Gaya on the other.

Indian sculpture in the 2nd and 1st centuries BC: relief sculpture of Andhradeśa. Besides the schools of northern India, a very accomplished style also existed in southeast India; the most important sites are Jaggayyapeta and Amarāvatī, activity at the latter site extending well into the 2nd century AD. The early remains are strikingly similar to those at Bhārhut, the relief generally even shallower and the modelling comparatively flat. In contrast to those found in northern India, the proportions of the human body are elongated; but in its flat, cubical modelling, angular, halting contours, and precise, detailed ornamentation, the style is essentially similar to contemporary work elsewhere, right down to the same conventional clothing and jewelry. The nervous, fluid treatment of surfaces, so characteristic of subsequent Andhra sculpture, is already present here. The preferred material is marble rather than the sandstone invariably used in the north.

The style of the Andhradeśa school developed in a manner consistent with other regions of India, becoming more voluminous and shedding the early rigidity fairly rapidly. A group of sculptures at Amarāvatī are characterized by the same qualities that distinguish the work at the Great Stūpa of Sānchi: full and lissome forms, modelling that emphasizes mass and weight, and sensuously rendered surfaces.

Rock-cut cave temples of the Western Ghāts

Indian sculpture in the 2nd and 1st centuries BC: relief sculpture of western India. The numerous rock-cut cave temples in the Western Ghāts are, comparatively speaking, much less profusely adorned with sculpture than remains from other parts of India. The earliest works are undoubtedly the bas-reliefs on a side wall of the porch of a small monastery at Bhājā. They are commonly interpreted as depicting the god Indra on his elephant and the sun god Sūrya on his chariot but are more probably illustrations of the adventures of the mythical universal emperor Māndhātā. What is immediately evident is that these sculptures are not imitations of wooden prototypes, like those at Bhārhut, but, rather, reflect a tradition of terra-cotta sculpture, abundant examples of which are found in northern India and Bengal, where this medium was very popular because of the easy availability of fine clay. The terra-cotta tradition is reflected in the amorphous, spreading forms of Bhājā and in the fine striations used in depicting ornaments and pleated cloth, techniques natural and appropriate to the fashioning of wet clay. The fact that there are some similarities to the Bhārhut style—the stilted postures of the figures and the flat contours of the body, for example—indicates that the beginnings of the western Indian school would also have to be placed about the middle of the 2nd century BC.

The next major group of sculptures in western India have been found at Pītalkhorā. The colossal plinth of a monastery decorated with a row of elephants, the large figures of the door guardians, and several fragments recovered during the course of excavations are among the more important remains. A great proportion of the work represents an advance over the style of Bhājā, though features derived from terra-cotta sculpture continue to be found: the figures are carved in greater depth and volume, but the texture of the drapery, the soft contours of the body, and the high relief of the jewelry, which sometimes gives the impression of having been fashioned separately and then applied, testify to the continuing strength of the terra-cotta tradition. Although the hard line and sharp cutting of some sculpture is reminiscent of the earlier, wood-carving tradition as seen at Bhārhut, the forms are more appropriate to the stone medium. Moreover, the expression is more explicit; and for the first time, both gently smiling and boldly laughing figures of *yakṣa*s appear, as well as the figure of a lover blissfully drunk on wine offered to him by his beloved. These features are also found in the later sculpture of the Great Stūpa at Sānchi and, to a more pronounced extent, in the sculpture of the Mathurā school of the 1st centuries AD—for example, in the happily smiling *yakṣī*s from Bhutesar.

The cave temple at Kondane has, above the entrance hall, four beautiful panels depicting pairs of dancers. The forms retain the robust and full modelling of the more developed sculpture at Pītalkhorā, but to this is added an ease of movement and considerable rhythmic grace. Traces of the terra-cotta tradition are now totally absent; nor do they occur in the next phase, best represented by a group of sculptures found in the rock-cut temples and monasteries at Bedsā and Nāsik and in the *caitya*, or temple proper, at Kārli. Sculpture at all these sites shows

P Chandra

many affinities to the Great Stūpa at Sānchi and should be approximately contemporary or a little earlier. Easily the most outstanding achievements of this region and period, and for that matter one of the greatest achievements of the Indian sculptor, are the large panels, depicting amorous couples, located in the entrance porch of the Kārli *caitya*. Here the promise of early work achieves its fulfillment, the full weighty forms imbued with a warm, joyous life and a free, assured movement. The resemblance to work at the Great Stūpa of Sānchi is obvious, though these figures at Kārli are on a much larger scale and possess a massiveness and monumentality that is a characteristic of the distinct western Indian idiom.

Sculpture decorating rock-cut monasteries

Indian sculpture in the 2nd and 1st centuries BC: relief sculpture of Orissa. Sculpture decorating the monasteries cut into the twin hills of Udayagiri and Khandagiri in Orissa represents yet another early Indian local idiom. The work is not of one period but extends over the first two centuries before Christ; the stages of development roughly parallel the styles observed at Sānchi Stūpa No. II, Buddh Gaya, and the Great Stūpa at Sānchi, but they possess, like other regional schools, fairly distinct and individual features. The earliest sculptures are the few simple reliefs found in the Alakāpurī cave, humble works that recall the bas-reliefs of Sānchi Stūpa II. The Mañcapurī, Tatowā Gumphā, and Anantā cave sculptures—particularly the image of Sūrya riding a chariot—are more advanced and resemble work at Buddh Gaya. The forms are heavy and solid and lack the accomplished movement of the later cave sculpture adorning the Rānī Gumphā monastery.

These, like other sculptures here, are in a poor state of preservation, but they represent the finest achievements at the site. Most remarkable is a long frieze, stretching between the arched doorways of the top story, representing a series of incidents that have not yet been identified. The work parallels that of the Great Stūpa at Sānchi, with the same supple modelling and crowded compositions. At the same time there is a nervous agitation, a fluid, agile movement together with a decided preference for tall, slender human figures. The reliefs on the guard rooms of Rānī Gumphā are also quite remarkable, depicting forested landscapes filled with rocks from which waterfalls flow into lakes that are the sporting grounds of wild elephants. The fine work of this cave strikes a romantic and lyrical note seldom found in Indian art.

Indian sculpture in the 2nd and 1st centuries BC: sculpture in the round and terra-cotta. The most important sculpture in the round are the life-size or colossal images of *yakṣa*s and *yakṣī*s, which reinterpret forms established by the two Patna *yakṣa*s and the Dīdarganj *yakṣī* of the Maurya period—very much as a few animal capitals, particularly the *makaras* (a crocodile-like creature) from Kauśāmbī and Vidiśā (Besnagar), echo the tradition of the superb Maurya animal capitals. It is the *yakṣa* figures, however, that deserve special attention, for they played a significant part in the iconographic developments of the 1st century AD and later and contributed substantially to the imagery of the anthropomorphic Buddha icon.

The most famous of the *yakṣa* images is a colossal figure recovered from the village of Pārkham, near Mathurā (Archaeological Museum). It is about $8^2/_3$ feet (2.6 metres) in height, and, though the two hands are broken and the head is considerably damaged, it is an image of great strength. Its squat neck, its head set close to the body, which tends toward corpulence, its swelling belly restrained by a flat band, and a broad chest adorned with necklaces—all of these features contribute to an image turgid with earthy power. The back is flat and cursively finished, so that the figure has the appearance more of a bifacial relief than of an image carved in the round. Although the forms retain some of the cubical modelling of Bhārhut, the swelling limbs and torso have a massive weightiness that makes the image an appropriate representation of a divinity that presides over the productive processes of nature and endows plenty and abundance on his worshippers.

Mathurā *yakṣa* images

The Mathurā region seems to have been an important centre of *yakṣa* worship, for several images, most of them fragmentary, have been discovered there. Some images have also been found from the ancient city of Vidiśā (Vidisha Museum), one of which is even larger than the Pārkham example and is in a better state of preservation. The god holds a bag in one hand (the other was held below the chest), and the hair is tied in a large top knot over the forehead. The image is accompanied by a female consort (*yakṣī*), wide-hipped and full-breasted, who also emphasizes and personifies the powers of fertility.

The widespread nature of the cult is evidenced by the occurrence of *yakṣa* images throughout India. Fragments in the round (not to speak of the relief representations in a Buddhist context) of the 2nd to 1st centuries BC have been found from Madhyadeśa, Orissa, Rājasthān, Andhradeśa, and Mahārāshtra. At Pītalkhorā there is an exceptionally fine image of a *yakṣa* conceived as a potbellied dwarf carrying a shallow bowl on his head; the features, with a gently laughing mouth, are suffused with good humour. Similar *yakṣa*s, employed as atlantes (male figures used as supporting elements), are also found on the western gateway of the Great Stūpa at Sānchi and at other sites, notably Sārnāth.

The latest in the series of cult images is the image of the Yakṣa Maṇibhadra, from Pawāyā (Gwalior Museum). The sculpture is at present headless, but the rest of the body is well preserved. The right hand holds a fly whisk that flares over the shoulder; the modelling of the legs and torso is sensitive, and the folds of the garment wrapped around the body are full and voluminous, recalling the style of sculpture at Sānchi.

The terra-cotta sculpture of the period consists mainly of relief plaques made from molds found at numerous sites in northern India. These generally depict popular divinities; a richly dressed female figure loaded with profuse jewelry, obviously a mother goddess, is the favoured subject. Scenes from daily life also abound—as well as what appear to be illustrations of current myths and stories. Superb examples have been found from Mathurā, Ahichhatrā, Kauśāmbī, Tāmlūk, and Chandraketugarh. The workmanship is often of the most exquisite clarity and delicacy, the style paralleling that of contemporary stone sculpture.

Indian sculpture from the 1st to 4th centuries AD. This period is characterized by the dominance in northern India of the ancient school of Mathurā. Other schools, such as those that flourished at Sārnāth and Sānchi in the first two centuries before Christ, for example, were markedly restricted in their artistic output. Much of their sculpture was imported from Mathurā, and the few images they produced locally were strongly influenced by Mathurā work. The narrative bas-relief tradition, consisting of elaborate compositions of edificatory character, was on the wane, and the emphasis was on carving individual figures, either in high relief or in the round. For the first time, images appear of the Buddha, *bodhisattva*s, and various other divinities including specifically Hindu images representing the gods Vishnu, Śiva, Varāha, and Devī slaying the buffalo demon; some of these figures begin to feature several arms, a characteristic of later iconography. There are also many images of *yakṣī*s, often in most alluring attitudes and gestures. Their enticing bodies are now presented as unified organic entities, lacking all traces of the stiff, puppet-like aspect that had not been entirely overcome even at the Great Stūpa of Sānchi. During this period, also, a

fresh incursion of foreign influence by way of western Asia was received, quickly assimilated, and transformed in the characteristic manner of Indian art.

The school of Gandhāra

The school of Gandhāra, with Taxila in Pakistan as its centre and stretching into eastern Afghanistan, flourished alongside the Kushān school of Mathurā. It is of a startlingly different aspect, stressing a relatively naturalistic rendering of form, ultimately of Greco-Roman origin. The school evolved a distinct type of Buddha image and was also rich in relief sculptures depicting Buddhist myth and legend. Drawing largely on Indian traditions of composition, it nevertheless reinterpreted them in its own manner. The schools of Mathurā and Gandhāra were in close proximity and undoubtedly influenced each other, but essentially each adheres to its own concept of style.

The ancient Indian relief style found its fullest expression and development at neither Mathurā nor Gandhāra but in Andhradeśa, notably at the great sites of Amarāvatī and Nāgārjunikoṇḍa. Railing pillars and other parts of *stūpa*s decorated with *Jātaka* tales and scenes from the Buddha's life are found in great number and are of the most exquisite quality. Free-standing images of the Buddha, on the other hand, are relatively rare, being found only toward the close of the period.

Indian sculpture from the 1st to 4th centuries AD: Mathurā. One of the most important contributions of the school of Mathurā was the development of the cult image of the Buddha, who had been previously represented by aniconic (not made as a likeness) symbols. There is a certain amount of controversy about whether Mathurā or Gandhāra originated the Buddha image, which appears to be insoluble in view of the circumstantial nature of the evidence. It is possible that the two schools independently developed their own separate types of images; but, at least as far as the Mathurā image is concerned, it is clear that it is a natural development from the tradition of large *yakṣa* sculptures found in this region. The development can easily be seen in a famous image (discovered at Sārnāth and now in the Sārnāth Museum) of Mathurā manufactured and dedicated by the monk Bala. Carved in the round, the image is shown in a pose of strict frontality, the left hand held at the waist and the right arm, now damaged, originally raised to the shoulder—a posture immediately recalling that of the *yakṣa* images. The jewelry, however, is appropriately omitted, and the body is clothed in simple monastic garments. The modelling throughout is strong and sensuous, and the radiant energy of the body, its affirmative, outgoing movement, is more appropriate to the personality of a *yakṣa* than to that of the Buddha. This standing Buddha image, as seen in the Bala statue, is the standard Mathurā type, several examples of which are known. Along with this one, a similar, seated type developed, of which the best example is the splendid image known as the Kaṭra Buddha (Archaeological Museum). The modelling of the body is refined, the breasts characteristically heavy and prominent, and the flesh of the torso, with its subtle modulations, as convincingly rendered as the Bala image.

Stone tablets

The new trends formulated early by the Mathurā school do not indicate a sharp break from the traditions of the earlier schools. This is clear in a series of magnificent *āyāgapaṭas,* or stone tablets originally set up outside *stūpa*s to receive worship and offerings. They are usually square or rectangular and richly decorated with auspicious and religious symbols as well as angelic and mythical beings. The extremely decorative, lavish surface treatment gives the immediate impression of a great profusion of multiple forms, akin in feeling to the sculpture of the Great Stūpa of Sānchi. The organization of these forms, however, has none of the easy freedom of Sānchi. The figures, for example, are often cast in a regular, winding shape imitating the movement of the undulating lotus creeper. The same movement is seen in rows of animals depicted with haunches raised and chests touching the ground, features seen in earlier art but now much more emphatically stylized. The bodies of the animals also begin to be overpowered by vegetal forms, the tails, for example, terminating in foliate tips; in a later age, this tendency results in the almost total disintegration of animal shapes under the pressure of the floral.

It is not to these bas-reliefs, however, that one turns for the most delightful creations of the Mathurā school (for they are in fact the last vestiges of a style rapidly passing out of favour) but to the large number of railing pillars usually carved with representation of *yakṣī*s engaged in playful and enticing activities such as plucking blossoms from trees or leaning on its branches, dancing, bathing under a waterfall, and adorning themselves. Among the most beautiful of these is a group that was recovered from Kaṅkālī Ṭīlā and now in the State Museum at Lucknow. The modelling of the figures is generally heavy, the soft, plump bodies suffused with a slow, languorous movement. What is important, however, is the emotion, which is no longer expressed in the face alone but in the whole attitude of the body. The pensive mood of a woman holding a lamp, for instance, is evoked not only by the serene features of the face but by the gentle sway of the relaxed body. Present throughout is a fresh movement of life, a marked striving for diverse and varied effects of posture, movement, expression, and even dress and ornament that brings about vital changes in the nature of Indian sculpture. A remarkable group of railing posts decorated with *yakṣī* images, which were recovered from Bhūtēsar near Mathurā (Archaeological Museum), represent an even more refined achievement than the Kaṅkālī Ṭīlā figures. The heavy proportions, in spite of the full breasts and the wide hips, have been overcome; the happy faces express carefree joy, and the postures of the body are so alive with rhythm as to give the impression of a dancing figure.

Mathurā, during this period, was ruled by the Kushān (Kuṣāṇa) dynasty. A group of portrait sculptures of these rulers (Archaeological Museum), recovered from a village called Māt in the environs of Mathurā, gives an interesting glimpse of the foreign influences entering India at the time. One of them (unfortunately lacking the head) represents the emperor Kaniṣka wearing heavy boots, a tunic, and a coat, and leaning on a mace. The image is quite

P. Chandra

different not only in dress but also in style from other contemporary works, being essentially linear, with the forms entirely set into the surface. The surfaces have little ornamentation and are marked by extreme simplicity; they are also uncompromisingly stiff and rigid. It is possible that these images represent attempts by a Mathurā artist to imitate a style preferred by his imperial masters; but it was not long before the foreign elements were assimilated into the Mathurā style proper, for later images of Kushān chiefs have the same expanding and voluminous form that characterizes other sculptures of this school. A large number of ornamental motifs that now appear in India for the first time undergo a similar process of transformation.

The extent of Mathurā influence on Indian art of this period can be gauged by the sculpture of the school found at several sites in different parts of northern India, notably Ahichhatrā, Kauśāmbī, Sārnāth, and Sānchi. Most of these sites had been flourishing centres earlier, but only a very limited amount of sculpture was produced during the ascendancy of the Mathurā school; and whatever local sculpture was produced at this time was heavily influenced by the Mathurā style. At Sārnāth, for example, both the Bala Buddha imported from Mathurā and its local imitations have been found.

Ivory plaques of Bagrām

Ivory plaques discovered at Bagrām (Begrām) in Afghanistan are closely related to the school of Mathurā. These are of great importance; for, though ivory must have been a favourite medium of sculpture, little has been preserved of the early work. Most of it is in very low engraved relief, with fluent, sweeping outlines. The figures are depicted in easy and elegant postures, and the workmanship often attains considerable virtuosity.

P Chandra

Bodhisattva of the Gandhāra school, schist sculpture, *c.* 2nd century AD. In the Municipal Museum, Allāhābād, Uttar Pradesh, India.

Indian sculpture from the 1st to 4th centuries AD: Gandhāra. Contemporary with the school of Mathurā, and extending almost into the 6th century, is the Gandhāra school, whose style is unlike anything else in Indian art. It flourished in a region known in ancient times as Gandhāra, with its capital at Taxila in the Punjab, and in adjacent areas including the Swāt Valley and eastern Afghanistan. The output of the school was very large; numerous images, mostly of Buddhas and *bodhisattvas*, and narrative reliefs illustrating scenes from the Buddha's life and legends have been found. The favoured material is gray slate or blue schist and, particularly during the later phases, stucco. Except for objects excavated at a few well-known sites (such as Taxila, Peshāwar, and the Swāt Valley, in Pakistan, and Jalālābād, Haḍḍā, and Bāmiān, in Afghanistan), most of the finds have been the result of casual discovery or clandestine treasure hunts and plunder, so that their correct provenance is not known. If to this are added the large variety of idioms that appear to have existed simultaneously and the total absence of securely dated images, the wide divergence of scholarly opinion with regard to the schools' evolution can be understood. In the present day, there is general agreement, however, that its most flourishing period probably coincided with Kushān rule, particularly the reigns of the emperor Kaniṣka and his successors, and that the school did not long outlast the growth of the Gupta school in the 5th century.

The origins of the Gandhāra style are ultimately Greco-Roman, though, recently, emphasis has been placed on Roman art as the more immediate source. It has also been suggested that the school was created by foreign craftsmen imported into India and by their Indian pupils.

The Gandhāra school is also credited by some scholars with the invention of the anthropomorphic Buddha image. Whether this is correct or not, the Gandhāra image is quite different from that of Mathurā and illustrates the difference between the two schools. Instead of the powerful images directly descended from *yakṣa* prototypes, the Gandhāra version is an adaptation of an Apollo figure, with rather sweet and sentimental features. The definite volume and substance given to the pleated folds of the monastic robes make this image more naturalistic than anything found in Indian art. At the same time, the iconographical features are of Indian origin. Large numbers of *bodhisattva* images conceived in the image of royalty, some with strongly individualized facial features, have also been found.

Narrative relief sculpture

In contrast to Mathurā, narrative relief sculpture was very popular in Gandhāra art. Again, in composition and iconography these reliefs are largely dependent on the earlier Indian schools, but the style is quite distinct. Instead of continuous narrative, incidents separated in time are separately represented, though often arranged in sequence. Violent emotions are realistically rendered. The compositions range from simple horizontal placement of figures to rich and complex arrangements, which often attempt to render space illusionistically.

In the course of time, Indian influence was increasingly felt in the art of Gandhāra, and an abstract vision began to obscure the Greco-Roman naturalism of the earlier forms. In spite of the new influence (and the many graceful but cloying stucco sculptures that are representative of this late phase) the style shows no signs of vital change. This conservatism, together with the large artistic production, gives an overall impression of considerable monotony. Without any real roots in India and with marked foreign features, the avenues of natural development seem to have been closed to the school, which thus finally disappeared. Nevertheless it made vital contributions to the art of Central and eastern Asia, and several features, drastically transformed, were incorporated in Gupta art.

Indian sculpture from the 1st to 4th centuries AD: Andhradeśa. Besides the schools of Mathurā and Gandhāra, a most accomplished school of sculpture flourished in Andhradeśa during the three centuries after Christ, the most important centres being Amarāvatī and Nāgārjunakoṇḍa. The remains consist mainly of carved railings and rectangular slabs that decorated the great Buddhist *stūpas*, which have largely disappeared. The finds are thus frag-

mentary and belong to several phases of construction or to separate monuments spanning the 1st, 2nd, and 3rd centuries AD.

Unlike the school of Mathurā, which concentrates on the carving of single figures, the Amarāvatī school carried to the fullest limit of its development the ancient tradition of relief sculpture, which flourished in the two centuries before Christ at sites such as Bhārhut, Sānchi, and Amarāvatī itself. The marble railing posts are decorated with central medallions and lunates at the top and bottom, all filled with lotus flowers of a very rich design. Often the medallions also contain reliefs illustrating scenes from the Buddha's life and from the *Jātaka* stories, and these are the principal glory of the site.

Two broad phases in the development of narrative relief can be distinguished. In the first, the artist builds on the achievements of early relief sculpture as seen on the Great Stūpa of Sānchi. The forms are still comparatively heavy, the figures increasingly soft and fleshy, the movement freer but still pervaded by a sense of calm repose. This type of work, represented by relatively few examples, is followed by a phase in which the compositions achieve an extraordinary elaboration and complexity. Most striking is the restless, energetic movement, often nervous and flurried, that possesses the participants in any given scene. Complex relationships and patterns are established between the figures; and space is so articulated that the eye participates in the swirling inner movement of the composition that effectually dissolves the ground on which the figures are carved, while the figures themselves flow out in an endless movement from the ground. The setting is dramatic in the extreme. The loving workmanship, reminiscent of ivory carving, and the superb technical proficiency mark the Amarāvatī reliefs as the culminating point of the entire relief style.

The figures, of both men and women, are of unprecedented suppleness and plasticity, the forms rendered in every variety of torsion and flexion. A fluent, gliding line, often more appropriate to painting than to sculpture, encloses the figures, and pervading the whole is a subtle voluptuousness. The reliefs are often only nominally religious, a pretext for the sculptor's pleasure in representing the leisured and sophisticated life of the time.

Nāgārjunakonḍa sculpture marks the last phase of the relief style. The figures become stiffer and puppet-like, the patterns of movement frozen and mechanical but still possessing the energy and richness that always characterize this style.

Buddha images of Andhradeśa

The Buddha is represented in Andhradeśa by both symbolic and anthropomorphic forms. The iconographic formula developed shows him clad in a rather thick garment with stylized folds, and the postures are not as formal and hieratic as the Mathurā. This type of Buddha exercised considerable influence in the development of the Buddha image in Ceylon. In several other features as well, the Andhra style also contributed to the development of early sculpture in Southeast Asia.

Indian sculpture from the 1st to 4th centuries AD: terracotta. The quality of terra-cotta figurines of this period is generally inferior to work produced in the first two centuries BC. Many heads of crude workmanship, with protruding eyes, apparently representing foreigners, were found at sites such as Mathurā, Ahichhatrā, and Kauśāmbī. At the same time, there are some well-modelled heads that imitate the style of stone sculpture and are equally expressive.

Gupta period (c. 4th–6th centuries AD). During the 4th and the 5th centuries, when much of northern India was ruled by the Gupta dynasty, Indian sculpture entered what has been called its classic phase. The promise of the earlier schools was now fully realized, and at the same time new forms and artistic ideals were formulated that served as the source for development in succeeding centuries. The more or less sensuous and earthy rendering of form was drastically transformed, so that artistic expression closely conformed to the religious vision. The forms are refined and treated with sure and unsurpassed elegance. The volumes, impelled by an inner life, still swell from within but are restrained and controlled, made to flow in smooth and abstract rhythms in an organic and unified concept in which the sensual and the spiritual are inextricably blended. The edificatory, didactic intent of early relief sculpture is abandoned; instead, the works produced are pronouncedly meditative; and the repose and calm that settles on the images of the Buddha, the master of the inner contemplative life, is also seen on images of other divinities. Decorative ornament is in perfect harmony with the volumes it adorns, each emphasizing the other, so that in every respect this classic style of the Gupta period is one of great composure and perfect balance.

Gupta period: Mathurā. The impetus for the new schools seems to have come from Mathurā, which is hardly surprising in view of the preponderant role played by the city in the preceding period. The transformation into the new idiom is best illustrated by a splendid image of the Buddha which is dated AD 384 (Indian Museum, Calcutta). Memories of the rather massive and ponderous weight of the earlier style are present, but the calm face no longer looks out at the world; rather, the vision is turned within, the mood being one of serene contemplation. The style, which consistently uses the local red sandstone, undergoes further refinement, seen in a series of magnificent life-size Buddha images of the 5th century (now scattered in museums throughout the world). The more delicate face radiates a feeling of calm inner bliss, and the body is most subtly modelled by smoothly flowing planes that both suggest the swelling force of life and subordinate it to

the spiritual vision of the whole. Mathurā images generally show the Buddha wearing a diaphanous robe, the folds of which are rendered by stringlike ridges in a reinterpretation of a Gandhāra convention. The gestures of the hand are delicate and varied. The hair is usually rendered by rows of small curls that conceal the conical protuberance. These Mathurā images established an iconographical type that became the norm for the Buddha image.

Mathurā Hindu images

In addition to the Buddha figure, Mathurā has yielded large numbers of images of the various Hindu divinities, particularly Vishnu-Krishna. This is in keeping with the increasing strength of the various Hindu cults and the intimate association of Mathurā with the god Krishna. The famous image of Vishnu from Kaṭrā Keśavadeva in Mathurā is one of the finest (National Museum, New Delhi). The god is conceived as a royal figure, wearing a crown and appropriate jewelry, his features imbued with a dignified calm that is suitable to his function as the preserver and is also characteristic of most Gupta art.

Gupta period: Sārnāth. This famous centre of Indian art developed a sweeter and more elegant version of the Buddha image than Mathurā's. Instead of the rather strict frontal posture, the weight of the body is thrown more on one leg, resulting in a very subtle contrapposto position, in which the hips, shoulders, and head are turned in different directions. This lends a certain movement to the figure, so that it does not quite possess the static, steadfast quality of Mathurā. The robes are no longer ridged with folds but are plain, and the surface of the stone is even more abstractly handled than is the Mathurā. The faces are heart-shaped, the transitions from one part of the body to another smoother, so that the images have great refinement even if they do not possess the strength of Mathurā. The characteristic Sārnāth style, the preferred material of which is the local buff Chunār sandstone, seems to have developed in the late 5th century, the few earlier works being closer to the Mathurā school. The most famous image from the site and one of the masterpieces of Indian art is that of the seated Buddha preaching (Sārnāth Museum). It is exceptionally well preserved and delicately carved. The face, with serene features and a gentle smile playing on the lips, suggests the joy of supreme spiritual achievement. The halo behind the Buddha is also very beautifully carved, with exquisite floral patterns. Large numbers of Buddha and *bodhisattva* images have been excavated at Sārnāth and are to be found in the museum at the site and in major collections throughout the world.

Gupta period: central India. In addition to the major schools of Sārnāth and Mathurā, important sculpture of the 5th and 6th centuries is found at several sites in central India. The sculptures here are often in their original locations, surviving not as isolated images torn from their architectural context but in association with the temples of which they formed a part. At Udayagiri, near Vidiśā, are a series of simple rock-cut caves of the opening years of the 5th century. The sculpture, made of soft stone, has suffered greatly, but whatever has survived reveals a style that stresses strength and power. Perhaps the most

magnificent work is a great relief panel depicting the boar incarnation of Vishnu lifting the earth goddess from the watery deeps into which she had been dragged by a demon. The massive figure of the god, with the body of a man and the head of a boar, is carved in a surging movement across the face of the rock, the goddess resting easily on his shoulder, while a host of beings, human and divine, celebrate this great triumph.

The Śiva temple at Bhumarā has also yielded some sculpture of fine quality. The stone is carved with great precision and skill, nowhere more evident than in the handling of exuberant floral ornament. Little in Indian decorative sculpture can match the brilliance of the large panels filled with lotus stems and floriated scrolls discovered at this site and at Nāchnā Kutharā.

Some of the finest Gupta sculpture adorns the walls of the Vishnu temple at Deogarh. Particularly striking are three large relief panels depicting Vishnu lying on the serpent Śeṣa, the elephant's rescue, and the penance of Nara-Nārāyaṇa. The compositions tend to be dramatic; the carving and decoration, sumptuous, the sturdy forms recalling Mathurā rather than the attenuated grace of Sārnāth. The doorframe of the sanctum of this temple is an especially fine example of architectural decoration popular in this period. Bands of floral scrolls, amorous couples, and flying angels of great elegance are carved around the entrance. Particularly impressive are groups of worshippers at the base, their swaying bodies related to each other with an easy rhythm.

Gupta period: Mahārāshtra. A great revival of artistic activity seems to have taken place in this region during the reign of the Vākāṭaka dynasty and its successors, best expressed in the splendid sculpture decorating the cave temples of Ajantā and Elephanta. The idioms established in the North were adapted here to the needs of a style that conceived figures on a massive scale, as determined by the demands of the great expanses of rock out of which they were carved. Although the sculpture at Ajantā (mostly of the late 5th century) combines the old weightiness with the new restraint and elegance, the style finds its supreme expression in the magnificent cave temple at Elephanta. The central image of this great temple is of immense size and in deep relief. It represents Śiva in his cosmic aspect, the central head clam, introspective, self-sufficient, and transcending time, the heads to the sides, in their sensuous beauty and awesome terror, reflecting the creative and the destructive aspects of the supreme divinity.

Sculpture of the Ajantā and Elephanta caves

Gupta period: other regions. The impact of the Gupta style of the 5th and 6th centuries was felt in many parts of India, though actual remains thus far discovered are more abundant in some parts than in others. There appears to have been, in Bihār, a distinct school characterized by rather heavy, compact forms; and Gujarāt and southern Rājasthān developed an individual style of considerable voluptuousness and plasticity. Among the notable sculpture of the Idar region are groups of mother goddesses whose massive forms are rendered with an easy grace and intimacy. In the Karnataka country, to the south, the cave temples of Bādāmi reveal yet another distinct idiom, somewhat direct and elemental but nevertheless belonging to the same general style, with local variations, that prevailed over the greater part of India.

Gupta period: terra-cotta. Terra-cotta sculpture, like art in other mediums, was greatly developed. Fairly large and elaborate plaques were used to adorn brick *stūpa*s and Hindu temples from Sind to Bengal. The polychrome relief images of the Buddha from Mīrpur Khās are delicate and slender, with traces of Gandhāra feeling. Representations of divinities and mythological scenes from temples in Bīkaner, Ahichhatrā, Bhītargaon, and Śrāvastī are works on a more popular level, possessing an earthy ponderousness. A large number of figurines, particularly fragments of heads with elaborate coiffures and delicate, smiling features, have been found at Rājghāt in Vārānasi (Benares) and at other sites.

Medieval Indian sculpture. Indian sculpture from the 7th century onward developed, broadly speaking, into two styles that flourished in northern and southern India, respectively. In each of these regions there also developed additional local idioms, so that there was a wide variety of schools. All, however, evolved in a consistent manner, the earlier phase marked by relatively plastic forms, the later phase by a style that emphasizes a more linear rendering. The sculpture was used mainly as a part of the architectural decor, and the quantity required was vast. This often entailed a mechanical production, with the result that works of quality are few in proportion to the numbers.

Detail of a wall of the Lakṣmaṇa temple at Khajurāho, Madhya Pradesh, India, sandstone, *c.* AD 941.
P Chandra

Besides the two main idioms, the local schools of Mahārāshtra and Karnataka are of particular interest because they possess considerable individuality and often show both northern and southern features.

Sculpture in bronze was also produced in fairly large quantities in this period. Again, several local schools can be distinguished, the most important of which are those of eastern and southern India.

Medieval Indian sculpture: North India. The history of North Indian sculpture from the 7th to the 9th centuries is one of the more obscure periods in Indian art. Two trends, however, are clear: one exhibits the decline and disintegration of classical forms established during the 5th and 6th centuries; and the other, the evolution of new styles that began to possess overall unity and stability only in the 10th century.

A breakdown of the Gupta formula is observable from at least the 7th century onward, if not a little earlier: harmonious proportion, graceful movement, and supple modelling begin to yield to squat proportions, a halting movement, and a more congealed form. Toward the 8th century, signs of a new movement become evident in a group of sculptures that departs from the progressively lifeless working out of the Gupta idiom. The modelling emphasizes breadth but with a pronounced feeling for rhythm, and the delineation of decorative detail is fairly restrained. In the 9th century, particularly during the second half, a distinct change came over the styles of all of northern India. A new elegance, a richer decorativeness, and a staccato rhythm so characteristic of the medieval styles of the 10th and 11th centuries begin to be clearly seen and felt. Sculpture of this period reaches a standard of elegance never surpassed in the medieval period: the grace and voluminousness of earlier work are modified

Signs of a new movement

but not lost; the harsh angularity of later work, avoided. An idea of the style can be formed from an important group of sculptures at Ābānerī, the Śiva temple at Indore, and the Telī-kā-Mandir temple at Gwalior, as well as from individual works in various North Indian museums.

With the 10th century, the conventions of North Indian sculpture became fairly well established. The style is represented by examples from such monuments as the Lakṣmaṇa temple at Khajurāho (dated 941), the Harasnāth temple at Mt. Harsha (*c.* mid-10th century), in Rājasthān, and numerous other sites scattered all over northern India. These works are executed in a style that has become harder and more angular, the figures covered with a profusion of jewelry that tends to obscure the forms it decorates. These features are further accentuated in the 11th century, when many temples of great size, adorned with prodigious amounts of sculpture, were erected all over northern India. There is a decline in the general level of workmanship: the carving is often entirely conventional and lifeless, the features rigid and masklike, and the contours stiff and unyielding. The ornamentation, consisting of a profusion of beaded jewelry, is for the most part as dull, repetitive, and lifeless as the rest of the sculpture. This phase of artistic activity is represented at important centres from Gujarāt to Orissa; one of them is Khajurāho, with a vast amount of sculpture, all in a good state of preservation but conceived and executed as perfunctory architectural ornamentation. Not all sculpture, however, is of inferior quality; the hard, metallic carving and angular, stylized line sometimes result in works possessing a cold brilliance.

The 12th century marks the end of traditional sculpture all over northern India, except for a few pockets not yet penetrated by the Islāmic invasions. A rigid line imposed itself on the forms, which in turn became desiccated and hard, so that whatever unity of surface may have existed was entirely shattered. A brief revival took place in parts of Gujarāt and Rājasthān in the 15th century, but the sculpture merely imitated the work of the late medieval phase. The pure geometry of their forms, however, sometimes results in works possessing a curious archaistic power.

Sculpture in eastern India

Sculpture in eastern India (consisting of Bangladesh and the modern Indian states of Bihār, West Bengal, and Orissa), though sharing in the broad pattern of development of the rest of northern India, nevertheless represents a distinct idiom. The flatness of planes and angularity of contours are less pronounced, the figures retaining a sense of mass and weight for a greater period of time and to a greater degree. This can be clearly seen in sculpture from Konārak, in Orissa. Dating to the 13th century, the style retains a considerable semblance of plasticity at a period when sculpture in other parts of northern India had assumed a very wooden appearance. In Bihār and Bengal a flourishing school of bronze sculpture also developed, as evidenced by the large number of finds, notably from the sites of Nālandā and Kurkihār. The style generally parallels works in stone, emphasizing plastic values to a great degree. The most flourishing period was the 9th century, when a series of magnificent images representing the gods and goddesses of the Buddhist pantheon were made at Kurkihār and Nālandā. The work of the 10th and 11th centuries is more decorative and often very skillfully and elaborately cast. Of relatively small size and therefore easily transportable, bronze sculpture from this area played an important part in the diffusion of Indian influence in Southeast Asia.

Kashmir sculpture tends to be weightier and more massive than works in other parts of India. Some Gandhāra memories surivive, particularly in the fleshy rendering of the body and the drapery, but the sculpture is very much a part of the stylistic developments in northern India. Representative examples of the style, dating to around the mid-9th century, have been found from Avantipura. A flourishing school of bronze sculpture also existed, numerous examples having come to light in recent years. One of the finest, discovered at Devsar (Sir Pratap Singh Museum, Srinagar), is a large 9th-century ornamental frame, 6½ feet (two metres) high, decorated with various incarnations of Vishnu, all filled with great energy and movement. A good number of ivory images of Kashmir

workmanship have also been preserved. These are generally of miniature size, polychromed, and of extremely fine and delicate workmanship. Influences of the Kashmir style of sculpture were strongly felt in the neighbouring Himalayan region, including both Tibet and Nepal.

Medieval Indian sculptures: southern India. The medieval phase in southern India opened with elegant 7th-

P Chandra

century sculptures at Mahābalipuram, by far the most impressive of which is a large relief depicting the penance of Arjuna (previously identified as an illustration of the mythical descent of the Ganges). It is carved on the face of a granite boulder with a deep cleft in the centre, representing a river, down which water actually flowed from a reservoir situated above. On both sides are carved numerous figures of divinities, human beings, and animals that crowd the hermitage where Arjuna, practicing penance, is visited by Śiva. The tall, slender figures, with supple tubular limbs, remotely recall the proportions of Amarāvatī, now greatly transformed; and the numerous animals, including the elephant herd with its young, show the same intimate feeling for animal life that characterizes all Indian sculture, but in a manner that has seldom been surpassed.

The light, aerial forms gained stability and strength in subsequent centuries, culminating in superb sculptures adorning small, elegant shrines built during the late 9th century when the Cōḷa dynasty was consolidating its power. The temples at Tiruvalīśvaram, Kodumbālūr, Kilaiyur, Śrīnivāsanālūr, Kumbakonam, and a host of other sites of this period are only sparingly adorned with sculpture, but it is of superb quality. With the 10th and 11th centuries, South Indian sculpture, like its counterpart in the north though to a lesser degree, was carved in flatter planes and more angular forms, and the fresh, blooming life of earlier work is gradually lost. This can be seen, for example, in the sculpture of the numerous temples of Thanjāvūr and Gaṅgaikoṇḍacōḷapuram. The subsequent phase, extending up to the 13th century, is represented by work at Dārāsuram and Tribhuvanam; although the forms become increasingly congealed, brittle works of fine quality—often capturing outer movement with great skill—continue to be produced. Sculpture in southern India continued when artistic activity was interrupted in the north by the Islāmic invasions but, in spite of technical virtuosity, became progressively lifeless. Artistic activity continued in the south into the 17th century, the elaborately sculptured halls at Madurā and the masses of stucco sculpture adorning the immense entrances, or *gopuras*, testifying to the prodigious output and the undistinguished quality of the work produced.

South Indian bronze sculpture

South Indian bronze sculpture has a special place in the history of Indian art. A large number of images were made (some of them still in worship in the mid-20th century and others unearthed from the ground by chance), but examples before the 8th century are quite rare. In bronze, as in stone, the 9th and 10th centuries were periods of high achievement, and many images of excellent quality have survived. They are all cast by the lost-wax, or cire perdue, process (in which a wax model is used) and technically are very accomplished. In the early stages the forms were smooth and flowing, with a fine balance maintained between the body and the complex jewelry, the lines of which follow and reinforce every movement of the plastic surface. The bronzes of the later period lose this cohesiveness, the ornament, by virtue of its hardness, tending to divide and fragment the body it covers. The modelling also became flatter and sharper, though not quite as rapidly in bronze sculpture as in stone. Ancient traditions of workmanship survive to the present day, and a few guilds of craftsmen continue to make competent if somewhat lifeless images.

Most South Indian bronze images are representations of Hindu divinities, notably Vishnu and Śiva. One particular form deserves special notice as a striking southern contribution to Indian iconography. It is that of a four-armed Śiva as Lord of the Dance (Naṭarāja), shown within a flaming halo, or aureole, one hand holding the doubleheaded drum symbolizing sound, or creation, and the other holding the fire that puts an end to all that is created. The palm of the third hand faces the devotee, assuring him of freedom from fear, while the fourth hand points to the raised foot, the place of refuge from ignorance and delusion, which are symbolized by the dwarf demon crushed beneath the other foot. Several splendid images are known, the finest being, perhaps, the great image still worshipped in the Bṛhadīśvara temple at Thanjāvūr.

Medieval Indian sculpture: Mahārāshtra and Karnataka. The Karnataka country possessed a flourishing school of sculpture in the 7th and 8th centuries, as seen in examples from Aihole, Pattadkal, and Ālampur. As in architecture, influences from the north are discernible, but the style is basically southern, emphasizing rugged strength and power compared to the more elegant and delicate forms of the Tamil country. In Mahārāshtra, cave temples at

P. Chandra

Ellora carry the most important examples of this phase of sculpture. Here the tradition is continued of images of great size that, in their primitive strength, partake of the nature of the rock out of which they are carved. A series of large, splendid panels (6th century AD) depicting incidents from Hindu mythology in high relief are to be found in the Rameśvara cave; notable among them is a fearsome representation of the dancing Kālī, goddess of death. The Kailāsa temple (*c.* 757–783) has a remarkable group of elephants struggling with lions all around the plinth. Of the several large reliefs, also at Kailāsa, the depiction of Rāvana shaking Kailāsa is a composition of considerable grace and charm.

Distinctive style of Karnataka

Toward the 13th and 14th centuries, a very distinctive style developed in the Karnataka country, which was then largely ruled by kings of the Hoysaḷa dynasty. The materials employed are varieties of stone that are soft when freshly quarried but harden on exposure, which may account partially for the extreme richness of the work. The sculpture is in very high relief, often undercut and literally covered with the most elaborate ornaments and jewelry from top to toe. This unrestrained extravaganza is unique even for Indian art, which shows a preference for intricate and elaborate ornament at all stages of its history.

Painting. Literary works testify to the eminence of painting as an art form in India, particularly in the decoration of walls, but climate has taken a devastating toll, leaving behind only a few tantalizing examples. By far the bulk of the preserved material consists of miniature painting, initially done on palm leaf but later on paper. The subject matter is generally religious (illustrating divinities, myths, and legends) and literary (illustrating poetry and romances, for example), though the Mughal school was also concerned with historical and secular themes. The styles were rich and varied, often closely connected with one another and sometimes developing and changing rapidly, particularly from the 16th century onward. The work also shows a surprising vitality under strained circumstances, surviving up to the very eve of the modern period when the other arts had deteriorated greatly.

Prehistoric and protohistoric periods. Painting in India should have a history stretching as far back as any of the other arts but, because of its perishable nature, little has survived. None of the examples found in rock shelters over almost all of India, and chiefly representing scenes of hunting and war, appears to be earlier than the 8th century BC, and all may be as late as the 10th century AD. A faint idea of the painter's art in the Indus Valley civilization can be had from the pottery, elaborately decorated with leaf designs and geometrical patterns.

Paintings at Ajantā

Ancient wall painting. The earliest substantial remains are those found in rock-cut cave temples at Ajantā, in western India. They belong to the 2nd or 1st century BC and are in a style reminiscent of the relief sculpture at Sānchi. Also found at Ajantā are the most substantial remains of Indian painting of about the 5th century AD and a little later, when ancient Indian civilization was in full flower. The paintings, the work of several ateliers, decorate the walls and ceilings of the numerous cave temples and monasteries at the site. They are executed in the tempera technique on smooth surfaces, prepared by application of plaster. The themes, nominally Buddhist, illustrate the major events of the Buddha's life, the *Jātaka* tales, and the various divinities of the expanding Buddhist pantheon. The ceilings are covered with rich motifs, based generally upon the lotus stem and the world of animals and birds. The style is unlike anything seen in later Indian art, expansive, free, and dynamic. The graceful figures are painted by a sweeping and accomplished brush; and they are given body and substance by modelling in colour and by a schematic distribution of light and shade that has little to do with scientific chiaroscuro. The narrative compositions, handled with utmost dexterity, are a natural outgrowth of the long traditions of relief sculpture and reflect the splendour and maturity of contemporary sculpture. The large images of the *bodhisattva*s in Cave 1, combining rich elegance with spiritual serenity, reflect a vision that sees the shifting world of matter and the transcendental calm of Nirvāṇa as essentially one.

Except for a large and magnificent painting of a dance scene found at the rock-cut cave at Bāgh—a painting executed in a style closely resembling Ajantā—hardly any other work of this great period survives. Cave temples at Bādāmi, in the Karnataka country, and Sittānavāsal, in Tamil Nadu, probably of the late 6th and 7th centuries AD are already but echoes of the style of the 5th century, which appears to have died out around this time.

Eastern Indian style. Small illustrations on palm leaf, chiefly painted at the great Buddhist establishments of eastern India, appear to have conserved some elements of this ancient style; but they have lost its dramatic impact, which is replaced by a studied preciosity and an inhibited meticulousness. The surviving paintings date from the 11th and 12th centuries and are conventional icons of the numerous Buddhist gods and goddesses, narrative representations having largely disappeared. With the destruction of these Buddhist centres by the Islāmic invader, the east Indian style seems to have come to an end.

Western Indian style. The style of Ajantā is succeeded in western India by what has been appropriately named the western Indian style. Among the earliest examples are a few surviving wall paintings of the Kailāsa temple (mid-8th century) at Ellora and the Jaina temples, built at the same site a hundred years later. The plastic sense of form, so evident at Ajantā, is emphatically replaced by a style that even at this early stage is heavily dependent on line. The contours of the figures are sharp and angular, the forms dry and abstract; and the fluent, stately rhythms of Ajantā have become laboured and halting.

Jaina manuscripts

The most copious examples of this style, however, have survived not on the walls of temples but in the large number of illustrated manuscripts commissioned by members of the Jaina community. The earliest of these are contemporary with eastern Indian manuscripts and are also painted on palm leaf; but the style, instead of attempting to cling to ancient traditions, moves steadily in the direction already established at Ellora. It is a perfect counterpart of contemporary sculpture in western India, relying for its effect on line, which progressively becomes more angular and wiry until all naturalism has been deliberately erased. The figures are almost always shown in profile,

the full-face view generally reserved for representations of the *tīrthaṅkaras*, or the Jaina saviours. A convention that appears unfailingly for the duration of the western Indian style is the eye projecting beyond the face shown in profile, meant to represent the second eye, which would not be visible in this posture. The colours are few and pure: yellow, green, blue, black, and red, which was preferred for the background. In the beginning, the illustrations are simple icons in small panels; but gradually they become more elaborate, with scenes from the lives of the various Jaina saviours as told in the *Kalpa-sūtra* and from the adventures of the monk Kālaka as related in the *Kālakācāryakathā* the most favoured.

Even greater elaboration was possible with the increasing availability of paper from the late 14th century; with larger surfaces to paint on, by the middle of the 15th century artists were producing opulent manuscripts, such as the *Kalpa-sūtra* in the Devasanopaḍā library, Ahmadābād. The text is written in gold on coloured ground, the margins gorgeously illuminated with richest decorative and figural patterns, and the main paintings often occupying the entire page. Blue and gold, in addition to red, are used with increasing lavishness, testifying to the prosperity of the patron. The use of such costly materials, however, did not necessarily produce works of quality, and one is often left with the impression of cursive and hasty workmanship. With some variations—but hardly any substantial departures from the bounds that it had set for itself—the style endured throughout the 16th century and even extended into the 17th. The political subjugation of the country by the forces of Islām may have contributed to the conservatism of the style but did not result in its total elimination, as seems to have been the case in eastern India. Indeed, in the course of its long life, the western Indian school became a national style, painting at other centres in India interpreting and elaborating its forms in their own individual manner. In the province of Orissa, painting on palm leaf and in a manner entirely dependent on the western Indian style has continued up to the present day.

Transition to the Mughal and Rajasthani styles. The belief held earlier by scholars that the new Islāmic rulers of India did not patronize any painting until the rise of the Mughal dynasty in the 16th century is being abandoned in the face of the literary testimony and the discovery or recognition of illustrated manuscripts that were painted at Indian courts. Nor should this be surprising, as the Muslim kings of India had before them the example of other rulers of the Islāmic world who were great patrons of painting in spite of the injunctions of orthodox Islām against the portrayal of living beings. The taste of these Indian rulers, however, did not turn to the western Indian style but to the flourishing traditions of Islāmic painting abroad, notably

Folio from an illustrated manuscript of *Candāyana*, *c.* first half of the 16th century. In the Prince of Wales Museum of Western India, Bombay.

P Chandra

neighbouring Iran. As many painters as architects had in all probability been invited from foreign countries; and illustrated manuscripts, handily transported, must have been easily available. As a result there appears to have developed what can only be called an Indo-Persian style, based essentially on the schools of Iran but affected to a greater or lesser extent by the individual tastes of the Indian rulers and by the local styles. The earliest known examples are paintings dating from the 15th century onward. The most important are the *Khamseh* ("Quintet") of Amīr Khosrow of Delhi (Freer Gallery of Art, Washington, D.C.), a *Bostān* painted in Mandu (National Museum, New Delhi), and, most interesting of all, a manuscript of the *Ne'mat-nāmeh* (India Office Library, London) painted for a sultan of Mālwa in the opening years of the 16th century. Its illustrations are derived from the Turkmen style of Shīrāz but show clear Indian features adapted from the local version of the western Indian style.

P Chandra

Folio from a series illustrating the *Caurapañcāśikā* of Bilhaṇa, *c.* mid-16th century AD. In the Municipal Museum, Ahmadābād, Gujarāt, India.

Though the western Indian style was essentially conservative, it was not unfailingly so. It began to show signs of an inner change most notably in two manuscripts from Mandu, a *Kalpa-sūtra* and a *Kālakācāryakathā* of about 1439, and a *Kalpa-sūtra* painted at Jaunpur in 1465. These works were done in the opulent manner of the 15th century, but for the first time the quality of the line is different, and the uncompromisingly abstract expression begins to make way for a more human and emotional mood. By the opening years of the 16th century, a new and vigorous style had come into being. Although derived from the western Indian style, it is clearly independent, full of the most vital energy, deeply felt, and profoundly moving. The earliest dated example is an *Araṇyaka Parva* of the *Mahābhārata* (1516; The Asiatic Society of Bombay), and among the finest are series illustrating the *Bhāgavata-Purāṇa* and the *Caurapañcāśikā* of Bilhaṇa, scattered in collections all over the world. A technically more refined variant of this style, preferring the pale, cool colours of Persian derivation, a fine line, and meticulous ornamentation, exists contemporaneously and is best illustrated by a manuscript of the ballad *Candāmyana* by Mullā Dāūd (*c.* first half of the 16th century; Prince of Wales Museum of Western India, Bombay). The early 16th century thus appears to have been a period of inventiveness and set the stage for the development of

Fifteenth-century changes in western Indian style

the Mughal and Rājput schools, which thrived from the 16th to the 19th century.

Mughal style: Akbar period (1556–1605). Although the Mughal dynasty came to power in India with the great victory won by Bābar at the Battle of Pānīpat in 1526, the Mughal style was almost exclusively the creation of Akbar. Trained in painting at an early age by a Persian master, Khwāja ʿAbd-uṣ-Ṣamad, who was employed by his father, Humāyūn, Akbar created a large atelier, which he staffed with artists recruited from all parts of India. The atelier, at least in the initial stages, was under the superintendence of Akbar's teacher and another great Persian master, Mīr Sayyid ʿAlī; but the distinctive style that evolved here owed not a little to the highly individual tastes of Akbar himself, who took an interest in the work, inspecting the atelier frequently and rewarding painters whose work was pleasing.

The work of the Mughal atelier in this early formative stage was largely confined to the illustration of books on a wide variety of subjects: histories, romances, poetic works, myths, legends, and fables, of both Indian and Persian origin. The manuscripts were first written by calligraphers, with blank spaces left for the illustrations. These were executed largely by groups of painters, including a colourist, who did most of the actual painting, and specialists in portraiture and in the mixing of colours. Chief of the group was the designer, generally an artist of top quality, who formulated the composition and sketched in the rough outline. A thin wash of white, through which the initial drawing was visible, was then applied and the colours filled in. The colourist's work proceeded slowly, the colour being applied in several thin layers and frequently rubbed down with an agate burnisher, a process that resulted in the glowing, enamel-like finish. The colours used were mostly mineral but sometimes consisted of vegetable dyes; and the brushes, many of them exceedingly fine, were made from squirrel's tail or camel hair.

The technique of Mughal painting

The earliest paintings (*c.* 1560–70) of the school of Akbar are illustrations of *Ṭūṭī-nāmeh* ("Parrot Book; Cleveland Museum of Art) and the stupendous illustrations of the *Dāstān-e Amīr Ḥamzeh* ("Stories of Amīr Ḥamzeh"; Österreichisches Museum für Angewandte Kunst, Vienna), which originally consisted of 1,400 paintings of an unusually large size (approximately 25 inches by 16 inches [65 by 40 centimetres]), of which only about 200 have survived. The *Ṭūṭī-nāmeh* shows the Mughal style in the process of formation: the hand of artists belonging to the various non-Mughal traditions is clearly recognizable, but the style also reveals an intense effort to cope with the demands of a new patron. The transition is achieved in the *Dāstān-e Amīr Ḥamzeh,* in which the uncertainties are overcome in a homogeneous style, quite unlike Persian work in its leaning toward naturalism and filled with swift, vigorous movement and bold colour. The forms are individually modelled, except for the geometrical ornament used as architectural decor; the figures are superbly interrelated in closely unified compositions, in which depth is indicated by a preference for diagonals; and much attention is paid to the expression of emotion. One of the last manifestations of this bold and vigorous early manner is the *Dārābnameh (c.* 1580) in the British Museum.

Immediately following were some very important historical manuscripts, including the *Tārīkh-e Khāndān-e Tīmūrīyeh* ("History of the House of Timūr," *c.* 1580–85; Khuda Baksh Library, Patna) and other works concerned with the affairs of the Tīmūrid dynasty, to which the Mughals belonged. Each of these manuscripts contains several hundred illustrations, the prolific output of the atelier made possible by the division of labour that was in effect. Historical events are recreated with remarkable inventiveness, though the explosive and almost frantic energy of the *Dāstān-e Amīr-Ḥamzeh* has begun to subside. The scale was smaller and the work began to acquire a studied richness. The narrative method employed by these Mughal paintings, like that of traditional literature, is infinitely discursive; and the painter did not hesitate to provide a fairly detailed picture of contemporary life—both of the people and of the court—and of the rich fauna and flora of India. Like Indian artists of all periods, the Mughal painter showed a remarkable empathy for animals, for through them flows the same life that flows through human beings. This sense of kinship allowed him to achieve unqualified success in the illustration of animal fables such as the *Anwār-e Suhaylī* ("Lights of Canopus"), of which several copies were painted, the earliest dated 1570 (School of Oriental and African Studies, London). It was in the illustrations to Persian translations of the Hindu epics, the *Mahābhārata* and the *Rāmāyaṇa,* that the Mughal painter revealed to the full the richness of his imagination and his unending resourcefulness. With little precedent to rely on, he was nevertheless seldom dismayed by the subject and created a whole series of convincing compositions. Because most of the painters of the atelier were Hindus, the subjects must have been close to their hearts; and, given the opportunity by a tolerant and sympathetic patron, they rose to great heights. It is no wonder, therefore, that the *Razm-nāmeh* (City Palace Museum, Jaipur), as the *Mahābhārata* is known in Persian, is one of the outstanding masterpieces of the age.

Illustrations for Persian translations of Hindu epics

In addition to large books containing numerous illustrations, which were the products of the combined efforts of many artists, the imperial atelier also cultivated a more intimate manner that specialized in the illustration of books, generally poetic works, with a smaller number of illustrations. The paintings were done by a single master artist who, working alone, had ample scope to display his virtuosity. In style the works tend to be finely detailed and exquisitely coloured. A *Dīvān* ("Anthology") of Anwarī (Fogg Art Museum, Cambridge, Massachusetts), dated 1589, is a relatively early example of this manner. The paintings are very small, none larger than five inches by $2^1/_2$ inches (12 by 6 centimetres) and most delicately executed. Very similar in size and quality are the miniatures illustrating the *Dīvān* of Ḥāfeẓ (Reza Library, Rāmpur). On a larger scale but in the same mood are the manuscripts that represent the most delicate and refined works of the reign of Akbar: the *Bahāristān* of Jāmī (1595; Bodleian Library, Oxford), a *Khamseh* of Neẓāmī (1593; British Museum, London), a *Khamseh* of Amīr Khosrow (1598; Walters Art Gallery, Baltimore and Metropolitan Museum of Art, New York), and an *Anwār-e Suhaylī* (1595–96; Bharat Kala Bhavan, Vārānasī).

Also prepared in the late 1590s were magnificent copies

P Chandra

of the *Akbar-nāmeh* ("History of Akbar"; Victoria and Albert Museum, London) and the *Kitāb-e Changīz-nāmeh* ("History of Genghis Khan"; Gulistan Library, Tehrān). These copiously illustrated volumes were produced by artists working jointly, but the quality of refinement is similar to that of the poetic manuscripts.

Of the large number of painters who worked in the imperial atelier, the most outstanding were Dasvant and Basāvan. The former played the leading part in the illustration of the *Razm-nāmeh*. Basāvan, who is preferred by some to Dasvant, painted in a very distinctive style, which delighted in the tactile and the plastic, and with an unerring grasp of psychological relationships.

Mughal style: Jahāngīr period (1605–27). The emperor Jahāngīr, even as a prince, showed a keen interest in painting and maintained an atelier of his own. His tastes, however, were not the same as those of his father, and this is reflected in the painting, which underwent a significant change. The tradition of illustrating books began to die out, though a few manuscripts, in continuation of the old style, were produced. For Jahāngīr much preferred portraiture; and this tradition, also initiated in the reign of his father, was greatly developed. Among the most elaborate works of his reign are the great court scenes, several of which have survived, showing Jahāngīr surrounded by his numerous courtiers. These are essentially large-scale exercises in portraiture, the artist taking great pains to reproduce the likeness of every figure.

Portraiture

The compositions of these paintings have lost entirely the bustle and movement so evident in the works of Akbar's reign. The figures are more formally ordered, their comportment in keeping with the strict rules of etiquette enforced in the Mughal court. The colours are subdued and harmonious, the bright glowing palette of the Akbarī artist having been quickly abandoned. The brushwork is exceedingly fine. Technical virtuosity, however, is not all that was attained, for beneath the surface of the great portraits of the reign there is a deep and often spiritual understanding of the character of the person and the drama of human life.

Many of the paintings produced at the imperial atelier are preserved in the albums assembled for Jahāngīr and his son Shāh Jahān. The Muraqqah-e Gulshan is the most spectacular. (Most surviving folios from this album are in the Gulistan Library in Tehrān and the Staatliche Museen Preussischer Kulturbesitz, Berlin; a section is temporarily housed in Tübingen.) There are assembled masterpieces from Iran, curiosities from Europe, works produced in the reign of Akbar, and many of the finest paintings of Jahāngīr's master painters, all surrounded by the most magnificent borders decorated with a wide variety of floral and geometrical designs. The album gives a fairly complete idea of Jahāngīr as a patron, collector, and connoisseur of the arts, revealing a person with a wide range of taste and a curious, enquiring mind.

Jahāngīr esteemed the art of painting and honoured his painters. His favourite was Abū al-Hasan, who was designated Nādir-uz-Zamān ("Wonder of the Age"). Several pictures by the master are known, among them a perceptive study of Jahāngīr looking at a portrait of his father. Also much admired was Ustād Manṣūr, designated Nādir-ul-ʿAṣr ("Wonder of the Time"), whose studies of birds and animals are unparalleled. Bishandās was singled out by the emperor as unique in the art of portraiture. Manohar, the son of Basāvan, Govardhan, and Daulat are other important painters of this reign.

Mughal style: Shāh Jahān period (1628–58). Under Shāh Jahān, attention seems to have shifted to architecture, but painting in the tradition of Jahāngīr continued. The style, however, becomes noticeably rigid. The portraits resemble hieratic effigies, lacking the breath of life so evident in the work of Jahāngīr's time. The colouring is jewel-like in its brilliance, and the outward splendour quite dazzling. The best work is found in the *Shāhjahānnāmeh* ("History of Shāh Jahān") of the Windsor Castle Library and in several albums assembled for the emperor. Govardhan and Bichitra, who had begun their careers in the reign of Jahāngīr, were among the outstanding painters; several

works by them are quite above the general level produced in this reign.

Mughal style: Aurangzeb and the later Mughals (1659–1806). From the reign of Aurangzeb (1659–1707), a few pictures have survived that essentially continue the cold style of Shāh Jahān; but the rest of the work is nondescript, consisting chiefly of an array of lifeless portraits, most of them the output of workshops other than the imperial atelier. Genre scenes, showing gatherings of ascetics and holy men, lovers in a garden or on a terrace, musical parties, carousals, and the like, which had grown in number from the reign of Shāh Jahān, became quite abundant. They sometimes show touches of genuine quality, particularly in the reign of Muḥammad Shāh (1719–48), who was passionately devoted to the arts. This brief revival, however, was momentary, and Mughal painting essentially came to an end during the reign of Shāh ʿĀlam II (1759–1806). The artists of this disintegrated court were chiefly occupied in reveries of the past, the best work, for whatever it is worth, being confined to copies of old masterpieces still in the imperial library. This great library was dispersed and destroyed during the uprising of 1857 against the British.

Genre scenes

Company school. Rising British power, which assumed political supremacy in the 19th century, resulted in a radical change of taste brought about by the Westernization of important segments of the population. Heavily influenced by Western ideas, a style emerged that represented the adjustment of traditional artists to new fashions and demands. Rooted at Delhi and the erstwhile provincial Mughal capitals of Murshidābād, Lucknow, and Patna, it ultimately spread all over India. Most of the works produced were singularly impoverished, but occasionally there were some fine studies of natural life.

Deccani style. In mood and manner, Deccani painting, which flourished over much of the Deccan Plateau from at least the last quarter of the 16th century, is reminiscent of the contemporary Mughal school. Again, a homogeneous style evolved from a combination of foreign (Persian and Turkish) and Indian elements, but with a distinct local flavour. Of the early schools, the style patronized by the sultans of Bijāpur—notably the tolerant and art-loving Ibrāhīm ʿĀdil Shāh II of Bijāpur, famous for his love of music—is particularly distinguished. Some splendid portraits of him, more lyrical and poetic in concept than contemporary Mughal portraits, are to be found. A wonderful series depicting symbolically the musical modes (*rāgamālā*) also survives. Of illustrated manuscripts, the most important are the *Nujūm-ul-ʿulūm* ("The Stars of the Sciences," 1590; Chester Beatty Library, Dublin) and the *Tārīf-e Ḥuseyn-Shāhī* (Bharata Itihasa Samshodhaka Mandala, Pune), painted around 1565 in the neighbouring state of Ahmadnagar. The sultanate of Golconda also produced work of high quality—for example, a manuscript of the *Dīvān* of Muḥammad Qulī Quṭb Shāh in the Salar Jang Library, Hyderābād, and a series of distinguished portraits up to the end of the 17th century (dispersed in various collections). The state of Hyderābād, founded in the early 18th century and headed by a grandee of the Mughal Empire, was a great centre of painting. The work that was produced there reflects both Golconda traditions and increasing Mughal and Rajasthani influences.

Rajasthani style. This style appears to have come into being in the 16th century, about the same time the Mughal school was evolving under the patronage of Akbar; but, rather than a sharp break from the indigenous traditions, it represented a direct and natural evolution. Throughout the early phase, almost up to the end of the 17th century, it retained its essentially hieratic and abstract character, as opposed to the naturalistic tendencies cultivated by the Mughal atelier. The subject matter of this style is essentially Hindu, devoted mainly to the illustration of myths and legends, the epics, and above all the life of Krishna; particularly favoured were depictions of his early life as the cowherd of Vraja, and the mystical love of Vraja's maidens for him, as celebrated in the *Bhāgavata-Purāṇa*, the *Gītagovinda* of Jayadeva, and the Braj Bhasa verses written by Sūrdās and other poets. The style of the painting, no less than the literature, is a product of the new religious movements, all of which stressed personal devotion to Krishna as the way to salvation. Related popular themes were pictorial representations of the musical modes (*rāgamālā*) and illustrations of poetical works such as the *Rasikapriyā* of Keśavadāsa, which dealt with the sentiment of love, analyzing its varieties and endlessly classifying the types of lovers and beloveds and their emotions. Portraits, seldom found in the early phase, became increasingly common in the 18th century—as did court scenes, scenes of sporting and hunting events, and other scenes concerned with the courtly life of the great chiefs and feudal lords of Rājasthān.

The Hindu basis of Rajasthani style

The Rajasthani style developed various distinct schools, most of them centring in the several states of Rājasthān, namely Mewār, Būndi, Kotah, Mārwār, Bīkaner, Kishangarh, and Jaipur (Amber). It also had centres outside the geographical limits of present-day Rājasthān, notably Gujarāt, Mālwa, and Bundel Khand. The study of Rajasthani painting is still in its infancy, for most of the material has been available for study only since the mid-1940s.

The Mughal and Rajasthani styles were always in contact with each other, but in general the Rajasthani schools were not essentially affected by the work produced at the Mughal court during the greater part of the 17th century. This became less true in the 18th century, when the sharp distinction between the two became progressively obscured, though each retained its distinctive features right up to the end.

Rajasthani style: Mewār. The Mewār school is among the most important. The earliest dated examples are represented by a *rāgamālā* series painted at Chawand in 1605 (Gopi Krishna Kanoria Collection, Patna). These simple paintings, filled with bright colour, are only a step removed from the pre-Rajasthani phase. The style became more elaborate in the first quarter of the 17th century when another *rāgamālā*, painted at Udaipur in 1628 (formerly in the Khajanchi Collection, Bīkaner; now dispersed in various collections), showed some superficial acquaintance with the Mughal manner. This phase, lasting until around 1660, was one of the most important for the development of painting all over Rājasthān. Ambitious and extensive illustrations of the *Bhāgavata*, the *Rāmāyaṇa*, the poems of Sūrdās, and the *Gītagovinda* were completed, all full of strength and vitality. The name of Sāhabadī is intimately connected with this phase; another well-known painter is Manohar. The intensity and richness associated with their

atelier began to fade toward the close of the 17th century, and a wave of Mughal influence began to affect the school in the opening years of the 18th century. Portraits, court scenes, and events in the everyday world of the ruling classes are increasingly found. Although the emotional fervour of the 17th century was never again attained, this work is often of considerable charm. The 19th century continued to create work in the tradition of the 18th, one of the most important centres being Nāthdwāra (Rājasthān), the seat of the Vallabha sect. Large numbers of pictures, produced here for the pilgrim trade, were spread over all parts of Rājasthān, northern India, Gujarāt, and the Deccan.

Earliest examples of Būndi school

Rajasthani style: Būndi and Kotah. A school as important as that of Mewār developed at Būndi and later at Kotah, which was formed by a partition of the parent state and ruled by a junior branch of the Būndi family. The earliest examples are represented by a *rāgamālā* series of extraordinarily rich quality, probably dating from the end of the 16th century. From the very beginning the Būndi style seemed to have found Mughal painting an inspiring source, but its workmanship was as distinctively Rajasthani as the work of Mewār. The artists of this school always displayed a pronounced preference for vivid movement, which is unique in all of Rājasthān. Toward the second half of the 17th century, work at Būndi came unmistakably under the influence of Mewār; many miniatures, including several series illustrating the *Rasikapriyā,* indicate that this was a period of prolific activity. The sister state of Kotah also appears to have become an important centre of painting at this time, developing a great fondness for hunting and sport scenes, all filled with great vigour and surging strength. This kind of work continued well into the 19th century, and if the workmanship is not always of the highest quality, the style maintained its integrity against the rapidly increasing Western influence right up to the end.

Rajasthani style: Mālwa. It has been suggested but not definitely determined that the school itself does not belong to Mālwa but to some other area, probably Bundelkhand. In contrast to the Būndi school, miniatures generally thought to have been painted in Mālwa are quite archaistic, with mannerisms inherited from the 16th century retained until the end of the 17th. The earliest work is an illustrated version of the *Rasikapriyā* (1634), followed by a series illustrating a Sanskrit poem called the *Amaru Śataka* (1652). There are also illustrations of the musical modes (*rāgamālā*), the *Bhāgavata-Purāṇa,* and other Hindu devotional and literary works. The compositions of all of these pictures is uncompromisingly flat, the space divided into registers and panels, each filled with a patch of colour and occupied by figures that convey the action. This conservative style disappeared after the close of the 17th century. The course of Mālwa painting in the 18th century and later is not known.

Rajasthani style: Mārwār. A *rāgamālā* series dated 1623 reveals that painting in this state shared features common to other schools of Rājasthān. Miniatures of the second half of the 17th century are distinguished by some splendid portraits that owe much to the Mughal school. A very large amount of work was done in the 19th century, all of which is highly stylized but strong in colour and often of great charm.

Rajasthani style: Bīkaner. Of all Rajasthani schools, the Bīkaner style, from its very inception in the mid-17th century, shows the greatest indebtedness to the Mughal style. This is due to the presence in the Bīkaner atelier of artists who had previously worked in the Mughal manner at Delhi. They and their descendants continued to paint in a style that could only be classed as a provincial Mughal manner had it not been for the quick absorption of influences from the Rajasthani environment and a sympathy for the religious and literary themes favoured by the royal Hindu patrons. Delicacy of line and colour are consistent characteristics of Bīkaner painting even when, toward the end of the 18th century, it assumed stylistic features associated with the more orthodox Rajasthani schools.

Characteristics of the Bīkaner style

Rajasthani style: Kishangarh. The Kishangarh school, which came into being toward the mid-18th century, was also indebted to the contemporary Mughal style but combined a rich and refined technique with deeply moving religious fervour. Its inspiring patron in the formative phase was Sāvant Singh, more of a devotee and a poet than a king. The style established by him, characterized by pronounced mystical leanings and a distinctive facial type, continued to the middle of the 19th century, though at a clearly lower level of achievement.

Rajasthani style: Jaipur (Amber). The rulers of the state

were closely allied to the Mughal dynasty, but paintings of the late 16th and early 17th centuries possessed all of the elements of the Rajasthani style. Little is known about the school until the opening years of the 18th century, when stiff, formal examples appear in the reign of Savāī Jai Singh. The finest works, dating from the reign of Pratāp Singh, are sumptuous in effect and include some splendid portraits and some large paintings of the sports of Krishna. Although the entire 19th century was extremely productive, the work was rather undistinguished and increasingly affected by Western influences. Of the Rajasthani styles of this period, the Jaipur school was the most popular, examples having been found all over northern India.

Pahari style. Closely allied to the Rajasthani schools both in subject matter and technique is the Pahari style, so-named because of its prevalence in the erstwhile hill states of the Himalayas, stretching roughly from Jammu to Gaṛhwāl. It can be divided into two main schools, the Basohlī and the Kāngra, but it must be understood that these schools were not confined to the centres after which they are named but extended all over the area. Unlike Rājasthān, the area covered by the Pahari style is small, and the probability of artists travelling from one area to another in search of livelihood was much greater. Thus, attempts to distinguish regional schools are fraught with controversy, and it has been suggested that a classification based upon ateliers and families is likely to be more tenable than those presently current among scholars. Because the Basohlī and the Kāngra schools show considerable divergences, scholars have postulated the existence of a transitional phase, named the pre-Kāngra style.

Pahari style: Basohlī school. The origins of this remarkable style are not yet understood, but it is clear that the style was flourishing toward the close of the 17th century. The earliest dated paintings are illustrations to the *Rasamañjarī* of Bhānudatta (a Sanskrit work on poetics), executed for a ruler of Basohlī (1690; Boston Museum of Fine Arts). Bold colour, vigorous drawing, and primitive intensity of feeling are outstanding qualities in these paintings, quite surpassing the work of the plains. In addition to other Hindu works such as the *Gītagovinda* and the *Bhāgavata-Purāṇa,* a fairly large number of idealized portraits have also been discovered.

Pahari style: Kāngra school. The Basohlī style began to fade by the mid-18th century, being gradually replaced by the Kāngra style, named after the state of Kāngra but, like the Basohlī style, of much wider prevalence. A curvilinear line, easy flowing rhythms, calmer colours, and a mood of sweet lyricism easily distinguish the work from that of the Basohlī style. The reasons for this change are to be sought in strong influences from the plains, notably the Mughal styles of Delhi and Lucknow. These influences account for the more refined technique; but whatever was borrowed was transmuted and given a fresh and tender aspect. Among the greatest works are large series illustrating the *Bhāgavata-Purāṇa* (National Museum, New Delhi), the *Gītagovinda,* and the *Satsaī* of Bihārī (both in the collection of the maharaja of Tehrī-Garhwāl), all painted in 1775–80. The corpus of work produced is very large and, although it seldom fails to please, works of high achievement are rare. The school flourished from about 1770 to almost the end of the 19th century, but the finest work was produced largely around 1775–1820.

Modern period. Toward the late 19th century traditional Indian painting was rapidly dying out, being replaced by feeble works in a variety of idioms, all strongly influenced by the West. A reaction set in during the early 20th century, symbolized by what is called the Bengal school. The glories of Indian art were rediscovered, and the school consciously tried to produce what it considered a truly Indian art inspired by the creations of the past. Its leading artist was Rabindranath Tagore and its theoretician was E.B. Havell, the principal of the Calcutta School of Art. Nostalgic in mood, the work was mainly sentimental though often of considerable charm. The Bengal school did a great deal to reshape contemporary taste and to make Indian artists aware of their own heritage. Amrita Sher-Gil, who was inspired by the Postimpressionists, made Indian painters aware of new directions. Mid-20th-century Indian painting is very much a part of the international scene, the artists painting in a variety of idioms, often attempting to come to terms with their heritage and with the emergence of India as a modern culture.

The Bengal school

Decorative arts. Fragmentary ivory furniture (*c.* 1st century AD) excavated at Begrām is one of the few indications of the existence in ancient India of a secular art concerned with the production of luxurious and richly decorated objects meant for daily use. Objects that can be clearly designated as works of decorative art become much more extensive for the later periods, during which Islāmic traditions were having a profound effect on Indian artistic traditions. The reign of the Mughal emperors, in particular, produced works of the most elaborate and exquisite craftsmanship; the decorative tradition is clearly preserved in architectural ornament, though surviving decorative objects themselves, particularly before the 17th century, are far fewer than might be expected. Economic conditions, including competition with machine-made goods imported from English factories, and a change in taste from increasing European influence had disastrous consequences for traditional craftsmanship, especially in the late 19th and 20th centuries.

Pre-Islāmic period. Of the very few objects surviving from the pre-Islāmic period, the most important are fragments of ivory caskets, chairs, and footstools found at Begrām, in eastern Afghanistan, but obviously of Indian origin and strongly reminiscent of the school of Mathurā in the 1st century AD. The work is profusely decorated with carved panels and confirms the wide reputation for superb ivories that India had in ancient times. Nothing as spectacular has come down from the succeeding periods, but stray examples such as the so-called Charlemagne chessman (*c.* 8th century; Cabinet des Medailles, Paris) and two magnificent throne legs, of Orissan workmanship, carved in the shape of griffins with elephant heads (13th century; Freer Gallery of Art, Washington D.C., and Philadelphia Museum of Art), indicate that ivory craftsmanship was always vital. Ancient traditions, relatively unaffected by Islāmic influence, continued in southern India up to modern times. An exquisitely carved box from Vijayanagar (16th century; Prince of Wales Museum of Western India, Bombay) is representative; many other exquisite objects of this period and later are among the treasures of South Indian temples.

Work in ivory

Ritual vessel from Kollur, Mysore, India, copper, *c.* 14th century. In the Prince of Wales Museum of Western India, Bombay.
P. Chandra

There is even less evidence of what the decorative work in metal was like. The practice of re-using the metal by melting unserviceable items may account for the paucity of objects, for there is little doubt that the craft was always flourishing. A hoard found at Kolhāpur, consisting of plates, various kinds of vessels, lamps and *objets d'art,* including a superb bronze elephant with riders, constitutes the most important surviving group of metal objects and is datable to about the 2nd century AD. Some fine examples of ritual utensils, notably elaborate incense burners, of the 8th–9th century have been excavated at Nālandā; and a large number of 14th-century ceremonial vessels of complex design and excellent workmanship, and apparently belonging to the local temple, were discovered at Kollur, in Mysore state.

Gold played an extremely important role in the manufacture of jewelry, but once again the finds are hardly commensurate with tradition. Small amounts of gold jewelry have been excavated at Mohenjo-daro and Harappā (3rd millennium BC); and, in the historical period, a very important group, of delicate workmanship, has been excavated at Taxila (*c.* 2nd century AD).

From earliest times, India has been famous for the variety and magnificence of its textiles. In this case, however, the Indian climate has been particularly destructive; virtually nothing has survived the heat and moisture. Besides the testimony of literature and the evidence of figural sculpture, only a few fragments of printed textiles are preserved—at Fusṭāṭ in Egypt, where they had been exported. These date approximately to the 14th century.

Islāmic period. Traditions of craftsmanship established during the Islāmic period came to full flower during the reign of the Mughal dynasty. Surviving works of decorative art are more abundant, though once again there are hardly as many examples as might be expected, particularly from the 16th and 17th centuries. According to literary testimony and the few available examples, the finest objects were undoubtedly made in the imperial workshops set up in large number at the capital and in the great cities of the empire, where they were nourished by local traditions. Well-organized, these shops specialized in particular items, such as textiles, carpets, jewelry, ornamental arms and armour, metalware, and jade. Textile manufacture must have been enormous, considering the demands of court and social etiquette and ritual. Contributing to the popularity of tapestries, curtains, draperies, canopies, and carpets in contemporary architecture were the nomadic tenting traditions of the Mughal rulers.

Popularity of textiles

P. Chandra

Detail of a Kashmir shawl, wool embroidery, 19th century. In the Prince of Wales Museum of Western India, Bombay.

The variety of techniques employed in the manufacture of textiles was infinite, ranging from printed and painted patterns to the exquisite embroidery decoration of woolen shawls and the costly figured brocading of silk. An important contribution to carpet weaving was the landscape carpet that reproduced pictorial themes inspired by miniature painting. Much of the surviving textile work dates from the 18th century or later, though the 16th and 17th centuries produced works of the most outstanding quality.

In response to growing European trade, a considerable amount of furniture (chairs, cabinets, chests of drawers, and the like) was produced, mostly wood inlaid with ivory. Many of these pieces have been preserved in the kinder European climate. Although the furniture made for export gives some idea of the craft in India, it must be emphasized that only the ornamental and figural work was Indian, while the form was European. Also in a hybrid Indo-European style were the Christian objects produced by a local school of ivory carvers at Goa.

Metal objects of sumptuous quality were also made, a unique example of which is a splendid, elaborately chiselled 16th-century cup in the Prince of Wales Museum of Western India in Bombay. This tradition was continued in the 17th and particularly the 18th century, when vessels made of a variety of metals and adorned with engraved, chiselled, inlaid, and enamelled designs were very popular. Arms and armour, in particular, were decorated with the skill of a jeweler. Particularly striking are the carved hilts, often done in animal shapes.

Jade or jadeite was much fancied by the rich and was used together with crystal to make precious vessels as well as sword and dagger hilts. A rather large number of 18th- and 19th-century objects have survived, but they are often of nondescript quality. The greatest period for jade carving seems to have been the 17th century; a few outstanding examples associated with the emperors Jahāngīr and Shāh Jahān are of singular delicacy and perfection. The practice of inlaying jade, and also stone, with precious or semiprecious stones became more popular with the reign of Shāh Jahān and increasingly characteristic of Indian jade craftsmanship from that time on.

Architectural decoration provides a clear idea of the range of ornamental patterns used by the Mughal artist. They consisted mainly of arabesques (intricate interlaced patterns made up of flower, foliage, fruit, and sometimes animal and figural outlines) and infinitely varied geometric patterns—motifs shared with the rest of the Muslim world—together with floral scrolls and other designs adapted from Indian traditions. As a whole, the Mughal decorative style tends to endow ornamental patterns with a distinctive plasticity not seen in the more truly two-dimensional Iranian and Arab work. From the 17th century, a type of floral spray became the most favoured motif and was found on almost every decorated object. The motif, symmetrical but relatively naturalistic at the beginning, became progressively stiff and stylized, but never lost its importance in the ornamental vocabulary.

VISUAL ARTS OF SRI LANKA (CEYLON)

The art of Sri Lanka is closely allied to that of India but presents several distinctive features that make a separate treatment convenient. There is, first, the considerable transformation of Indian influences, resulting in an idiom of great power and individuality. Sri Lanka also often served as a geographical pocket in which styles that had disappeared in India were preserved, which accounts for the anachronistic features of some phases of Sinhalese art. It also appears that although predominant influences were from neighbouring southern India, this was not exclusively

Distinction between art of Sri Lanka and that of India

Abhayagiri *dagāba* in the Jetavana at Anurādhapura, Sri Lanka, *c.* 4th century.
ZEFA

so, and styles flourishing in western and northern India, too, contributed to the formulation of Sinhalese art. The difficulties in the study of the art are considerable: the long, unbroken Buddhist traditions and the piety of the rulers and the people have led to the successive renovation of monuments; and in the absence of firmly dated monuments, one of the few relatively reliable tools of study is comparison with Indian art, an approach full of pitfalls and shortcomings.

Architecture. The most impressive monuments are the great *stūpa*s, some of gigantic size and considerable antiquity but often reconstructed in the course of the centuries. They generally have a triple circular base, and as in early Indian *stūpa*s, a hemispherical dome with a miniature railing on top, and a multiple parasol that tends to solidify into a conical structure in the course of time. The material is brick, sometimes covered with plaster and white paint. An important feature are the platforms (*vāhalakaḍa*s) at the cardinal points, often adorned with sculpture. There are many *stūpa*s at the ancient capital of Anurādhapura, at Polonnaruva, and at other sites; of these the Jetavana at Anurādhapura is the largest, though now largely ruined.

ZEFA

The *vaṭadāgē* at Polonnaruva, Sri Lanka, 12th century.

Small *stūpa*s were often placed in a circular building with a domical metal and timber roof supported by concentric rows of stone pillars. This type of building, known in ancient India as the *caityagṛha,* was very popular in Sri Lanka, though it had disappeared at a fairly early period in the country of its origin. A famous example is the *vaṭadāgē* at Polonnaruva, a structure of great elegance. The dome itself, being of perishable material, has not survived. The *geḍigē,* or large rectangular hall with a corbelled brick vault, housing a Buddha image, is first found in Sri Lanka from the 8th century AD; the most impressive example is the Laṅkātilaka at Polonnaruva built by Parākramabāhu I in the 12th century.

Literature testifies to the existence of elaborate royal and priestly residences of wood, which have largely disappeared. The Lohapāsāda at Anurādhapura, traditionally ascribed to Duṭṭhagāmaṇi (101–77), was originally a nine-story building, now destroyed except for the large number of stone pillars that supported the upper floors. Sigiriya, a 6th-century fortress city with extensive remains, is another notable example of secular architecture.

Sculpture. The earliest sculpture, perhaps, is from the platforms, or *vāhalakaḍa*s, of the Kaṇṭaka Cetiya, at Mihintalē, and reveals an archaistic style indebted to 1st-century-BC Indian sculpture of Sānchi and Amarāvatī regions. A certain simplicity and restraint characteristic of most Sinhalese work is present even at this early stage. The first Buddha images show a pronounced relationship to examples from Andhradeśa of the 2nd–3rd century AD but often possess considerable vigour, revealing the contribution of the local sculptor. Several fine images are known, one of the best of which is at Ruanveli, Anurādhapura, now very badly restored.

Dated monuments are absent from the 5th to the 12th centuries, but an approximate idea of stylistic development can be obtained by a comparative study of Indian examples. An outstanding image, rather hideously repaired in recent years, is a great seated Buddha in Anurādhapura, the smooth and abstract modelling of which recalls the school of Sārnāth of the 5th–6th century. At Isurumuni, near Anurādhapura, are some marvellous reliefs carved on rocks. One of these depicts elephants at play, and another, a seated man with the head of a horse carved in the background. These fine sculptures recall the South Indian style of the 7th century. A radiant amorous couple carved

Nāga stele from Anurādhapura, Sri Lanka, 10th century.
George Holton—Photo Researchers

in relief on a stone slab, also at Isurumuni, represents Sinhalese sculpture at its most joyous.

Sculptured staircases

Of about the same period or a little later, are exquisitely sculptured staircases decorated with moonstones, and stelae, or commemorative pillars, carved with a guardian *nāga,* a spirit with combined superhuman and serpent qualities. The latter are among the finest examples of Sinhalese sculpture, the full and weighty modelling relieved by the skillful movement of clearly chiselled ornament. The Ratnapāsāda at Anurādhapura and the eastern staircase of the *vaṭadāgē* at Polonnaruva possess particularly superb specimens. Moonstones—decorated with bands of floral motifs, geese, and a row of animals consisting of a lion, bull, elephant, and horse—placed at the bottom of the staircase, testify to the great taste and elegance that mark Sinhalese decorative carving. At Anurādhapura and related sites a certain freedom characterizes the work, while the slightly later examples at Polonnaruva are stiffer but technically brilliant.

P. Chandra

Painted figure of an *apsaras* from Sigiriya, Sri Lanka, 6th century.

A colossal Buddha, 42 feet (13 metres) high, at Avukana, testifies to the increasing hardness of the Sinhalese style, which, even so, never ceases to be moving. Large images of the Buddha at the Gal Vihāra and a figure supposedly representing Parākramabāhu at Potgal Vihāra, both at Polonnaruva, are of the 12th century. They are figures of great majesty and surpass contemporary work in southern India. After the 13th century, Sinhalese sculpture began to decline, though work of some decorative value was produced up to the 19th century.

Painting. The rock at Sigiriya is adorned with a series of exquisitely painted *apsaras*es (nymphs) showering flowers, their torsos emerging from clouds. The paintings are dated to the 6th century AD; in their plastic resiliency they are reminiscent of contemporary work in India. The next important group of wall paintings come from Tivaṁkapatimā-ghara at Polonnaruva. Although dated to the 12th or 13th century, the figures continue to be modelled, relatively unaffected by the linear distortions of the western Indian style that was flourishing in India. Eighteenth-century paintings, with their flat figures arranged in horizontal rows, reflect contemporary styles of southern India.

(P.Ch.)

BIBLIOGRAPHY

Literature: (Sanskrit, Pāli, and Prākrit): The old literature of Southeast Asia has been more extensively described than any of the modern literatures. Though antiquated, MORIZ WINTERNITZ, *Geschichte der indischen litteratur,* 3 vol. (1908–22; Eng. trans., *A History of Indian Literature,* 2nd ed. 1959–67), is still very useful. So is ARTHUR B. KEITH, *A History of Sanskrit Literature* (1928, reprinted 1956), which, however, does not include the Sanskrit theatre. For the old literature of the Veda, ARTHUR A. MACDONNELL, *A History of Sanskrit Literature* (1900), remains very helpful as a survey. A full inventory of the literature is given by S.N. DAS GUPTA and S.K. DE, *A History of Sanskrit Literature, Classical Period,* 2nd ed. (1962). The epochal material is best treated by EDWARD W. HOPKINS, *The Great Epic of India* (1901). On the Sanskrit play specifically, the study by the French scholar SYLVAIN LEVI, *Le Théâtre indien* (1890), remains an important contribution. The best introduction to the narrative literature is to be found in CHARLES H. TAWNEY (trans.), *The Ocean of Story,* ed. by NORMAN M. PENZER, 10 vol. (1923–28, reprinted 1968). GEORGE L. HART, *The Relation Between Tamil and Classical Sanskrit Literature* (1976), is an argument that the two literatures stem from a common source.

Modern Indian literatures: The literatures in the modern Indian languages are bibliographically underrepresented in English. For some of them the best sources are to be found written in those languages themselves. The following bibliography must confine itself to works written in more accessible languages. (*Hindi*): A good though incomplete inventory of the older literature in Hindi and Hindustani is found in JOSEPH GARCIN DE TASSY, *Histoire de la littérature hindouie et hindoustanie,* 2nd ed., 3 vol. (1870–71, reprinted 1968). A useful guide up to its date is EDWIN GREAVES, *A Sketch of Hindi Literature* (1918). A survey of the more modern literature in Hindi is R.A. DWIVELDI, *A Critical Survey of Hindi Literature* (1966). (*Assamese*): Among the few works available is B.K. BARUA, *Assamesè Literature* (1941) and *A History of Assamese Literature* (1965). (*Bengali*): The best extensive introduction to the literature in Bengali is that of SUKUMAR SEN, *History of Bengali Literature* (1960). Another useful source is J.C. GHOSH, *Bengali Literature* (1948). (*Marathi*): Many works on Marathi literature are written in Marathi itself. A good guide is G.C. BHATE, *History of Modern Marathi Literature, 1800–1938* (1939). (*Gujarati*): Little is written in English on Gujarati literature. To be recommended is K.M. MUNSHI, *Gujarāt and Its Literature from Early Times to 1852,* 3rd ed. (1967). A useful older study is K.M. JHAVERI, *Milestones in Gujarati Literature* (1914). (*Punjabi*): A good survey of Punjabi is given by MOHAN SINGH, *An Introduction to Panjabi Literature* (1951). For information about literature in the smaller Indo-Aryan languages, see the symposium of the All-India Writers' Conference, *Writers in Free India* (1950). (*Muslim contributions*): The best short introduction to the cultural and intellectual life of the Moslems of the subcontinent is AZIZ AHMAD, *An Intellectual History of Islam in India* (1969). A comprehensive survey of the literature in Urdu produced in South India, especially in the medieval kingdoms of Bijāpur and Golconda and in the later state Hyderābād is the Urdu work *Dekan men Urdu* by NASIRRUDDIN HASHMI (1963). A study of the convention of classical Urdu poetry in the light of the writings of three Urdu poets of 18th-century Delhi is RALPH RUSSELL and KHURSHIDUL ISLAM, *Three Mughal Poets: Mir, Sauda, Mir Hasan* (1968). The latest and most comprehensive survey of literature produced in Persian in various countries,

including India and Pakistan, is JAN RYPKA, *History of Iranian Literature* (1968). A useful introduction is MUHAMMAD SADIQ, *A History of Urdu Literature* (1964). (*Tamil*): KAMIL V. ZVELEBIL, *Tamil Literature* (1974), is an introduction to and critical study of the literature. Much useful information is found in XAVIER S. THANI NAYAGAM, *A Reference Guide to Tamil Studies* (1966). Fuller treatment is given in C. and H. JESUDASAN, *A History of Tamil Literature* (1961). Especially recommended are also T.P. MEENAKSHISUNDARAM, *A History of Tamil Literature* (1965); and J.M. SOMASUNDARAM PILLAI, *A History of Tamil Literature with Texts and Translations from the Earliest Times to 600 A.D.* (1968). A good account of Telugu literature is P. CHENCHAYYA and R.M. BHUJANGA RAO BHADUR, *A History of Telugu Literature* (1928). More recent is P.T. RAJU, *Telugu Literature* (1944); and GIDUGU VENKAJA SITAPATI, *History of Telugu Literature* (1968). Very little has been written on Kannada literature. Mention can be made of the older EDWARD P. RICE, *A History of Kanarese Literature*, 2nd ed. rev. and enl. (1921); and of H. THIPPERUDA SWAMY, *The Vīraśaiva Saints* (1968). The literature in Malayalam is sketched in K.M. GEORGE, *A Survey of Malayalam Literature* (1968). Further mention can be made of K.K. NAIR, *A History of Malayalam Literature* (1971); and of P.K. PARAMESWARAN NAIR, *History of Malayalam Literature* (Eng. trans. 1967). Finally, among the very few books in English on the literature of Ceylon (Sri Lanka), prominent mention can be made of CHARLES EDMUND GODAKUMBURA, *The Literature of Ceylon* (1963).

Music: ARNOLD A. BAKE, "The Music of India," in *The New Oxford History of Music*, vol. 1 (1957), a general chapter on Indian music dealing with the philosophical background, Vedic chant, the ancient musical system, the modern classical system, and musical instruments; ELISE B. BARNETT, "Special Bibliography: The Art Music of India," *Ethnomusicology*, 14:278–312 (1970), a listing of books and articles on Indian music, published since 1959, which includes some publications on folk and religious music, dance, and drama; SUDHIBHUSHAN BHATTACHARYA, *Ethnomusicology and India* (1968), a synchronic approach attempting to relate folk, tribal, religious, and classical music in terms of the cultural background—includes outline notations in Indian *sargam;* ALAIN DANIELOU, *The Rāga-s of Northern Indian Music* (1968), an individualistic interpretation of modern North Indian *ragas*, based partly on ancient theory; B.C. DEVA, *Psychoacoustics of Music and Speech* (1967), a collection of articles on various aspects of music and speech, with emphasis on acoustics and the scientific study of Indian music; ARTHUR H. FOX-STRANGWAYS, *The Music of Hindostan* (1914, reprinted 1965), a work of wide scope including discussion of Vedic chant, folk music, and modern Indian classical music (includes notations in Western staff and analogies with Western music); O.C. GANGOLY, *Rāgas and Rāginīs*, 2 vol. (1934–35, reprinted 1948), a historical study that traces the systems of classifying *ragas* in Indian musical treatises, including a discussion of the time-theory of *ragas* as well as their iconography; NAZIR A. JAIRAZBHOY, *The Rāgas of North Indian Music* (1971), a technical work dealing with the structure and evolution of North Indian *ragas* (includes a 45 r.p.m. record of *raga* demonstrations performed on the *sitar* by VILAYAT KHAN, and extensive notations in Western staff and Indian *sargam*); BABURAO JOSHI and A. LOBO, *Introducing Indian Music* (n.d.), a series of four long-playing records, including musical examples and commentary, illustrating the main features of North Indian classical music, with accompanying booklet; WALTER KAUFMANN, *The Rāgas of North India* (1968), description and notations, in Western staff, of about 230 *ragas* of modern North Indian music; ALLEN KEESE, *The Sitar Book* (1968), an elementary guide to the *sitar*, with some description of playing techniques, musical exercises, and *gats* in ten *ragas;* HERBERT A. POPLEY, *The Music of India*, 3rd ed. (1970), a general work including discussion of historical background, scale, *raga, tala*, musical form, and instruments, with notations in Western staff and Indian *sargam;* HAROLD S. POWERS, "Indian Music and the English Language: A Review Essay," *Ethnomusicology*, 9:1–12 (1965), a survey of the most important literature on Indian music written in the English language; and "An Historical and Comparative Approach to the Classification of Rāgas (with an Appendix on Ancient Indian Tunings)," in *Selected Reports* of the Instiute of Ethnomusicology, UCLA, 1:1–78 (1970), a scholarly monograph that attempts to show the relationship between North and South Indian *ragas* that bear the same name but now differ in scale—includes material on ancient Indian music and gives many musical examples in Western staff; SWAMI PRAJNANANDA, *A History of Indian Music*, vol. 1 (1963), a technical work dealing with the origins and the music of the ancient period; P. SAMBAMOORTHY, *South Indian Music*, 5 vol. (1958–69), a comprehensive work covering many aspects of South Indian musical theory, both synchronically and diachronically; RAVI SHANKAR, *My Music, My Life* (1969), a general book combining autobiographical and biographical material with a discussion of Indian music history, theory, and instruments, including a manual for the *sitar*. BONNIE C. WADE, *Music in India: The Classical Traditions* (1979), a discussion of performance, theory, and basic instruments of both the North and South; M.R. GUATAM, *The Musical Heritage of India* (1981), a history with emphasis on classical traditions of both the North and South; WIM VAN DER MEER, *Hindustan: Music in the Twentieth Century* (1980), an introduction with emphasis on vocal music; DANIEL M. NEUMAN, *The Life of Music in North India* (1980), an analysis of the place in society of the musician.

Dance and theatre: The main source book of Indian classical dance and theatre is the *Nātya-śāstra*, ascribed to BHARATA MUNI, trans. by MANMOHAN GHOSH, 2 vol. (1950–61), which deals with ceremonies, gesture language, architecture, production styles, makeup, and costumes. A.K. COOMARASWAMY, *The Dance of Shiva*, rev. ed. (1957), brings alive the philosophy and aesthetics of Hindu dance. For general understanding of classical dance forms and techniques, see RINA SINGHA and REGINALD MASSEY, *Indian Dances* (1967), which includes semiclassical styles, modern ballet, and biographical notes on dancers and gurus. FAUBION BOWERS, *The Dance in India* (1953), is a fascinating description of the four major classical dances. K. BHARATHA IYER, *Kathakali* (1955), is perhaps the best work on this dance-drama, with detailed descriptions of characters, historical background, and interpretation of dramatic symbols, with photographs and line drawings. KAPILA VATSYAYAN, *Classical Indian Dance in Literature and the Arts* (1968), surveys dance as found in temple sculpture, the plastic arts, and literature—a scholarly work with photos. For tribal dances and ceremonies of Central India, see VERRIER ELWIN, *The Muria and Their Ghotul* (1947; abridged ed., *The Kingdom of the Young*, 1968). For dramatic forms, production techniques, and classical rules the best source book is also the *Nātya-śāstra*, ascribed to BHARATA MUNI, *op. cit.* ARTHUR B. KEITH, *Sanskrit Drama in Its Origin, Development, Theory and Practice* (1924, reprinted 1959), remains a standard scholarly critical work for comparative analysis of Sanskrit plays. P. LAL, *Great Sanskrit Plays* (1964) are actable transcreations in crisp modern English. A delightfully-written survey is FAUBION BOWERS, *Theatre in the East* (1956), which puts Indian dance and theatre in the larger perspective of South Asia with vivid and perceptive descriptions. For a general survey of classical, folk, and modern drama with sidelights on opera and ballet, illustrated by photographs and sketches, see BALWANT GARGI, *Theatre in India* (1962). HEMENDRA NATH DAS GUPTA, *The Indian Stage*, 4 vol. (1934–44), deals mainly with the growth of Bengali theatres, actors, and productions in exhaustive detail with reproductions of period notebooks and papers. BALWANT GARGI, *Folk Theatre in India* (1966), is an eyewitness account of religious, secular, and masked dramas in villages, with over 100 photographs and line sketches. See also J.C. MATHUR, *Drama in Rural India* (1964). BERYL DE ZOETE, *Dance and Magic Drama in Ceylon* (1957), is a vivid account of rituals and magical masked dances in a diary form of day-to-day performances. E.R. SARACHCHANDRA, *The Folk Drama of Ceylon*, 2nd ed. (1966), is a scholarly work on the development and background of Sinhalese folk dramas and cults of exorcism. For puppets and masks, see two small pamphlets: J. TILAKASIR, "Puppetry in Ceylon" and SIRI GUNASINGHE, "Masks of Ceylon" (both published by the Department of Cultural Affairs, Ceylon, 1962). For the history of Kolam and description of various characters see O. PERTOLD, "The Ceremonial Dances of the Sinhalese." *Archiv Orientální*, vol. 2 (1930). For Devil Dances and their interpretation in the light of witchcraft rituals, see DANDRIS DE SILVA GUNARATNA, "Demonology and Witchcraft in Ceylon," *J. Ceylon Brch. R. Asiat. Soc.*, vol. 4, no. 13 (1861); PAUL WIRZ, *Exorzismus und Heilkunde auf Ceylon* (1941); RACHEL VAN M. BAUMER and JAMES R. BRANDON (eds.), *Sanskrit Drama in Performance* (1981), essays on Ancient Indian theatrical performance.

Visual arts (General works): VINCENT A. SMITH, *A History of Fine Art in India and Ceylon*, 3rd ed. rev. and enl. (1962); A.K. COOMARASWAMY, *History of Indian and Indonesian Art* (1927, reprinted 1965); and BENJAMIN ROWLAND, *Art and Architecture of India*, 3rd ed. rev. (1967), are general introductions with good bibliographies. A.K. COOMARASWAMY, *Figures of Speech or Figures of Thought* (1946), and *Tranformation of Nature in Art* (1934, reprinted 1956), contain important essays which discuss Indian aesthetic theories from the traditional point of view. A clear classification of Hindu images with particular reference to south India has been made in T.A. GOPINATHA RAO, *Elements of Hindu Iconography*, 2 vol. in 4 (1914–16, reprinted 1968); and J.N. BANERJEA, *The Development of Hindu Iconography*, 2nd ed. rev. and enl. (1956), is an analytical introduction to the subject. N.K. BHATTASALI, *Iconography of Buddhist and Brahmanical Sculptures*

in the Dacca Museum (1929); BENOYTOSH BHATTACHARYYA, *The Indian Buddhist Iconography*, 2nd ed. (1958); and ALFRED FOUCHER, *Étude sur l'iconographie bouddhique de l'Inde*, 2 vol. (1900–05), are important studies of Buddhist iconography. A.K. COOMARASWAMY, *Yaksas*, 2 vol. (1928–31), is a masterly study of early iconography. HEINRICH ZIMMER, *Myths and Symbols in Indian Art and Civilization* (1946, reprinted 1963), discusses some important symbols of Indian art. Good collections of photographs are in JAMES BURGESS, *The Ancient Monuments, Temples and Sculptures of India*, 2 vol. (1897–1911); A.K. COOMARASWAMY, *Viśvakarma* (1912); STELLA KRAMRISCH, *The Art of India* (1954); and HEINRICH ZIMMER, *The Art of Indian Asia*, 2 vol. (1955).

Architecture: JAMES FERGUSSON, *History of Indian and Eastern Architecture*, rev. ed., 2 vol. (1910, reprinted 1967); PERCY BROWN, *Indian Architecture*, 2 vol., 5th ed. (1965); and S.K. SARASWATI, "Architecture," in R.C. MASUMDAR (ed.), *History and Culture of the Indian People*, vol. 3 and 5 (1954–57), are standard works that survey the entire history of Indian architecture. JAMES FERGUSSON and JAMES BURGESS, *The Cave Temples of India* (1880, reprinted 1969), is a comprehensive account of rock-cut architecture. STELLA KRAMRISCH, *The Hindu Temple*, 2 vol. (1946), is concerned with principles and symbolism, and KRISHNA DEVA, *Temples of North India* (1969), presents a synoptic view of the various north Indian styles. G. JOUVEAU-DUBREUIL, *Archéologie du sud de l'Inde*, 2 vol. (1914), analyses the south Indian style. K.R. SRINVASAN, *Cave Temples of the Pallavas* (1964); and ARTHUR H. LONGHURST, *Pallava Architecture*, 3 vol. (1924–30), are important studies of early south Indian architecture. SIR JOHN MARSHALL, "The Monuments of Muslim India," in *The Cambridge History of India*, vol. 3, pp. 568–640 (1928, reprinted 1965); and PERCY BROWN, "Monuments of the Mughal Period," *ibid.*, vol. 4, pp. 523–576 (1937, reprinted 1963), are important essays on Islamic architecture in India. See also ELIZABETH S. MERKLINGER, *Indian Islamic Architecture: The Deccan 1347–1686* (1981).

Sculpture: S.K. SARASVATI, *A Survey of Indian Sculpture* (1957); and STELLA KRAMRISCH, *Indian Sculpture* (1933), discuss the broad historical and stylistic trends. LUDWIG BACHHOFER, *Early Indian Sculpture* (1929), is a fine stylistic analysis of sculptures from the third century B.C. to the third century A.D. The classic work on Gandhāra art is ALFRED FOUCHER, *L'Art gréco-bouddhique du Gandhâra*, 2 vol. (1905–41), though several of its conclusions are no longer tenable. SIR JOHN MARSHALL, *Taxila*, 3 vol. (1951), discusses works recovered from that site; and HAROLD INGHOLT, *Gandharan Art in Pakistan* (1957, reprinted 1971), provides excellent photographic documentation. R.D. BANERJI, *The Age of the Imperial Guptas* (1933), has a general discussion of the Gupta style; D.R. SAHNI, *Catalogue of the Museum of Archaeology at Sārnāth* (1914), contains information of interest on the school of Sārnāth. ELIKY ZANNAS, *Khajurāho* (1960); K.C. PANIGRAHI, *Archaeological Remains at Bhubaneswar* (1961); and R.D. BANERJI, *Eastern Indian School of Medieval Sculpture* (1933), are monographs on schools of north Indian medieval sculpture. A.H. LONGHURST, *op. cit.*; and K.A. NILAKANTA SASTRI, *The Cōlas*, 2nd ed. rev. (1955), contain information on the south Indian medieval styles. C. SIVARAMAMURTI, *South Indian Bronzes* (1963); P.R. SRINIVASAN, *Bronzes of South India* (1963); DOUGLAS E. BARRETT, *Early Cōla Bronzes* (1965), are important studies of south Indian bronzes; FREDERICK M. ASHER, *The Art of Eastern India: 300–800* (1980), a study of the pre-Pala period.

Painting: In considering the published literature it is important to remember that the study of Indian painting, confined to a limited number of scholars, is of comparatively recent growth, and is therefore full of controversies and uncertainties which keep shifting with the discovery of fresh materials. The standard work on Ajanta is GHULAM YAZDANI, *Ajanta*, 4 vol. (1930–55); and on the western Indian style, MOTI CHANDRA, *Jain Miniature Paintings from Western India* (1949). Much interesting information on the period of transition to the Rajasthani and Mughal styles has been brought together in KARL J. KHANDALAVALA and MOTI CHANDRA, *New Documents of Indian Painting* (1969). The Mughal school has been ably presented in PERCY BROWN, *Indian Painting under the Mughals, A.D. 1550 to A.D. 1750* (1924); and STUART C. WELCH, *The Art of Mughal India* (1964). DOUGLAS E. BARRETT, *Painting of the Deccan, XVI–XVII Century* (1958), is a brief introduction to the subject. The main publication on the Company style is MILDRED and WILLIAM G. ARCHER, *Indian Painting for the British, 1770–1880* (1955). The classic work on Pahari and Rajasthani painting is A.K. COOMARASWAMY's pioneering *Rajput Painting*, 2 vol. (1916). Fresh discoveries which have considerably changed the understanding of its history are summarized in KARL KHANDALAVALA, MOTI CHANDRA, and PRAMOD CHANDRA, *Miniature Painting: A Catalogue of the Exhibition of the Sri Motichand Khajanchi Collection* (1960). MOTI CHANDRA, *Mewar Painting in the Seventeenth Century* (1957); WILLIAM G. ARCHER, *Indian Painting in Bundi and Kotah* (1959); PRAMOD CHANDRA, *Bundi Painting* (1959); ERIC DICKINSON and KARL KHANDALAVALA, *Kishangarh Painting* (1959); WILLIAM G. ARCHER, *Central Indian Painting* (1958); and ANAND KRISHNA, *Malwa Painting* (1963), are informative summaries of the growing knowledge of the various schools of Rājasthān. The standard work, illustrated copiously, on the Pahari style is KARL KHANDALAVALA, *Pahārī Miniature Painting* (1958), and different in its account from WILLIAM G. ARCHER, *Indian Painting in the Punjab Hills* (1952). Books which cover most of the schools and are profusely illustrated include N.C. MEHTA, *Studies in Indian Painting* (1926); WILLIAM G. ARCHER, *Indian Miniatures* (1960); ROBERT SKELTON, *Indian Miniatures from the XVth to the XIXth Centuries* (1961); DOUGLAS E. BARRETT and BASIL GRAY, *Painting of India* (1963); and STUART C. WELCH and MILO C. BEACH, *Gods, Thrones and Peacocks: Northern Indian Painting from Two Traditions, Fifteenth to Nineteenth Centuries* (1965). (*Ceylon*): Standard works on Sinhalese art are SENERAT PARANAVITANA, *The Stūpa in Ceylon* (1946), *Art and Architecture of Ceylon: Polonnaruva Period* (1954), and *Ceylon: Paintings from Temple, Shrine and Rock* (1957). MOTI CHANDRA, *Studies in Early Indian Painting* (1975), covers the 5th through 16th centuries; CALAMBUR SIVARAMAMURTI, *The Art of India* (1977), covering all types of art with 1175 illustrations; STUART C. WELCH, *Room for Wonder: Indian Painting During the British Period, 1760–1880* (1978), an exhibition catolog with detailed comments on 125 illustrations.

Decorative arts: Scholarly literature on the decorative arts in India is scanty and mainly in learned journals. The *Journal of Indian Art and Industries* (1886–1916) is the most important and contains numerous pioneering studies. SIR GEORGE WATT, *Indian Art at Delhi* (1903); and SIR GEORGE BIRDWOOD, *The Industrial Arts of India*, 2 vol. (1880), are for the most part descriptive texts emphasizing the technical aspects of the decorative arts as they had survived up to the closing years of the 19th century. JOHN IRWIN, "Textiles and the Minor Arts," in LEIGH ASHTON (ed.), *The Art of India and Pakistan*, pp. 201–237 (1950), is a brief historical survey of the subject. MOTI CHANDRA, "Ancient Indian Ivories," *Bulletin of the Prince of Wales Museum of Western India*, no. 6, pp. 4–63 (1957–59), is a monograph on the history of Indian ivory carving. THOMAS H. HENDLEY, *Asian Carpets* (1905), treats Indian examples in the important collections of the Maharaja of Jaipur. GEORGE P. BAKER, *Calico Painting and Printing in the East Indies in the XVIIth and XVIIIth Centuries* (1921), is the most important work on the subject; WILBRAHAM EGERTON, *An Illustrated Handbook of Indian Arms* (1880), catalogs and describes the wide range and achievement of the armourer's craft.

Southeast Asia

Southeast Asia is the vast region of Asia situated east of the Indian subcontinent and south of China. It consists of two dissimilar portions: a continental projection (commonly called mainland Southeast Asia) and a string of archipelagoes to the south and east of the mainland (insular Southeast Asia). Extending some 700 miles (1,100 kilometres) southward from the mainland into insular Southeast Asia is the Malay Peninsula; this peninsula structurally is part of the mainland, but it also shares many ecological and cultural affinities with the surrounding islands and thus functions as a bridge between the two regions.

Mainland Southeast Asia is divided into the countries of Cambodia, Laos, Myanmar (Burma), Thailand, Vietnam, and the small city-state of Singapore at the southern tip of the Malay Peninsula; Cambodia, Laos, and Vietnam, which occupy the eastern portion of the mainland, often are collectively called the Indochinese Peninsula. Malaysia is both mainland and insular, with a western portion on the Malay Peninsula and an eastern part on the island of Borneo. Except for the small sultanate of Brunei (also on Borneo), the remainder of insular Southeast Asia consists of the archipelagic nations of Indonesia and the Philippines.

Southeast Asia stretches some 4,000 miles at its greatest extent (roughly from northwest to southeast) and encompasses some 5,000,000 square miles (13,000,000 square kilometres) of land and sea, of which about 1,736,000 square miles is land. Mount Hkakabo in northern Myanmar on the border with China, at 19,295 feet (5,881 metres), is the highest peak of mainland Southeast Asia. Although the modern nations of the region are sometimes thought of as being small, they are—with the exceptions of Singapore and Brunei—comparatively large. Indonesia, for example, is more than 3,000 miles from west to east (exceeding the west-east extent of the continental United States) and more than 1,000 miles from north to south; the area of Laos is only slightly smaller than that of the United Kingdom; and Myanmar is considerably larger than France.

All of Southeast Asia falls within the tropical and subtropical climatic zones, and much of it receives considerable annual precipitation. It is subject to an extensive and regular monsoonal weather system (*i.e.*, one in which the prevailing winds reverse direction every six months) that produces marked wet and dry periods in most of the region. Southeast Asia's landscape is characterized by three intermingled physical elements: mountain ranges, plains and plateaus, and water in the form of both shallow seas and extensive drainage systems. Of these, the rivers probably have been of the greatest historical and cultural significance, for waterways have decisively shaped forms of settlement and agriculture, determined fundamental political and economic patterns, and helped define the nature of Southeast Asians' worldview and distinctive cultural syncretism. It also has been of great importance that Southeast Asia, which is the most easily accessible tropical region in the world, lies strategically astride the sea passage between East Asia and the Middle Eastern–Mediterranean world.

Within this broad outline, Southeast Asia is perhaps the most diverse region on Earth. The number of large and small ecological niches is more than matched by a staggering variety of economic, social, and cultural niches Southeast Asians have developed for themselves; hundreds of ethnic groups and languages have been identified. Under these circumstances, it often is difficult to keep in mind the region's underlying unity, and it is understandable that Southeast Asia should so often be treated as a miscellaneous collection of cultures that simply do not quite fit anywhere else.

Yet from ancient times Southeast Asia has been considered by its neighbours to be a region in its own right and not merely an extension of their own lands. The Chinese called it Nanyang and the Japanese Nan'yō, both names meaning "South Seas," and South Asians used such terms as Suvarnabhūmi (Sanskrit: "Land of Gold") to describe the area.

Modern scholarship increasingly has yielded evidence of broad commonalities uniting the peoples of the region across time. Studies in historical linguistics, for example, have suggested that the vast majority of Southeast Asian languages—even many of those previously considered to have separate origins—either sprang from common roots or have been long and inseparably intertwined. Despite inevitable variation among societies, common views of gender, family structure, and social hierarchy and mobility may be discerned throughout mainland and insular Southeast Asia, and a broadly common commercial and cultural inheritance has continued to affect the entire region for several millennia. These and other commonalities have yet to produce a conscious or precise Southeast Asian identity, but they have given substance to the idea of Southeast Asia as a definable world region and have provided a framework for the comparative study of its components. (W.H.F.)

This article first provides a general overview of the Southeast Asian region, followed by a detailed treatment of Brunei, Cambodia, Laos, Malaysia, Myanmar, Singapore, Thailand, and Vietnam. Although Indonesia and the Philippines are discussed below in their regional context, the detailed treatments of these two countries are found, respectively, in the articles INDONESIA and PHILIPPINES.

THE REGION

Physical and human geography

THE LAND

Geology and relief. The physiography of Southeast Asia has been formed to a large extent by the convergence of three of the Earth's major crustal units: the Eurasian, Indian-Australian, and Pacific plates. The land has been subjected to a considerable amount of faulting, folding, uplifting, and volcanic activity over geologic time, and much of the region is mountainous. There are marked structural differences between the mainland and insular portions of the region.

Mountain ranges

Mainland Southeast Asia. The mainland is characterized by a series of generally north–south-trending mountain ranges separated by a number of major river valleys and their associated deltas. In many ways these ranges resemble ribs in a fan, where the interstices are deep trenches carved by the rivers. Although the mainland as a whole is similar in a structural sense, its various geologic components and the time periods of their orogenic (mountain-building) episodes differ. Much of the region has been affected by the gradual, continuing collision of the Indian subcontinent with the Eurasian Plate over roughly the past 50 million years, an event that—with diminishing intensity from west to east—has been responsible for deforming the land. Nonetheless, mainland Southeast Asia is relatively stable geologically, with no active or recently active volcanoes and, except in the northwest and north, little seismic activity.

The ranges fan out southward from the southeastern corner of the Plateau of Tibet, where they are tightly spaced. A major rib of this system extends through the entire western margin of Myanmar (Burma); describing an elongated letter S, it consists of (from north to south) the Pātkai Range, Nāga Hills, Chin Hills, and Arakan Mountains. Farther to the south the same rib emerges from beneath the sea to become the Andaman and Nicobar Islands of India.

Another major system extends along a straight north-south axis from eastern Myanmar east of the Salween River through northwestern Thailand to south of the Isthmus of Kra on the Malay Peninsula. It consists of a series of elongated blocks rather than one continuous ridge. The core of these blocks is granite, which has intruded into previously folded and faulted limestone and sandstone. The altitudes of the ranges diminish from above 8,000 feet (2,440 metres) on the Chinese border in the north to below 4,000 feet on the Isthmus of Kra, and the ranges are spread farther apart toward the south.

John Elk/Tony Stone Images

Karst-limestone landscape of the Malay Peninsula along the Krabi River, southern Thailand.

The easternmost major mountain feature on the mainland is the Annamese Cordillera (Chaîne Annamitique) in Laos and Vietnam. In the portion between Laos and Vietnam, the chain forms a nearly straight spine of ranges from northwest to southeast, with a steep face rising from the South China Sea to the east and a more gradual slope to the west. The mountains thin out considerably south of Laos and become asymmetrical in form. The upland zone is characterized by a number of plateau remnants.

The rather neat fanlike pattern of the mountain ranges is interrupted occasionally by several old blocks of strata that have been folded, faulted, and deeply dissected. These ancient massifs now form either low platforms or high plateaus. The westernmost of these, the Shan Plateau of eastern Myanmar, measures some 250 miles (400 kilometres) from north to south and 75 miles from east to west and has an average elevation of about 3,000 feet. The largest of these features is the Korat Plateau in eastern Thailand and west-central Laos. This area actually is more of a low platform, which on average is only a few hundred feet above the floodplains of the surrounding rivers. It consists of a string of hills that direct surface drainage eastward to the Mekong River. The hills range in elevation from 500 to 2,000 feet, with the highest altitudes occurring near the southwestern rim.

Plateaus

The broad river valleys between the uplands and the even wider deltas at the southernmost points contain most of the mainland's lowland areas. These regions generally are covered with alluvial sediments that support much of the mainland's cultivation and, in turn, most of its population centres. The most extensive coastal lowland is the lower Mekong basin, which encompasses most of Cambodia and southern Vietnam. The Cambodian portion is a broad, bowl-shaped area lying just above sea level, with numerous hill outcrops jutting above the landscape; at its centre is a large freshwater lake, the Tonle Sap. To the south the river's vast, flat delta occupies the entire southern tip of Vietnam. Outside the river deltas, the coastal lowlands are little more than narrow strips between the mountains and the sea, except around the southern half of the Malay Peninsula.

The Malay Peninsula stretches south for some 900 miles from the head of the Gulf of Thailand (Siam) to Singapore and thus extends the mainland into insular Southeast Asia. The narrowest point, the Isthmus of Kra (about 40 miles wide), also roughly divides the peninsula into two parts: the long linear mountain ranges of the northern part described above give way just south of the isthmus to blocks of short, parallel ranges aligned north-south, so that the southern portion trends to the southeast and becomes much wider. In areas such as the west coast between southern Thailand and northwestern Malaysia, distinctive karst-limestone landscapes have developed. Peaks on the peninsula range from 5,000 to 7,000 feet in elevation.

Insular Southeast Asia. Characteristic of insular (or archipelagic) Southeast Asia are the chains of islands—the Malay and Philippine archipelagoes—that have been formed along the boundaries of the three crustal segments of the Earth that meet there. Crustal instability is marked throughout the region. Earthquakes and volcanic activity are quite common along the entire southern and eastern margin. One consequence of the seismic activity is that a large number of lakes are found in the region.

The Sunda Shelf

Dominating the region is the Sunda Shelf, the portion of the Asian continental shelf that extends southward from the Gulf of Thailand to the Java Sea. Where the shelf meets and overrides the oceanic crust to the south, the vast volcanic arc of the Greater and Lesser Sunda islands have been formed. The islands are characterized by highland cores, from which flow short rivers across the narrow coastal plains. The shallow waters of the Sunda Shelf are as important to the inhabitants as the land, since the sea has facilitated communication and trade among the islands. At one time, sea levels were considerably lower than now, and land bridges existed on the Sunda Shelf

that connected the islands and allowed plants and animals to migrate throughout the region.

The extreme southeastern islands of Southeast Asia—the eastern Moluccas (Maluku) and the island of New Guinea—lie on the Sahul Shelf, a northwestern extension of Australia, and structurally are not part of Asia. In the east the Philippine Islands rise between two blocks of sinking (subducted) oceanic crust at the boundary of the Eurasian and Pacific plates.

Drainage. Mainland Southeast Asia is drained by five major river systems, which from west to east are the Irrawaddy, Salween, Chao Phraya, Mekong, and Red rivers. The three largest systems—the Irrawaddy, Salween, and Mekong—have their origins in the Plateau of Tibet. These three rivers are somewhat atypical: their middle and upper drainage basins are not broad catchment areas with many small tributaries feeding larger ones but rather consist of a few streams confined to narrow, closely spaced valleys.

The Irrawaddy River flows through western Myanmar, draining the eastern slope of the country's western mountain chain and the western slope of the Shan Plateau. Although the river itself is shorter than either the Salween or the Mekong rivers, its lowland areas are more extensive. Most conspicuous is its delta, which is about 120 miles wide at its base and is expanding rapidly into the Andaman Sea.

The Salween River flows for several hundred miles through southern China before entering eastern Myanmar. In contrast to the Irrawaddy, the Salween is a highlands river throughout nearly all of its course. Its drainage basin is highly restricted with few tributaries, and its delta area is small. Even though the Salween's catchment area is limited and is sheltered from seasonal rains, its water volume fluctuates considerably from season to season.

The Mekong basin

The Mekong—one of the world's great river systems—is the longest river of mainland Southeast Asia and has the largest drainage basin. After flowing for some 1,200 miles through southern China, the Mekong flows for nearly 1,500 more miles through Laos (where it also forms much of the western border of the country), Cambodia, and Vietnam. The Tonle Sap in Cambodia, the largest lake in Southeast Asia, drains into the vast Mekong delta. The area of the lake varies greatly with the precipitation cycle of the region.

The Chao Phraya River is the major river of Thailand and the shortest of the great rivers of the mainland. Rising in the northwestern highlands of Thailand, it drains the western portion of northern Thailand. The densely populated delta contains Bangkok, Thailand's capital and the largest city on the mainland. The Red River of northern Vietnam has the smallest drainage basin of the major rivers. The river follows a narrow valley through southern China and northwestern Vietnam before flowing into a relatively small lowland.

Soils. Southeast Asia, on balance, has a higher proportion of relatively fertile soils than most tropical regions, and soil erosion is less severe than elsewhere. Much of the region, however, is covered by tropical soils that generally are quite poor in nutrients. Often the profusion of plant life is more related to heat and moisture than to soil quality, even though these climatic conditions intensify both chemical weathering and the rate of bacterial action that usually improve soil fertility. Once the vegetation cover is removed, the supply of humus quickly disappears. In addition, the often heavy rainfall leaches the soils of their soluble nutrients, hastens erosion, and damages the soil texture. The leaching process in part results in laterites of reddish clay that contain hydroxides of iron and alumina.

Laterite soils are common in parts of Myanmar, Thailand, and Vietnam and also occur in the islands of the Sunda Shelf, notably Borneo. The most fertile soils occur in regions of volcanic activity, where the ejecta is chemically alkaline or neutral. Such soils are found in parts of Sumatra and much of Java in Indonesia. The alluvial soils of the river valleys also are highly fertile and are intensively cultivated.

Climate. All of Southeast Asia falls within the warm, humid tropics, and its climate generally can be characterized as monsoonal (*i.e.*, marked by wet and dry periods). Changing seasons are more associated with rainfall than with temperature variations. There is, however, a high degree of climatic complexity within the region.

Temperatures. Regional temperatures at or near sea level remain fairly constant throughout the year, although monthly averages tend to vary more with increasing latitude. Thus, with the exception of northern Vietnam, annual average temperatures are close to 80° F (27° C). Increasing elevation acts to decrease average temperatures, and such locations as the Cameron Highlands in peninsular Malaysia and Baguio in the Philippines have become popular tourist destinations in part because of their relatively cooler climates. Proximity to the sea also tends to moderate temperatures.

Precipitation. Much of Southeast Asia receives more than 60 inches (1,500 millimetres) of rainfall annually, and many areas commonly receive double and even triple that amount. The rainfall pattern is distinctly affected by two prevailing air currents: the northeast (or dry) monsoon and the southwest (or wet) monsoon.

The two monsoons

The northeast monsoon occurs roughly from November to March and brings relatively dry, cool air and little precipitation to the mainland. As the southwestward-flowing air passes over the warmer sea, it gradually warms and gathers moisture. Precipitation is especially heavy where the airstream is forced to rise over mountains or encounters a landmass. The east coast of peninsular Malaysia, the Philippines, and parts of eastern Indonesia receive the heaviest rains during this period.

The southwest monsoon prevails from May to September, when the air current reverses and the dominant flow is to the northeast. The mainland receives the bulk of its rainfall during this period. Over much of the southern Malay Peninsula and insular Southeast Asia there is little or no prolonged dry season. This is especially marked in much of the equatorial region and along the east coast of the Philippines.

While the dry and wet monsoons are important in explaining rainfall patterns, so too are such factors as relief, land and sea breezes, convectional overturning and cyclonic disturbances. These factors often are combined with monsoonal effects to produce highly variable rainfall patterns over relatively short distances. While many of the cyclonic disturbances produce only moderate rainfall, others mature into tropical storms—called cyclones in the Indian Ocean and typhoons in the Pacific—that bring heavy rains and destruction to the areas over which they pass. The Philippines are particularly affected by these storms.

Plant life. The seasonal nature and pattern of Southeast Asia's rainfall, as well as the region's physiography, have strongly affected the development of natural vegetation. The hot, humid climate and enormous variety of habitats have given rise to an abundance and diversity of vegetative forms unlike that in any other area of the world. Much of the natural vegetation has been modified by human action, although large areas of relatively untouched land still can be found.

The vegetation can be grouped into two broad categories: the tropical-evergreen forests of the equatorial lowlands and the open type of tropical-deciduous, or "monsoon," forests in areas of seasonal drought. The evergreen forests are characterized by multiple stories of vegetation, consisting of a variety of trees and plants. Although a large diversity of tree species is found in these forests, members of the Dipterocarpaceae family account for roughly half of the varieties. Deciduous forests are found in eastern Indonesia and those parts of the mainland where annual rainfall does not exceed 80 inches. Just as in the equatorial forest, a wide variety of species is normally the rule. Certain species, such as teak, have become highly valued commercially. Teak is found in parts of Indonesia, Myanmar, Thailand, and Laos.

In addition to these two basic types of vegetation, other regional patterns reflect topography. Especially noteworthy are coastal and highland plant communities. Mangrove belts, of which there are more than 30 varieties, occur where silt is deposited in coastal areas. Upland forests dominated by maples, oaks, and magnolias are found especially on mainland mountain slopes.

Deforestation

Human activity has been rapidly altering the stands of virgin forest in Southeast Asia. Most deforestation results from removal for fuelwood and clearing for agriculture and grazing. Although only a relatively small portion of the total land area has been permanently cleared for cultivation—*e.g.*, in Java (Indonesia) and western Luzon (the Philippines)—in some areas shifting cultivation has brought about the replacement of virgin forest with secondary growth. In addition, nearly all countries have commercial logging industries; notable are those in Indonesia, Malaysia, Thailand, and Myanmar. A growing problem has been illegal logging. Thus, timber harvesting has come to contribute significantly to deforestation. Programs in social forestry and reforestation have yet to halt the rapid denuding of the landscape.

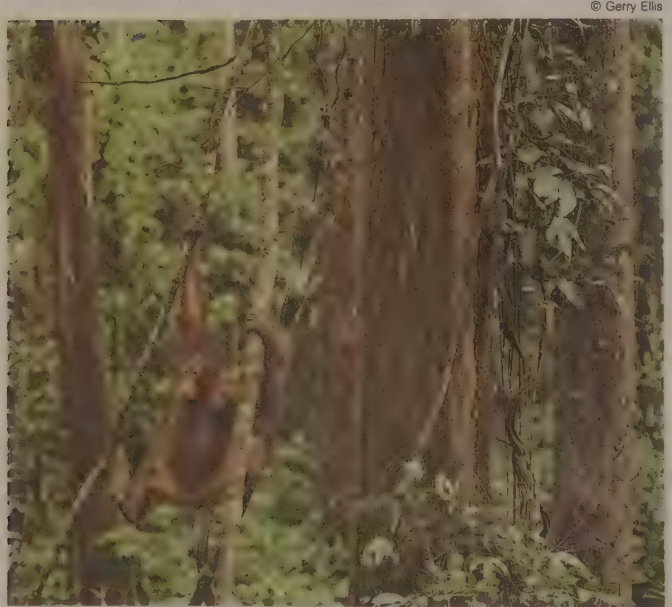
Animal life. Southeast Asia is situated where two major divisions of the world's fauna meet. The region itself constitutes the eastern half of what is called the Oriental, or Indian, zoogeographic region (part of the much larger realm of Megagaea). Bordering along the south and east is the Australian zoogeographic region, and the eastern portion of insular Southeast Asia—Celebes (Sulawesi), the Moluccas, and the Lesser Sunda Islands—constitutes a transition zone between these two faunal regions.

Southeast Asia is notable, therefore, for a considerable diversity of wildlife throughout the region. These differences are especially striking between the species of the eastern and western fringes as well as between those of the archipelagic south and the mainland north. The differences stem largely from the isolation, over varying lengths of geologic time, of species following their migration from the Asian continent. In addition, the tropical rain forests in many parts of the region, with their great diversity of vegetation, have made possible the development of complex communities of animals that fill specialized ecological niches. Especially numerous are arboreal and flying creatures.

The distinction between the two faunal regions is best depicted by their mammal populations. In general, Australia is inhabited largely by marsupials (pouched mammals) and monotremes (egg-laying mammals), while Southeast Asia contains placental mammals and such hybrid species as the bandicoot of eastern Indonesia. Small mammals such as monkeys and shrews are the most numerous, while in many areas the larger mammals have been pushed into more remote areas and national preserves. Bears, gibbons, elephants, deer, civets, and pigs are found in both mainland and insular Southeast Asia, as are diminishing numbers of tigers. The Malayan tapir, a relative of the rhinoceros, is native to the Malay Peninsula and Sumatra, while the tarsier is found in the Philippines and parts of Indonesia. A number of rare endemic species are found in Indonesia and East (insular) Malaysia, including the Sumatran and Javan rhinoceros, the orangutan, the anoa (a dwarf buffalo), the babirusa (a wild swine), and the palm civet.

Rare species

As the pace of development accelerates and populations continue to expand in Southeast Asia, concern has increased regarding the impact of human activity on the region's environment. A significant portion of Southeast Asia, however, has not changed greatly and remains an unaltered home to wildlife. The nations of the region, with only few exceptions, have become aware of the need to maintain forest cover not only to prevent soil erosion but to preserve the diversity of flora and fauna. Indonesia, for example, has created an extensive system of national parks and preserves for this purpose. Even so, such species as the Javan rhinoceros face extinction, with only a handful of the animals remaining in western Java.



A young orangutan in the tropical-evergreen forest of northern Borneo, Sabah, East Malaysia.

THE PEOPLE

By the late 20th century, Southeast Asia's population (including Indonesia and the Philippines) was approaching a half billion, or about one-twelfth of the world's total. This population, however, was unevenly distributed within the region. By far the nation with the largest population was Indonesia, with about two-fifths of the regional total; in contrast, Brunei's population was only a tiny fraction of that. Nearly half of the regional population was accounted for by the mainland states, with Vietnam and Thailand being the most populous.

Settlement patterns. Southeast Asia is predominantly rural: three-fourths of the people live in nonurban areas. Moreover, population is heavily clustered in fertile river valleys and especially in delta areas, such as those of the Mekong and Irrawaddy rivers. Historical, cultural, and environmental influences also have affected the settlement patterns. Java and other core areas such as the Bangkok (Thailand), Hanoi, and Manila metropolitan areas contain high population densities.

While the rate of urbanization in Southeast Asia is relatively low compared with those of other developing regions, it is increasing rapidly. Singapore is unique in that it is essentially totally urban. In addition, the Philippines has a much higher than average level of urbanization, in part because of its Spanish and American colonial history. The largest cities—Jakarta (Indonesia), Bangkok, and Manila—are among the world's most populous. The growth of cities of all sizes is being fueled primarily by natural increase, but rural-urban migration also is a significant contributor. Rural dwellers continue to be attracted by the promise of employment and other opportunities, but for many migrants the informal (undocumented) economic sector in these large cities is the only hope for some form of employment.

Settlement patterns in rural areas tend to be associated with agricultural practices. Shifting cultivation is still common in some parts of the region (notably the remote interior areas of Myanmar, Vietnam, and the island of Borneo), although the amount of land so utilized is gradually shrinking. The village is the unit of settlement and often functions collectively, and typically it is moved from time to time. By contrast, wet-rice cultivation, the dominant form of agriculture in Southeast Asia, is sedentary and results in relatively large rural agglomerations with well-developed village life and customs. Dry and upland farming often produces scattered homesteads.

Resettlement

Population resettlement to provide agricultural employment and access to land is important in some Southeast Asian countries, notably Indonesia, Malaysia, and Vietnam. By far the largest program has been conducted in Indonesia, where more than four million people have been voluntarily resettled from Java and Bali to the less populated islands. Despite considerable success, the program has been plagued by such problems as improper site selection, environmental deterioration, migrant adjustment, land conflicts, and inadequate financing. A program in Malaysia also has been quite successful, in part because it has set much smaller resettlement targets and has been

better funded. Vietnamese development policy also has utilized the resettlement of people in an effort to revitalize areas outside the major population centres.

Ethnic composition. Southeast Asia's population includes a wide variety of ethnic groups and cultures. This diversity is related to its position as a focus of converging land and sea routes. In addition, over the span of human habitation, the region alternately has been a bridge and a barrier to the movement of people. The peopling of Southeast Asia took place through various southward migrations. The initial peoples arrived from the Asian continental interior. Successive movement displaced these initial settlers and created a complex ethnic pattern.

On the mainland the Khmer peoples of Cambodia remain as ancestors of earlier Pareoean peoples. Similarly, remnants of the Mon group are found in parts of Myanmar and Thailand; the ethnic mixture there has been produced by overlaying Tibeto-Burman and Tai, Lao, and Shan peoples. The contemporary Vietnamese population originated from the Red River area in the north and may be a mixture of Tai and Malay peoples. Added to these major ethnic groups are such less numerous peoples as the Karens, Chins, and Nāgas in Myanmar, who have affinities with other Asiatic peoples. Insular Southeast Asia contains a mixture of descendants of Proto-Malay (Nesiot) and Pareoean peoples who were influenced by Malayo-Polynesian and other groups. In addition, Arabic, Indian, and Chinese influences have affected the ethnic pattern of the islands.

In modern times the Burmans account for more than two-thirds of the ethnic stock of Myanmar, while ethnic Thais and Vietnamese account for about four-fifths of the respective populations of those countries. Indonesia is clearly dominated by the Javanese and Sundanese ethnic groups, while Malaysia is more evenly split between the Malays and the Chinese. Within the Philippines, the Tagalog, Cebuano, Ilocano, and Bicol groups are significant.

Four major language families

Linguistic composition. Language patterns in Southeast Asia are highly complex and are rooted in four major language families: the Sino-Tibetan, Tai, Austro-Asiatic, and Austronesian (Malayo-Polynesian). Languages derived from the Sino-Tibetan group are found largely in Myanmar, while forms of the Tai group are spoken in Thailand and Laos. Austro-Asiatic languages are spoken in Cambodia, Laos, and Vietnam. The languages of Malaysia, Indonesia, and the Philippines are rooted in an Austronesian and Polynesian stock. Despite this broad generalization, it must be noted that innumerable separate languages as well as dialects are used in the region. This linguistic diversity is especially conspicuous in fragmented areas such as the Philippines and Indonesia and in highland and remote areas on the mainland, and it has been a retarding factor in national integration and development. Notable in this regard is Myanmar.

Dominant languages do exist in most of the nations. Burmese and Thai are spoken by large groups of people in Myanmar and Thailand, respectively. Similarly, Khmer is the primary language in Cambodia, as is Vietnamese in Vietnam. Within the Philippines, Pilipino (Filipino) and English are the official languages, but Tagalog and Visayan also are important. Malay and Indonesian are, respectively, the official languages of Malaysia and Indonesia; these languages are quite similar and are mutually intelligible. Indonesian is a good example of a true national language and is spoken widely across the archipelago. Thus, unlike in Myanmar, language actually has been a unifying element in the country.

Numerous languages also have been introduced into the region by immigrant populations. Perhaps most significant are the variety of dialects spoken by the Chinese communities in many Southeast Asian countries. The most commonly used are Cantonese, Hokkien, Hakka, and Teochew, reflecting the southern Chinese coastal origins of many of the immigrants. The largest concentration of Chinese speakers is in Singapore, where they constitute the majority population. Concentrations of ethnic Chinese also live in most of the larger urban areas of the region.

Indian immigrants also are numerous and are associated with the economic development of several Southeast Asian nations. Their role as labourers on the rubber plantations of Malaysia is well known, and Tamil and Hindi speakers form significant minorities in the country. Indian communities also are scattered throughout the region and are especially conspicuous in Singapore and Myanmar.

Religions. Buddhism, Islām, and Christianity are all practiced within Southeast Asia. Buddhism, particularly the more orthodox Theravāda form, dominates the religious pattern of most of the mainland; only in northern Vietnam is the more liberal Mahāyāna Buddhism more common.

Islām

Islām is predominant in the southern half of the Malay Peninsula, the Malay Archipelago, and the southern Philippines. As a result of the large Muslim population in Indonesia, Islām is the religion of some two-fifths of Southeast Asians. The diffusion of the religion began in the early 14th century through contact with Muslim traders in northern Sumatra. Perhaps more than any of the other religions, Islām has been a strong force in binding together its adherents. It has profoundly affected cultural, social, political, and economic matters in areas where it is practiced.

The spread of Christianity came with European contact. Roman Catholicism was introduced to insular Southeast Asia by the Spanish and the Portuguese in the 16th century and somewhat later to the Indochinese Peninsula by the French. Catholicism is most important in the Philippines and southern Vietnam. Protestantism also is locally important. The Batak and Minangkabau peoples in Sumatra and a growing number of Chinese in Singapore and elsewhere adhere to various Protestant denominations.

Hinduism, once much more widespread, now is practiced by many people in the region's Indian communities. In addition, this religion, modified by animism and other influences, is the primary faith on the island of Bali in Indonesia. Various forms of animism also are practiced in the region's more remote areas, particularly in central Borneo, northern Laos, and northern Myanmar.

Demographic trends. The annual rate of natural increase in Southeast Asia averages slightly higher than the annual world rate. Considerable variation exists, however, among the region's countries. The Philippines, Laos, Malaysia, Vietnam, and Brunei are characterized by higher growth; Singapore, Thailand, and Indonesia, on the other hand, have considerably lower rates, primarily because of the implementation of effective family-planning programs in these countries. In general, the pace of fertility decline is accelerating, although it is being offset by declining infant mortality and increasing life expectancy. Infant mortality for the region approximates the world average. In the more developed nations—especially Singapore, Malaysia, and Thailand—health care programs for infants and children have helped bring about mortality rates well below world averages, while the scarcity of these programs in such countries as Cambodia and Laos has contributed to continued high rates. Life expectancy in the region is somewhat below the world average, with Cambodia having the lowest average and Singapore the highest.

Population change also is directly related to internal and external migration. As noted above, rural-to-urban migration continues to be a major aspect of change in nearly all Southeast Asian nations. In certain countries, considerable evidence exists for movements between rural areas (*e.g.*, Thailand) and mobility between urban areas (Indonesia). Internal migration in the Philippines is dominated by movements to Manila and to the frontier areas in the south. Perhaps most significant, given the increasing mobility of the population and access to transport services, is the growth of nonpermanent population movements. Seasonal and other forms of circular migration for limited periods of time are conspicuous, especially in Malaysia, Indonesia, and Thailand. The growth in transport access also has created greater commuting ranges for individuals who in the past often had to leave their homes and fields for extended periods to take up work.

Refugee movements

Refugee movements have been conspicuous in the region, particularly since the mid-1970s. The Vietnamese out-migration to Malaysia, Thailand, Hong Kong, and Indonesia is noteworthy. Cambodian and Laotian peoples

also have experienced displacement. In addition, there have been numerous instances of religious minorities fleeing persecution, such as the departure of Muslim Burmans in the early 1990s.

THE ECONOMY

Even prior to the penetration of European interests, Southeast Asia was a critical part of the world trading system. A wide range of commodities originated in the region, but especially important were such spices as pepper, ginger, cloves, and nutmeg. The spice trade initially was developed by Indian and Arab merchants, but it also brought Europeans to the region. First the Portuguese, then the Dutch, and finally the British and French became involved in this enterprise in various countries. The penetration of European commercial interests gradually evolved into annexation of territories, as traders lobbied for an extension of control to protect and expand their activities. As a result, the Dutch moved into Indonesia, the British into Malaya, and the French into Indochina.

Europe's interest and activity in the region was further enhanced by the opening of the Suez Canal, the development of telegraphic communications, the adoption of steam shipping, and the prospects for trade with China. In the case of Malaya, the gradual diffusion of British administration provided systems of law and order and of taxation and allowed for the gradual development of infrastructure, principally reliable transport systems. This environment attracted Chinese immigrants, and the growth of the tin mining industry soon followed. Later rubber plantations were established, which brought about still further immigration. Similar developments took place in Burma (Myanmar), Vietnam, and Indonesia. In Siam (Thailand) during the second half of the 19th century, a rapid expansion of Western enterprise occurred, though not by colonization. Both British and American firms began trading in the region. The impact of the Western activity was essentially to remove trade from what had been a Chinese monopoly and to emphasize the export of a single commodity, rice. Established indigenous textile and sugar-processing industries were replaced by imports, and the economy slowly became dependent on rice exports. The Philippines gradually developed a plantation farming system under Spanish and later American influence, although rice, sugar, and tobacco continued to be produced by small-scale growers and processed by Chinese enterprises until the mid-19th century.

The incorporation of Southeast Asia into the world economy had a major impact on the distribution of the region's economic development, and it created more uneven patterns of population growth and economic activity. It also brought about a stronger sense of class distinction and resulted in a larger discrepancy between the wealthy and poor. The worldwide economic depression of the 1930s severely affected the commercialized areas most dependent on the world economy. Unemployment rose, and the period produced the seeds of political change and activism that culminated in the independence of most of the region's countries after World War II. Effects of the depression

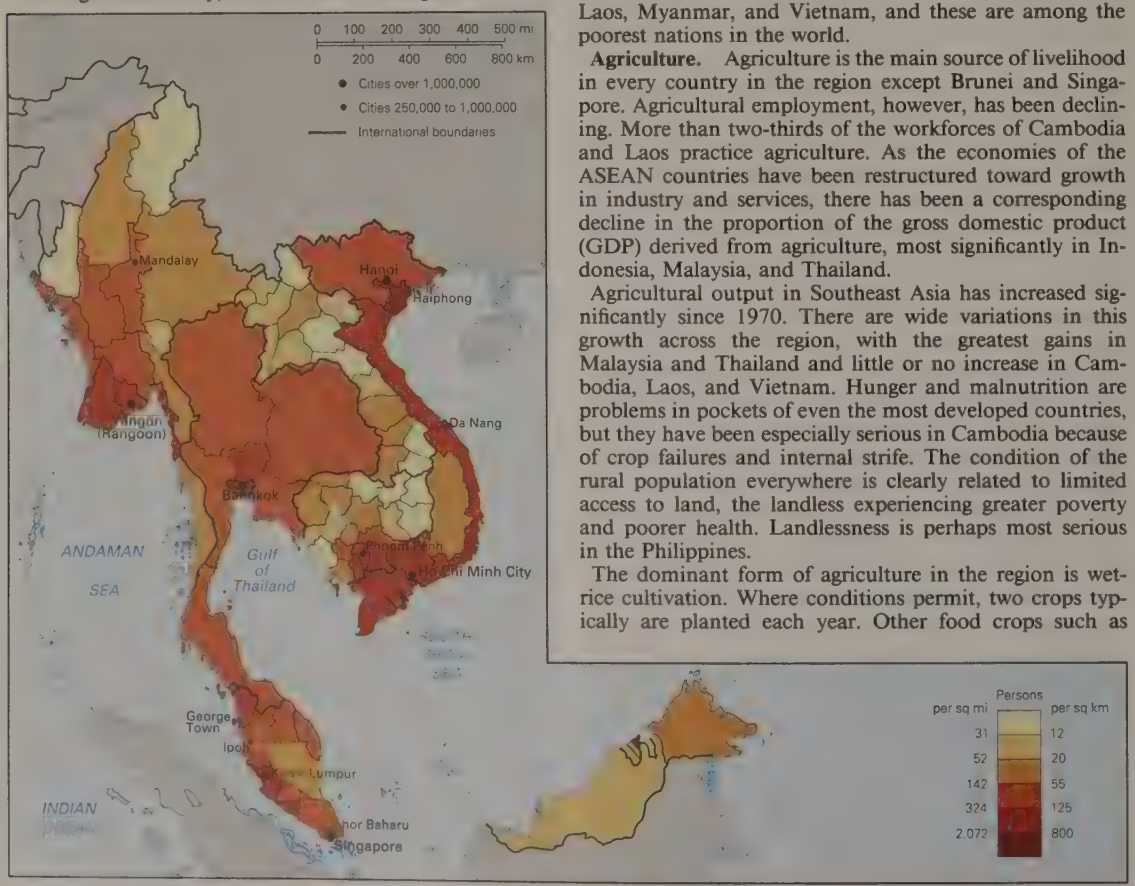
Since the 1950s the economic development strategies of virtually all the capitalist Southeast Asian states have emphasized urban industrialization, while agricultural development generally has been viewed as subsidiary to industrial growth. These strategies have met with mixed success. Indeed, the trading pattern of the region by and large has continued to be one of producing and exporting raw materials and importing manufactured goods. Only Singapore has reached an advanced level of industrialization, in the process becoming one of the world's great centres of industry and commerce.

There is great disparity in development rates within the region, especially between the member and nonmember countries of the Association of Southeast Asian Nations (ASEAN). Those belonging to this grouping—Brunei, Indonesia, Malaysia, the Philippines, Singapore, and Thailand—generally have experienced significant economic development since the mid-1960s; the exception has been the Philippines, the economy of which has grown at a much slower rate. Development has been extremely slow or nonexistent in the non-ASEAN countries of Cambodia, Laos, Myanmar, and Vietnam, and these are among the poorest nations in the world.

Agriculture. Agriculture is the main source of livelihood in every country in the region except Brunei and Singapore. Agricultural employment, however, has been declining. More than two-thirds of the workforces of Cambodia and Laos practice agriculture. As the economies of the ASEAN countries have been restructured toward growth in industry and services, there has been a corresponding decline in the proportion of the gross domestic product (GDP) derived from agriculture, most significantly in Indonesia, Malaysia, and Thailand.

Agricultural output in Southeast Asia has increased significantly since 1970. There are wide variations in this growth across the region, with the greatest gains in Malaysia and Thailand and little or no increase in Cambodia, Laos, and Vietnam. Hunger and malnutrition are problems in pockets of even the most developed countries, but they have been especially serious in Cambodia because of crop failures and internal strife. The condition of the rural population everywhere is clearly related to limited access to land, the landless experiencing greater poverty and poorer health. Landlessness is perhaps most serious in the Philippines.

The dominant form of agriculture in the region is wet-rice cultivation. Where conditions permit, two crops typically are planted each year. Other food crops such as Rice



Population density of Southeast Asia.

corn (maize), cassava, and pulses (legumes) frequently are grown in drier areas where there is too little water for a second planting of rice. Rice production requires a reliable water supply. Thailand and the Philippines rely heavily on rain-fed systems, while Indonesia utilizes irrigation to a large extent. Irrigation or some other form of water control is especially critical in the cultivation of the high-yielding varieties (HYVs) of rice that have been introduced since the 1960s. The spread of the so-called Green Revolution—in which HYVs and chemical fertilizers and pesticides are utilized—has brought mixed results. There is little doubt that production has increased because of the higher yields of these hybrid strains and because their more rapid maturation increases the possibility of multiple annual crops. Frequently, however, poorer farmers are not able to take advantage of these strains, because of the high cost of their use. The goal of rice self-sufficiency has been difficult to achieve for most countries.

A large variety of cash crops are grown for the local and export markets, both on large commercial estates and by individual growers or smallholders. Tree crops are the most important in terms of value, although the area devoted to them is limited largely to equatorial areas. Rubber and palm oil are significant in Malaysia, Indonesia, and southern Thailand, while coconuts and sugar are important in the Philippines. Other major export crops are cacao, coffee, and spices, while crops grown largely for local and regional consumption include chilies, sweet potatoes, peanuts (groundnuts), and tobacco. The cultivation of opium poppies is important in parts of Myanmar and Thailand.

The emphasis on rubber and palm oil production is in response to a considerable (though fluctuating) worldwide demand for these commodities and because of a nearly continuous harvest period that provides year-round employment. Foreign corporations once dominated production, but, as the region's countries gained independence, much of the production was nationalized. Government ownership continues to predominate, with increasing private ownership.

Fishing contributes only a token amount to the GDP of Southeast Asian countries, but it is an important livelihood in certain areas and supplies a significant portion of the local diet. Marine output has gradually expanded with new technologies. The maritime nations of Thailand, Indonesia, Malaysia, and the Philippines all have globally important fishing industries. Shrimp catches are especially in demand in the world economy. Aquaculture has become increasingly important in the region, such species as shrimp, carp, and grouper being raised in excavated ponds.

Industry. Industrialization in Southeast Asia is a relatively recent phenomenon, much of the development having occurred only since the early 1960s. As mentioned above, industrialization policies have been critical goals in the market economies of the ASEAN countries; and, in all of them except Brunei, industry's share of the GDP has grown considerably. The most significant increases have occurred in Singapore, Thailand, and the Philippines. Manufacturing in particular has accounted for the greatest changes, with Indonesia, Malaysia, and Thailand making especially large gains during the 1980s.

Growth in manufacturing

Small factories dominate, both in terms of the number of companies and the number of workers employed. Agricultural processing is most important in virtually all nations. The notable exception is Singapore, where the manufacture of a variety of products, headed by electrical and electronic and transport equipment, is dominant. In Thailand, Myanmar, and the Philippines, textiles and clothing are significant, as is the chemical industry in Thailand and Indonesia. Light, labour-intensive goods, such as electrical and electronic products, are increasingly important. It is in the manufacture of these products and textiles that the most employment has been gained.

Tin is the most important metallic mineral in the region in terms of value, and Thailand, Malaysia, and Indonesia account for more than half of world production. In Malaysia and elsewhere, however, alluvial lodes are becoming depleted, and the remaining concentrations are less economical to mine. Fluctuating market prices have also discouraged tin production. Nickel, copper, and chromite are also mined, although the quantities produced in the region are minor in terms of world production. Southeast Asia has considerable reserves of oil and natural gas, notably in Indonesia, Malaysia, and Brunei.

Trade. Given Southeast Asia's strategic location and the early development of trade there, it is not surprising that trade is especially important to all nations in the region. The value of regional trade is about one-third that of the United States. Most striking is the almost total dominance of trade by the market economies. Exports, as a percentage of the GDP, are small in Cambodia, Myanmar, Vietnam, and Laos and moderately so in Thailand, the Philippines, and Indonesia. Countries with a relatively large proportion of export trade are Singapore, Malaysia, and Brunei. Composition of exports is important. In this respect, Indonesia—the trade structure of which long has been dominated by oil—has been relatively successful in diversifying its exports toward plywood, rattan, coffee, rubber, and textiles. Conversely, Malaysia, with a trade pattern of exporting palm oil, tropical hardwoods, and tin, now derives the majority of its export income from petroleum products. This revenue has been used to build up the country's industrial base. Thailand exhibits a much less diverse export structure, where food and manufactured goods account for nearly all of its total trade. Likewise, Brunei relies almost entirely on its petroleum exports. Singapore, however, has utilized its unique geographic position and highly educated labour force to attract multinational corporations. As a result, investment in the manufacturing and, increasingly, service sectors has greatly expanded.

Intraregional trade among the ASEAN members, while important, accounts for only about one-fifth of Southeast Asia's total trade. Philippine trade within the region is especially small, reflecting its long-term orientation toward the United States. Far more important, therefore, is the trade with countries outside the region, dominated by that with Japan, Europe, and the United States; increasingly significant, however, is the trade with Taiwan, Hong Kong, and South Korea.

Trading partners

Transportation and communications. Before World War II the various colonial powers of the region attempted to provide reliable transport systems. Emphasis first was placed on developing road networks, followed by railways. The infrastructure that was built during the colonial period, however, deteriorated rapidly after the war; since achieving independence, many of the countries gradually have been restoring and extending their road networks. This activity has been notable in Indonesia, where, because of the country's vastness, the task has been enormous. Transport systems in Myanmar and the countries of the Indochinese Peninsula in general are poorly developed, except in some parts of Vietnam, where improvements were made during wartime.

Road transport continues to be of overwhelming importance in the region. Since all countries but Laos have maritime access, water transport is next in importance. It is especially vital in archipelagic Indonesia and the Philippines and also is significant in Malaysia and Thailand. Railways are of minor importance, in part because the region's archipelagic nature is not conducive to their construction but more critically because the relatively short hauling distances allow road transport to be more competitive. Even in Thailand—where the potential for rail transport is greatest—an extensive highway system and the availability of reliable vehicles provide a formidable challenge to rail.

All of the ASEAN countries have strong domestic air transport systems. The most extensive is in Indonesia, which provides critical links between the islands. In addition, the Indonesian government maintains subsidized air services to the smaller islands. Most ASEAN nations also have international air fleets, the largest of which are maintained by Singapore, Malaysia, and Thailand.

There has been increased emphasis on the development of communications throughout the ASEAN states. Singapore has become renowned for its extensive communications infrastructure and capability. Telephone service is

most abundant in the urban areas of the more developed states, although telecommunications in the rural areas of the Philippines, Indonesia, and Thailand remains deficient. Indonesia has made significant improvements in its communications infrastructure through the deployment of satellites that enhance television and telephone transmission to remote areas of the archipelago. (T.R.L.)

History

EARLY SOCIETY AND ACCOMPLISHMENTS

Origins. Knowledge of the early prehistory of Southeast Asia has undergone exceptionally rapid change as a result of archaeological discoveries made since the 1960s, although the interpretation of these findings has remained the subject of extensive debate. Nevertheless, it seems clear that the region has been inhabited from the earliest times. Hominid fossil remains date from approximately 1,500,000 years ago, and those of *Homo sapiens* from approximately 40,000 years ago. Furthermore, until about 7000 BC the seas were some 150 feet (50 metres) lower than they are now, and the area west of Makassar Strait consisted of a web of watered plains that sometimes is called Sundaland. These land connections perhaps account for the coherence of early human development observed in the Hoabinhian age, which lasted from about 13,000 to 5000 or 4000 BC. The stone tools used by hunting and gathering societies across Southeast Asia during this period show a remarkable degree of similarity in design and development. When the sea level rose to approximately its present level about 6000 BC, conditions were created for a more variegated environment and, therefore, for more extensive differentiation in human development. While migration from outside the region may have taken place, it did not do so in a massive or clearly punctuated fashion; local evolutionary processes and the circulation of peoples were far more powerful forces in shaping the region's cultural landscape.

Technological developments and population expansion. Perhaps because of a particular combination of geophysical and climatic factors, early Southeast Asia did not develop uniformly in the direction of increasingly complex societies. Not only have significant hunting and gathering populations continued to exist into the 20th century, but the familiar cultural sequences triggered by such events as the discovery of agriculture or metallurgy do not seem to apply. This is not to say that the technological capabilities of early Southeast Asian peoples were negligible, for sophisticated metalworking (bronze) and agriculture (rice) were being practiced by the end of the third millennium BC in northeastern Thailand and northern Vietnam, and sailing vessels of advanced design and sophisticated navigational skills were spread over a wider area by the same time or earlier. Significantly, these technologies do not appear to have been borrowed from elsewhere but were indigenous and distinctive in character.

Rate of societal change

These technological changes may partially account for two crucial developments in Southeast Asia's later prehistory. The first is the extraordinary seaborne expansion of speakers of Proto-Austronesian languages and their descendants, speakers of Austronesian (or Malayo-Polynesian) languages, which occurred over a period of 5,000 years or more and came to encompass a vast area and to stretch nearly half the circumference of the Earth at the Equator. This outward movement of people and culture was evolutionary rather than revolutionary, the result of societal preference for small groups and a tendency of groups to hive off once a certain population size had been reached. It began as early as 4000 BC, when Taiwan was populated from the Asian mainland, and subsequently it continued southward through the northern Philippines (3rd millennium BC), central Indonesia (2nd millennium BC), and western and eastern Indonesia (2nd and 1st millennia BC). From approximately 1000 BC on the expansion continued both eastward into the Pacific—where that immense region was populated in a process continuing to about AD 1000 as voyagers reached the Hawaiian Islands and New Zealand—and westward—where Malay peoples reached and settled the island of Madagascar sometime between AD 500 and 700, bringing with them (among other things) bananas, which are native to Southeast Asia. Thus, for a considerable period of time, the Southeast Asian region contributed to world cultural history, rather than merely accepting outside influences, as frequently has been suggested.

The second development, which began possibly as early as 1000 BC, centred on the production of fine bronze and the fashioning of bronze-and-iron objects, particularly as they have been found at the site in northern Vietnam known as Dong Son. The earliest objects consisted of socketed plowshares and axes, shaft-hole sickles, spearheads, and such small items as fishhooks and personal ornaments. By about 500 BC the Dong Son culture began producing the bronze drums for which it is known. The drums are large objects (some weigh more than 150 pounds [70 kilograms]), and they were produced by the difficult lost-wax casting process and decorated with fine geometric shapes and depictions of animals and humans. This metal industry was not derived from similar industries in China or India. Rather, the Dong Son period offers one of the most powerful—though not necessarily the only or earliest—examples of Southeast Asian societies transforming themselves into more densely populated, hierarchical, and centralized communities. Since typical drums, either originals or local renditions, have been found throughout Southeast Asia and since they are associated with a rich trade in exotics and other goods, the Dong Son culture also suggests that the region as a whole consisted not of isolated, primitive niches of human settlement but of a variety of societies and cultures tied together by broad and long-extant trading patterns. Although none of these societies possessed writing, some displayed considerable sophistication and technological skill; and, although none appears to have constituted a territorial, centralized state, new and more complex polities were forming.

Dong Son culture

Influence of China and India. Between approximately 150 BC and AD 150, most of Southeast Asia was first influenced by the more mature cultures of its neighbours to the north and west. Thus began a process that lasted for the better part of a millennium and fundamentally changed Southeast Asia. In some ways the circumstances were very different. China, concerned about increasingly powerful chiefdoms in Vietnam disturbing its trade, encroached into the region and by the end of the 1st century BC had incorporated it as a remote province of the Han empire. For generations, the Vietnamese opposed Chinese rule, but they were unable to gain their independence until AD 939. From India, however, there is no evidence of conquests, colonization, or even extensive migration. Indians came to Southeast Asia, but they did not come to rule; and no Indian power appears to have pursued an interest in controlling a Southeast Asian power from afar, a factor that may help to explain why only the Vietnamese accepted the Chinese model. Yet, in other ways the processes of Indianization and Sinicization were remarkably similar. Southeast Asia already was socially and culturally diverse, making accommodation easy. Furthermore, indigenous peoples shaped the adaption and adoption of outside influences and, indeed, seem to have sought out concepts and practices that enhanced rather than redirected changes already underway in their own societies. They also rejected some components: for example, some of the vocabulary and general theories related to the Indian notions of social hierarchy were borrowed but much of the specific practices were not, and neither Indian nor Chinese views of women as socially and legally inferior were accepted. In the later stages of the assimilation process—particularly in the Indianized areas—local syncretism often produced exuberant variations, which, despite familiar appearances, were expressions of local genius rather than just inspired borrowings.

Still, Chinese and Indian influences were anything but superficial. They provided writing systems and literature, systems of statecraft, and concepts of social hierarchy and religious belief, all of which were both of intrinsic interest and pragmatic significance to Southeast Asians of the day. For elites seeking to gain and retain control over larger and more complex populations, the applications of these

Artistic expression

ideas were obvious; but it would also seem that the sheer beauty and symbolic power of Hindu and Buddhist arts tapped a responsive vein in the Southeast Asian soul. The result was an imposing array of architectural and other cultural wonders, at first very much in the Indian image and hewing close to current styles and later in more original, indigenous interpretations. The seriousness and profundity with which all this activity was undertaken is unmistakable. By the 7th century AD Palembang in southern Sumatra was being visited by Chinese and other Buddhist devotees from throughout Asia, who came to study doctrine and to copy manuscripts in institutions that rivaled in importance those in India itself. Later, beginning in the 8th century, temple and court complexes of surpassing grandeur and beauty were constructed in central Java, Myanmar, and Cambodia; the Borobudur of the Śailendra dynasty in Java, the myriad temples of the Burman dynastic capital of Pagan, and the monuments constructed at Angkor during the Khmer empire in Cambodia rank without question among the glories of the ancient world.

Rise of indigenous states. In the realm of politics, Indian influence accompanied the rise of new political entities, which, since they do not readily fall under the Western rubric of "states," have been called *mandalas*. The *mandala* was not so much a territorial unit as a fluid field of power that emanated, in concentric circles, from a central court and depended for its continued authority largely on the court's ability to balance alliances and to influence the flow of trade and human resources. Such a conception of political organization already had surfaced among Southeast Asians, but Indian civilization provided powerful metaphors for the change underway and for ways of extending it. The *mandala* was the predominant form of the Southeast Asian state until it was displaced in the 19th century.

Between approximately the 2nd century BC and the 6th century AD, *mandala* polities appeared throughout Southeast Asia in the major river valleys and at strategic landfalls for sea traffic—generally, locations where routes for local and international trade crossed. These communities took different forms, depending on their physical setting. For example, walled and moated settlements predominated in much of the mainland but do not seem to have been constructed in insular Southeast Asia. Yet they served similar purposes to and frequently shared characteristics with *mandalas* in the same immediate region. *Mandala* sites have been located in the Mekong, Chao Phraya, and Irrawaddy river valleys; along the coasts of central Vietnam, western and northern Java, and eastern Borneo; and on the Isthmus of Kra. One of the most intriguing sites,

Oc Eo

called Oc Eo, is in the Mekong delta region of southern Vietnam. This port settlement, which flourished between the 1st and 6th centuries AD amid a complex of other settlements connected by canals (some up to 60 miles long), was not only an extraordinarily rich emporium dealing in articles from as far as Rome and inner Asia, but it was also a local manufacturing centre producing its own jewelry, pottery, and other trade goods. Almost certainly it also fed itself from wet-rice agriculture practiced in the surrounding delta. Little is known, however, about the nature of state structure in Oc Eo, although it seems to have been one of—and perhaps was prime among—an assemblage of local *mandala*-type principalities.

After the 6th century there emerged a number of larger and more powerful *mandala* states, principally in Cambodia, Myanmar, Sumatra, and Java. Often designated kingdoms or empires, these states nevertheless functioned and were structured upon the same principles that had governed their predecessors. They were, in some respects, unstable and prone to fluctuation because of shifting relations with outside powers and constant internal struggles for the position of overlordship, but they also were remarkably durable. No two states were exactly alike, each occupying a particular ecological niche and exploiting a particular combination of opportunities to survive by trade, agriculture, and war. The cultural impact of their courts long outlasted their political grasp and continued to inform their societies until modern times. Perhaps the outstanding example of this durability is Śrīvijaya, the great Sumatran trading "empire" that dominated much of Southeast Asian commerce from about the 7th to the 13th century. Śrīvijaya does not appear to have been heavily urbanized or to have had a continuously occupied capital during its roughly 700 years of existence, nor does it seem to have possessed boundaries and clearly delineated territories. Its armies, while they could be mustered and quickly dispatched overseas, were weapons of limited use. Instead, Śrīvijaya maintained its authority in a shifting and extremely varied trading world largely by means of a shrewd brand of cultural and economic politics that involved, among other things, offering a protective and mutually beneficial trading environment to all comers and maintaining a courtly culture from which the idiom of overlordship issued grandly and convincingly. Śrīvijaya was ruled by a formula supple enough to attract trade from all quarters and to exploit it at the same time.

The Khmer state

Whatever the achievements of Śrīvijaya, the Khmer (Cambodian) state that flourished in the Tonle Sap region roughly between the 9th and mid-13th centuries is widely regarded as the most impressive of the concentrically arranged ancient Southeast Asian states. This admiration largely stems from the state's extensive architectural remains, including the renowned Angkor Thom and Angkor Wat temple complexes. In many respects, however, the Angkorian imperial achievement was singular. Though informed by the *mandala* paradigm, the Khmer carried it further and shaped it more distinctively than other Southeast Asians before or since. Not only was the *devarāja* ("a god who is king") cult a Khmer innovation, but the Khmer also uniquely transformed their physical environment to support their state. They created what may be the ancient world's most intricate and capacious system of water catchment and dispersal, making it possible to grow three or even four crops of rice annually in an area not especially hospitable to raising even one. At its zenith, Angkor may have supported a population of one million in a relatively small area, with an elite apparatus and a population of bondsmen far greater than any of Cambodia's neighbours. In achieving this, however, the Khmer state surrendered the flexibility and balance critical to the *mandala* pattern and eventually fell victim to its own brittleness. Other concentric states in early Southeast Asia rose and fell; the Khmer proved unable to revive theirs once it had fallen.

THE CLASSICAL PERIOD

Components of a new age. By about 1300 much of Southeast Asia had entered a period of transition from ancient times. No single factor can account for the disruption, which lasted longer in some places than in others. The Mongol attacks of the second half of the 13th century and the disintegration of Khmer and Śrīvijayan power undoubtedly were of significance, but less dramatic changes, such as slowly changing trade patterns and political competition, may also have played an important role. Whatever the case, the shifts were not of a type or severity to bring about major disruptions; they instead paved the way for the coalescing of what can best be termed a classical age. In this period the major civilizations of Southeast Asia achieved a broader influence and greater coherence than before. They integrated rival political and cultural forms into their own, and the patterns they established were widely imitated by smaller powers that were drawn into their orbit. Regional and international trade reached a high level of development, bringing greater well-being to larger numbers of Southeast Asians than ever before. It also was an age of great change and challenges—especially in the form of new and often foreign religious, political, and economic influences—and one of constant warfare. But it was a measure of the confidence and balance of the era that these influences were absorbed and digested with little difficulty, leaving more than a millennium of creative synthesis essentially undisturbed until as late as the end of the 18th century. Many Southeast Asian civilizations can be said to have reached their definitive premodern shape during this "golden" age, which also is modern scholarship's best source of information on the classical cultures

of the region before the ravages of 19th- and 20th-century colonialism.

Five major powers

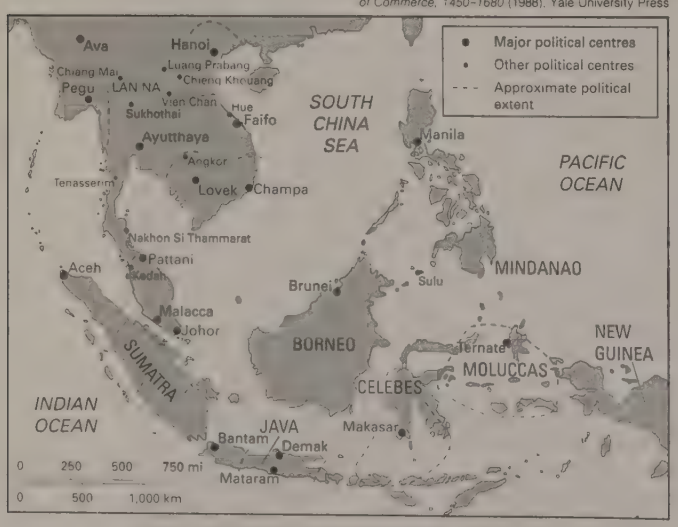
State and society. There were five major powers in Southeast Asia between the 14th and 18th centuries: Myanmar under the rulers of Ava (1364–1752), especially the Toungoo dynasty during most of that period; an independent Vietnam under the Later Le dynasty (1428–1788); the Tai state of Ayutthaya, or Ayudhia (1351–1767); Majapahit, centred on Java (1292–*c.* 1527); and Malacca (Melaka) centred on the Malay Peninsula (*c.* 1400–1511). Particularly with the waning of Indian influence (the last known Sanskrit inscription dates from the late 13th century), each power had developed in distinctive ways: more than ever, what constituted being "Javanese" or "Burman," for example, was taking focus, and the Vietnamese, too, sought to clarify what was their own as opposed to what was Chinese. Remarkably enough, the process by which this was accomplished was characterized not by elimination or purification but by absorption. The syncretic powers developed in earlier periods had by no means weakened. The Tai, comparative newcomers, absorbed much of Khmer civilization during this period and, beginning with their written language, shaped it to their requirements. The Burmans absorbed Mon civilization in a similar fashion, and the Javanese of Majapahit could not help but make adjustments with the Malay and other cultures of the archipelago that they came to dominate. Even the Vietnamese, who had decided after several generations of struggle to adopt the outlines of a Confucian state that they had inherited from China, in the late 14th and early 15th centuries not only modified that model but also absorbed important influences from the culture of the Cham, an Indianized people whose kingdom, Champa, they had decisively (though not finally) defeated in 1471. This integrative approach may not have represented a conclusive departure from the behaviour of the ancient *mandala* states, but it does seem to have sustained larger and more far-reaching states, as well as richer and more complex elite cultures.

At the same time, however, a galaxy of smaller states appeared, some of them very powerful for their size and all of them ambitious. These states were especially numerous in insular Southeast Asia, where Aceh, Bantam (Banten), Makasar (Macassar), and Ternate were only the most prominent of many such Islāmic sultanates; on the mainland, Chiang Mai (Chiengmai), Luang Prabang, and Pegu at various times during the period were powerful enough to be taken seriously. They both imitated and contributed to the court cultures of their larger neighbours and made alliances, war, and peace with many powers.

Rise of trade

Above all, these states participated in a dynamic and prosperous trade, not merely in exotics or high-value goods (such as gems and metal items) but in such relatively mundane goods as salted dried fish, ceramics, and rice.

Adapted from A.J.S. Reid *Southeast Asia in the Age of Commerce, 1450–1680* (1988), Yale University Press



Major political centres of Southeast Asia, *c.* 1600.

While institutions of servitude were structured somewhat differently from those of the West, there was no mistaking that a lively trade in human beings prized for their labour or craftsmanship took place. The proliferation of states and the rapid growth of an accompanying intricate web of local cultural and commodity exchange laid the foundation for both greater local autonomy and increased regional interdependency.

The dynamics of regional trade brought change to most Southeast Asian societies during this period. These changes were by no means uniform; the effect on hill tribes subject to periodic raiding, for example, was understandably different from that on coastal communities suddenly wealthy from trade. In some instances the alterations must have been dramatic: the native sago diet of many inhabitants of the Moluccas (Maluku) region, for example, was displaced by one based on rice brought from Java, more than 1,500 miles to the west. Yet it does seem that some changes were felt widely, especially in the larger states. Perhaps the most important was that, while old ideas of kingship and sovereignty were cultivated, in reality much power—and in some places critical power—had fallen into the hands of a merchant class. The royal courts themselves often dabbled in trade to an unprecedented degree. It perhaps is not accurate to say that kingship as an institution was weakening, but the courts, particularly in insular Southeast Asia, became more complicated centres of elite power.

Urbanization was another development of importance. Although some societies, notably that of the Javanese, seem not to have been affected, the growth of large and densely populated centres was a widespread phenomenon. By the 16th century some of these rivaled all but the very largest European cities. Malacca, for example, may have had a population of 100,000 (including traders) in the early 16th century; in Europe only Naples, Paris, and perhaps London were larger at that time. Finally, Southeast Asians during the 16th and 17th centuries appear to have enjoyed good health, a varied diet, and a comparatively high standard of living, especially when compared with most of the population of Europe of the same period.

Religion and culture. New religions appeared in Southeast Asia, accompanying the currents of trade and often entwined with social changes already underway. Gradually, in most areas, these religions filled the gaps left by weakening local Hindu-Buddhist establishments and beliefs, and by the mid-18th century the region had assumed something much like its modern religious configuration. On the mainland, Theravāda Buddhism, which had been making inroads in Cambodia since the 11th century, underwent revitalization, the result especially of royal patronage and direct contact with Theravāda monasteries in Sri Lanka. Both the general idiom and many precepts of Theravāda already were familiar in Indianized societies, making this a gentle, nearly silent revolution that despite its subtlety was no less important. In Ayutthaya and the other Tai kingdoms and in the Mon-Burman states, Theravāda Buddhism buoyed the kingship and introduced a vigorous intellectual leadership; it also spread broadly among the populace and thus played an important role as a cohesive social and cultural force from which the people of modern Thailand and Myanmar later were to draw much of their sense of identity.

Christianity

Christianity made its appearance in the early 16th century, brought by the Portuguese, Spanish, and, somewhat later, the French. It spread easily in the northern Philippines, where Spanish missionaries did not have to compete with an organized religious tradition and could count on the interested support of a government bent on colonization. Unlike the religions with which Southeast Asia had been familiar, Christianity showed no interest in syncretic accommodation of local animist or other beliefs. The Spanish friars rooted out whatever they could find in the way of indigenous tradition, destroying much of cultural value, including, it appears, a native writing system. By the 18th century, most of the Philippines, except the Muslim south, was Roman Catholic, and a society that was both Filipino and Christian had begun to evolve. Elsewhere in Southeast Asia, however—with the exception of Vietnam and parts of the Moluccas island

group of eastern Indonesia—Christianity attracted little interest. It did not go unopposed and was resisted, for example, by Buddhist monks in Thailand and Cambodia in the 16th century, but Christian doctrines do not appear to have attracted the general populace. There were few conversions, and rulers were not unduly disturbed by the presence of missionaries, except on occasions when they were accompanied by political and economic adventurers; these people were crushed.

Islām, however, captured the imagination of Southeast Asians in the archipelago. It was proselytized primarily by Malacca and Aceh after 1400 and by the late 17th century was the dominant faith from the western tip of Sumatra to the Philippine island of Mindanao. The conversion process was gradual, for Muslim traders from the Middle East and India long had traveled the sea route to China; it seems likely that they traded and settled in the port cities of Sumatra and Java as early as the 9th or 10th century. Perhaps as a result of weakening of the Hindu-Buddhist courts and the rise of smaller, independently minded trading states and social classes, Islām made important inroads among both ruling elites and others.

Conversion was comparatively easy and promised certain practical advantages, especially in trade, to members of the Islāmic community (the *ummah*). In addition, Islām was itself diverse, offering a spectrum of approaches from mystical to fundamentalist, and in practice Muslim proselytizers often were tolerant of syncretic behaviour. In addition, Islāmic culture, especially poetry and philosophy, was particularly attractive to courts anxious to enhance their status as cultural hubs. While the spread of Islām throughout the archipelago was not entirely peaceful, for the most part it proceeded in evolutionary fashion and without remarkable disturbance. Javanese Muslims, perhaps even members of the court, lived peacefully in the capital of Hindu-Buddhist Majapahit, for example, and Muslims and non-Muslims everywhere continued to trade, enter into alliances, and inhabit the same general cultural world. What change there was tended to occur slowly in the face of robust and deeply rooted tradition. In some societies the cultural response was original and lively. Along the northern coast of Java, for example, architecture, batik cloth-dyeing motifs, and the literature and performance of the wayang (shadow-puppet theatre) were deeply affected by Islāmic ideas and produced vital new forms to accompany the old.

Chinese and Western incursions. Southeast Asia, unlike many other parts of the world on the eve of European expansion, long had been a cosmopolitan region acquainted with a diversity of peoples, customs, and trade goods. The arrival of Europeans in force in the early 16th century (others had made visits earlier, beginning with Marco Polo in 1292) caused neither wonderment nor fear. Long-distance travel by then was no novelty, and already there was impressive precedence for the arrival of foreign delegations rather than of individual trading vessels. A century before the Portuguese first arrived at Malacca in 1509, that port and a number of others in Southeast Asia had been visited by a succession of Chinese fleets. Between 1403 and 1433 Ming-dynasty China had sent several enormous flotillas of as many as 63 large vessels and up to 30,000 people on expeditions that carried them as far as Africa. The purpose of these journeys, led by the Muslim court eunuch Cheng Ho, was to secure diplomatic and trade advantages for the Chinese and to extend the sovereign lustre of the ambitious Yung-lo Emperor. Yet, except for efforts to regain Dai Viet (Vietnam) as a province, these expeditions had no permanent military or colonial ambitions and did not much disturb the Southeast Asian region. Perhaps in part because of the sound defeat the Vietnamese handed a Ming occupying army in 1427, China lost interest in its new and far-flung initiatives, and the voyages came to an abrupt end.

Voyages of Cheng Ho

Europeans presented a rather different prospect for Southeast Asia, however, above all because they sought riches and absolute control over the sources of this wealth. The Europeans were few in number, often poorly equipped, and generally could not claim great technological superiority over Southeast Asians, but they were also determined, often well-organized and highly disciplined fighters, and utterly ruthless and unprincipled. Except for the Spanish in the Philippines, they were not interested in colonization but rather in the control of trade at the lowest financial cost. These characteristics made Europeans a formidable—though by no means dominant—new force in Southeast Asia. Except in a few locales and special circumstances, for the better part of 250 years Europeans could accomplish little politically or militarily without strong Southeast Asian allies. Individual adventurers often were useful to a particular Southeast Asian ruler or aspirant to the throne, but they were carefully watched and, when necessary, dispatched. Constantine Phaulkon, the Greek advisor to the Siamese court who was executed in 1688 on charges of treason, was only the most dramatic example. In economic affairs, Europeans soon discovered that they were quite unable, even by the most drastic means, to monopolize the spice trade for which they had come. They generally were forced to engage in commerce by Southeast Asian rules and soon found themselves dependent on the local carrying trade for survival. For these reasons, the celebrated Portuguese conquest of Malacca in 1511 did not signal the dawn of an age of Western dominance in Southeast Asia. The majority of the population and much of the trading activity deserted the port, the sultan moved his court elsewhere, and by the end of the 16th century Malacca was a backwater; the Malay trade flourished elsewhere into the 18th century.

Yet it would be a mistake to conclude that the Western presence represented nothing more than a minor irritant. European commercial tools, especially the ability to amass large amounts of investment capital, were different and, from a capitalistic point of view, more sophisticated and dynamic than those of the Southeast Asians. The Dutch and British East India companies often were able to make inroads on certain markets simply by having a large amount of money available, and it was possible for them to adopt long-term strategies by carrying large deficits and debts. Although company directors in Europe warned against the dangers—and costs—of involvement in local affairs, the representatives on the spot often could see no other course. Thus, soon after permanently establishing themselves on Java in 1618, the Dutch found themselves embroiled in the succession disputes of the court of Mataram and, by the late 1740s, virtual kingmakers and shareholders in the realm. Finally, Europeans did bring with them much that was new. Some items shaped Southeast Asian life in unexpected ways: the chili pepper, which the Spanish introduced from the New World, came to hold such an important place in the region's diet that today Southeast Asian cuisine can hardly be imagined without it. Another import, however, was coffee, with a more ominous effect. Smuggled into Java in 1695 against Dutch East India Company rules, coffee by the early 18th century had become a company monopoly produced through a unique relationship between the Dutch and the local Javanese elite in a system that prefigured the one adopted by the 19th-century colonial state.

Introduction of coffee

PATTERNS OF A COLONIAL AGE

Crisis and response. In the last half of the 18th century, all the major states of Southeast Asia were faced with crisis. The great political and social structures of the classical states had begun to decay, and, although the reasons for this disintegration are not altogether clear, the expanded size of the states, the greater complexity of their societies, and the failure of older institutions to cope with change all must have played a part. It is also likely that European efforts to choke and redirect the region's trade had already done much to destroy the general prosperity that trade previously had provided, though Europeans were neither ubiquitous nor in a position to rule, even in Java. The most serious circumstances were undoubtedly those of Vietnam, where from 1771 to 1802 there raged a struggle—the Tay Son rebellion—over the very nature of the state. This rebellion threatened to sweep away the entire Confucian establishment of Vietnam, and perhaps would have done so if its leader had not attempted to accomplish too much too quickly. Elsewhere, war and

confusion held societies in their grip for much shorter periods, but everywhere rulers were compelled to think of changed circumstances around them and what they meant for the future.

In the mainland states three great rulers of three new dynasties came to the fore: Bodawpaya (ruled 1782–1819) in Myanmar, Rama I (1782–1809) in Siam (Thailand), and Gia Long (1802–20) in Vietnam. All three were fully aware of the dangers, internal as well as external, that faced them and their people, and their efforts were directed at meeting these challenges. As their armies extended their reach beyond earlier limits, these rulers vigorously pursued a combination of traditional and new policies designed to strengthen their realms. Of particular importance were efforts to bring villages under closer state control, curb shifting patron-client relationships, and centralize and tighten the state administrative apparatus. The institution of kingship itself seemed to become more dynamic and intimately involved in the direction of the state. In retrospect, some of these policies had a recognizably modern ring to them, and taken together they represented, if not a revolution, at least a concerted effort at change. Even Gia Long, whose conscience and circumstance both demanded that he give special attention to reviving the classical Confucian past, quietly incorporated selected Western and Tay Son ideas in his government. Nor were the changes ineffectual, for by 1820 the large mainland states stood at the height of their powers. Nevertheless, it was uncertain whether these efforts would be sufficient to withstand the pressures of the immediate future.

In insular Southeast Asia the Javanese state confronted a similar crisis, but it had far less freedom with which to respond. The Gianti Agreement (1755) had divided the realm and given the Dutch decisive political and economic powers. Though resistance was not impossible, it was difficult, especially since the rulers and their courts were now largely beholden to the Dutch for their positions. The elite's response to these circumstances generally has been interpreted as a kind of cultural introversion and avoidance of reality, a judgment that probably is too harsh. The Javanese culture and society of earlier days was no longer serviceable, and court intellectuals sought to find a solution in both a revitalization of the past and a clear-eyed examination of the present. Neither effort was successful, though not for want of trying. The idea of opposing Dutch rule, furthermore, was not abandoned entirely, and it was only the devastating Java War (1825–30) that finally tamed the Javanese elite and, oddly enough, left the Dutch to determine the final shape of Javanese culture until the mid-20th century.

The Java War

Western dominance. Except in Java and much of the Philippines, the expansion of Western colonial rule in most of Southeast Asia was a phenomenon only of the 19th and the beginning of the 20th centuries. In the earlier period Europeans tended to acquire territory as a result of complicated and not always desired entanglements with Southeast Asian powers, either in disputes or as a result of alliances. After about 1850, Western forces generally were more invasive, requiring only feeble justification for going on the attack. The most important reasons for the change were a growing Western technological superiority, an increasingly powerful European mercantile community in Southeast Asia, and a competitive scramble for strategic territory. Only Siam remained largely intact and independent. By 1886 the rest of the region had been divided among the British, French, Dutch, and Spanish (who soon were replaced by the Americans), with the Portuguese still clinging to the island of Timor. What were often called "pacification campaigns" were actually colonial wars—notably in Burma (Myanmar), Vietnam, the Philippines, and Indonesia—and continued well into the 20th century. More peaceful Western encroachments on local sovereignty also occurred until the 1920s. Full-blown, modern colonial states existed for only a short period, in many cases for not much more than a generation.

These colonial regimes, however, were not insubstantial, as they put down strong bureaucratic roots and—though often co-opting existing administrative apparatuses—formed centralized, disciplined structures of great power. They were backed by the enormous economic resources of the industrialized Western nations; and by the early 20th century, having effectively disarmed the indigenous societies, they possessed a monopoly on the means of violence. There is no mistaking the impact of Western colonial governments on their surroundings, and nowhere is this more evident than in the economic sphere. Production of tin, oil, rubber, sugar, rice, tobacco, coffee, tea, and other commodities burgeoned, driven by both government and private activity; this brought rapid changes to the physical and human landscape and coupled Southeast Asia to a new worldwide capitalist system.

Indeed, colonial domination was only a variant condition in a rapidly changing world. Siam, which through a combination of circumstance and the wise leadership of Mongkut (ruled 1851–68) and Chulalongkorn (1868–1910) avoided Western rule, nevertheless was compelled to adopt policies similar to, and often even modeled on, those of the colonial powers in order to survive. Modernization appeared to require such an approach, and the Thai did not hesitate to embrace it with enthusiasm. Bangkok in the late 1920s surpassed even British Singapore as a centre of such modern amenities as electric lighting and medical facilities, and the state itself had achieved an enviable degree of political and economic viability among its colonial neighbours. The Thai may have "colonized themselves," as some critics have noted, but in so doing they also escaped or diluted some of the more corrosive characteristics of Western rule, among them racism and cultural destruction. They also do not appear to have experienced the same degree of rural unrest that troubled their colonial neighbours in the 1920s and '30s. They were unable, however, to avoid other concomitants of state expansion and modernization.

Siamese response

Transformation of state and society. It was not the purpose of the new states to effect rapid or broad social change. Their primary concerns were extending bureaucratic control and creating the conditions for success in a capitalist world economy; the chief necessity was stability or, as the Dutch called it, *rust en orde* ("tranquillity and order"). Boundaries were drawn, villages defined, laws rewritten—all along Western lines of understanding, often completely disregarding indigenous views and practices—and the new structure swiftly replaced the old. Social change was desired only insofar as it might strengthen these activities. Thus, the Thai began early on to send princes to Europe for their education, employing them throughout the government on their return. The Dutch created exclusive schools for the indigenous administrative elite—a kind of petty royalty—and invented ways of reducing social mobility in this group, as, for example, by making important positions hereditary. But the new governments did not provide Western-style learning to most Southeast Asians, primarily because it was an enormous, difficult, and expensive task and also because policymakers worried about the social and political consequences of creating an educated class. Except in the Philippines, by the mid-1930s only a small percentage of indigenous children attended government-run schools, and only a fraction of those studied above the primary-school level. Some Southeast Asian intellectuals soon drew the conclusion that they had better educate themselves, and they began establishing their own schools with modern, secular courses of study. Some, like the Tonkin Free School in Vietnam (1907), were closed by the colonial regimes, their staffs and pupils hounded by police; others, like the many so-called "wild schools" in Indonesia in the 1930s, were much too numerous to do away with altogether, but they were controlled as carefully as possible.

Nevertheless, during the 1920s and '30s a tiny but thoughtful and active class of Westernized Southeast Asian intellectuals appeared. They were not the first to literally and figuratively speak the language of the colonial rulers and criticize them, for by the turn of the 20th century Java and Luzon, with the longest experience under Western rule, had already produced individuals like the Javanese noblewoman Raden Adjeng Kartini and the Filipino patriot José Rizal. The newer generation, however, was more certain in its opposition to colonial rule (or, in Siam,

Rise of nationalist leaders

rule by the monarchy), clearer and far more political in its conception of a nation, and unabashedly determined to seize leadership and initiative in their own societies. In Burma this group called themselves *thakin* (Burmese: "master"), making both sarcastic and proud use of an indigenous word that had been reserved for Burmese to employ when addressing or describing Europeans. These new intellectuals were not so much anti-Western as they were anticolonial. They accepted the existing state as the foundation of a modern nation, which they, rather than colonial officials, would control. This was the generation that captained the struggles for independence (in Siam, independence from the monarchy) and emerged in the post-World War II era as national leaders. The best-known figures are Sukarno of Indonesia, Ho Chi Minh of Vietnam, and U Nu of Burma (subsequently Myanmar).

The chief problem facing the new intellectuals lay in reaching and influencing the wider population. Colonial governments feared this eventuality and worked to prevent it. Another obstacle was that the ordinary people, especially outside cities and towns, inhabited a different social and cultural world from that of the emerging leaders. Communication was difficult, particularly when it came to explaining such concepts as nationalism and modernization. Still, despite Western disbelief, there was considerable resentment of colonial rule at the lower levels of society. This was based largely on perceptions that taxes were too numerous and too high, bureaucratic control too tight and too prone to corruption, and labour too coercively extracted. In many areas there also was a deep-seated hatred of control by foreigners, whether they be the Europeans themselves or the Chinese, Indians, or others who were perceived as creatures of their rule. Most of the new intellectual elite were only vaguely aware of these sentiments, which in any case frequently made them uneasy; in a sense they, too, were foreigners. In the 1930s, however, a series of anticolonial revolts took place in Burma, Vietnam, and the Philippines; though they failed in their objectives, these revolts made it clear that among the masses lay considerable dissatisfaction and, therefore, radical potential. The revolts, and the economic disarray of the Great Depression, also suggested that European rule was neither invulnerable nor without flaws. When the outbreak of war in Europe and the Pacific showed that the colonial powers were much weaker militarily than had been imagined, destroying colonial rule and harnessing the power of the masses seemed for the first time to be real possibilities.

Japanese occupation. The arrival of the Japanese armed forces in Southeast Asia in 1941–42 did not, however, occasion independence. A few leaders perhaps had been naive enough to think that it might—and some others clearly admired the Japanese and found it acceptable to work with them—but on the whole the attitude of intellectuals was one of caution and, very quickly, realization that they were now confronted with another, perhaps more formidable and ferocious, version of colonial rule. The Japanese had no plans to radicalize or in any way destabilize Southeast Asia—which, after all, was slated to become part of a Tokyo-centred Greater East Asia Co-prosperity Sphere; in the short term they sought to win the war, and in the long run they hoped to modernize the region on a Japanese model. Continuity served these purposes best, and in Indochina the Japanese even allowed the French to continue to rule in return for their cooperation. Little wonder that before long Southeast Asians began to observe that, despite "Asia for the Asians" propaganda, the new and old colonial rulers had more in common with each other than either had with the indigenous peoples.

Difference from Western rule

Still, for two distinct reasons the period does represent a break from the past. First, the Japanese attempted to mobilize indigenous populations to support the war effort and to encourage modern, cooperative behaviour on a mass scale; such a thing had never been attempted by Western colonial governments. Virtually all of the mobilization efforts, however, were based on Japanese models, and the new rulers were frustrated to discover that Southeast Asians did not behave in the same fashion as Japanese. Frequently the result was disorder, corruption, and, by the end of the war, a seething hatred of the Japanese. It was also the case that, both because the war was going against them and because the response to other approaches was unenthusiastic, the Japanese were compelled before long to utilize local nationalism in their mobilization campaigns, again something quite impossible under European rule. The consequences were to benefit local rather then Japanese causes and, ironically, to contribute handsomely to the building of anti-Japanese sentiments.

A second difference between Western and Japanese colonialism was in the opportunities the occupation provided the new educated elite. The Japanese were wary of these people because of their Western orientation but also favoured them because they represented the most modern element in indigenous society, the best partner for the present, and the best hope for the future. Often dismissed as "pseudo-intellectuals" by the Western colonial governments and prevented from obtaining any real stake in the state, the new intellectuals under the Japanese were accorded positions of real (though not unlimited or unsupervised) authority. Nor could Southeast Asians who found themselves in these positions easily fault the policies they now accepted responsibility for carrying out or at least supporting, since many of these policies were in fact—if not always in spirit—similar to ones they had endorsed in earlier decades. In short, the Western-educated elite emerged from the Japanese occupation stronger in various ways than they had ever been. By August 1945 they stood poised to inherit (or, given the variety of political conditions at the end of the war, to struggle among themselves over inheriting) the mantle of leadership over their own countries.

Southeast Asia was changed in an evolutionary, rather than revolutionary, way by the Japanese occupation. Although returning Europeans and even some Southeast Asians themselves complained that Japanese fascism had deeply influenced the region's societies, there is not much evidence that this was the case. Japanese rule, indeed, had destroyed whatever remained of the mystique of Western supremacy, but the war also had ruined any chances that it might be replaced with a Japanese mystique. There was clearly little clinging to Japanese concepts except where they could be thoroughly indigenized; even the collaboration issue, so important to Europeans and their thinking about the immediate postwar era, failed to move Southeast Asians for long. And, if the general population appeared less docile in 1945 than four years earlier, the reason lay more in the temporary removal of authority at the war's end than in the tutelage of the Japanese.

CONTEMPORARY SOUTHEAST ASIA

Postwar events

Struggle for independence. The swift conclusion of the war in the Pacific made it impossible for the former colonial masters to return to Southeast Asia for several weeks, in some areas for months. During the interim, the Japanese were obliged by the Allies to keep the peace, but real power passed into the hands of Southeast Asian leaders, some of whom declared independence and attempted with varying degrees of success to establish government structures. For the first time since the establishment of colonial rule, firearms in large numbers were controlled by Southeast Asians. Such was the groundwork for the establishment of new, independent states.

Prewar nationalism had been most highly developed in Vietnam and Indonesia, and the colonial powers there were least inclined to see the new realities created by the war, perhaps because of the large numbers of resident French and Dutch and because of extensive investments. The result in both countries was an armed struggle in which the Western power was eventually defeated and independence secured. The Indonesian revolution, for all its internal complexities, was won in little more than four years with a combination of military struggle and civilian diplomacy. The revolution of the Vietnamese, who had defeated the French by 1954, continued much longer because of an internal political struggle and because of the role Vietnam came to play in global geopolitics, which ultimately led to the involvement of other external powers, among them the United States. In both cases, however, independence

was sealed in blood, and a mythologized revolution came to serve as a powerful, unifying nationalist symbol. In the rest of Southeast Asia, the achievement of independence was, if not entirely peaceful, at least less violent. Malaysia and the Philippines suffered "emergencies" (as armed insurgencies were euphemistically called), and Burma, too, endured sporadic internal military conflict. For better or worse, these conflicts were no substitutes for a genuine revolutionary experience.

Whether by revolution or otherwise, decolonization proceeded rapidly in Southeast Asia. The newly independent states all aspired toward democratic systems more or less on the Western model, despite the lack of democratic preparation and the impress of nationalist sentiment. None expressed a desire to return to precolonial forms of government, and, although some Western observers professed to see in such leaders as Indonesia's Sukarno Southeast Asian societies returning to traditional behaviour, their judgment was based more on ephemeral signs than on real evidence. For one thing, societies as a whole had been too much altered in the late 19th and early 20th centuries to make it clear what "tradition" really was. For another, the new leadership retained the commitment to modernization that it had developed earlier. They looked forward to a new world, not an old one. The difficulty, however, was that there was as yet little consensus on the precise shape this new world should take, and colonial rule had left indigenous societies with virtually no experience in debating and reaching firm decisions on such important matters. It is hardly surprising that one result of this lack of experience was a great deal of political and intellectual conflict. Often forgotten, however, is another result: an outpouring of new ideas and creativity, particularly in literature. This signaled the beginning of a kind of cultural renaissance, the dimensions and significance of which are still insufficiently understood.

Early independence period

Defining new states and societies. The first two decades of independence constituted a period of trial and error for states and societies attempting to redefine themselves in contemporary form. During this time, religious and ethnic challenges to the states essentially failed to split them, and (except in the states of former Indochina) both communism and Western parliamentary democracy were rejected. Indonesia, the largest and potentially most powerful nation in the region, provided the most spectacular examples of such developments, ending in the tragic events of 1965–66, when between 500,000 and 1,000,000 lives may have been lost in a conflict between the Indonesian Communist Party and its opponents. Even Malaysia, long the darling of Western observers for its apparent success as a showcase of democracy and capitalist growth, was badly shaken by violence between Malays and Chinese in 1969. The turmoil often led Southeast Asia to be viewed as inherently unstable politically, but from a longer perspective—and taking into account both the region's great diversity and the arbitrary fashion in which boundaries had been set by colonial powers—this perhaps has been a shortsighted conclusion.

The new era that began in the mid-1960s had three main characteristics. First, the military rose as a force in government, not only in Vietnam, Burma, and Indonesia but also in the Philippines and—quietly—in Malaysia. The military establishments viewed themselves as actual or potential saviours of national unity and also as disciplined, effective champions of modernization; at least initially, they frequently had considerable support from the populace. Second, during this period renewed attention was given by all Southeast Asian nations to the question of unifying (secular and national) values and ideology. Thailand, Indonesia, and Vietnam had been first in this area in the 1940s and '50s, but the others followed. Even Singapore and Brunei developed ideologies, with the express purpose of defining a national character for their people. Finally, virtually all Southeast Asian states abandoned the effort of utilizing foreign models of government and society—capitalist or communist—and turned to the task of working out a synthesis better suited to their needs and values. Each country arrived at its own solution, with varying degrees of success. By the 1980s what generally had emerged were quasi-military bourgeois regimes willing to live along modified democratic lines—*i.e.*, with what in Western eyes appeared to be comparatively high levels of restriction of personal, political, and intellectual freedom. Whatever their precise political character, these were conservative governments. Even Vietnam, the most revolutionary-minded among them, could not stomach the far-reaching and murderous revolution of the Khmer Rouge in Cambodia in the mid-1970s and by the end of the decade had moved to crush it.

Tempting as it may be to conclude that greater doses of authoritarian rule (some of it seemingly harking back directly to colonial times) merely stabilized Southeast Asia and permitted the region to get on with the business of economic development, this approach was not successful everywhere. In Burma (called Myanmar since 1989) the military's semi-isolationist, crypto-socialist development schemes came to disaster in the 1980s, revealing the repressive nature of the regime and bringing the country to the brink of civil war by the end of the decade. In the Philippines the assault by President Ferdinand Marcos and his associates on the old ruling elite class brought a similar result, in addition to a spectacular level of corruption and the looting of the national treasury. In Vietnam, where the final achievement of independence in 1975 brought bitter disappointment to many and left the country decades behind the rest of the region in economic development, public and internal Communist Party unrest forced an aging generation of leaders to resign and left the course for the future in doubt as never before.

Failures in authoritarianism

The states generally thought to be most successful to date—Thailand, Indonesia, Malaysia, and especially Singapore—have followed policies generally regarded as moderate and pragmatic. All are regarded as fundamentally stable and for that reason have attracted foreign aid and investment; all have achieved high rates of growth since the mid-1970s and enjoy the highest standards of living in the region. Their very success, however, has created unexpected social and cultural changes. Prosperity, education, and increasing access to world media and popular culture have all given rise, for example, to various degrees of dissatisfaction with government-imposed limitations on freedom and to social and environmental criticism. Particularly in Indonesia and Malaysia, there has been a noticeable trend toward introspection and discussion of national character, as well as a religious revival in the form of renewed interest in Islām. It appears that the comparatively small and unified middle class, including a generally bureaucratized military, is becoming larger, more complex, and less easily satisfied. That was undoubtedly not the intent of those who framed governmental policy, but it is a reality with which they must deal.

Reappearance of regional interests. After the end of the 17th century, the long-developed polities of Southeast Asia were pulled into a Western-dominated world economy, weakening regional trade networks and strengthening ties with distant colonial powers. In the early years of independence these ties often remained strong enough to be called neocolonial by critics, but after the mid-1960s these partnerships could no longer be controlled by former colonial masters, and the new Southeast Asian states sought to industrialize and diversify their markets. On the one hand, this meant a far greater role for Japan in Southeast Asia; that country is by far the most important trading partner of most Southeast Asian nations. On the other, it meant that many countries began to rediscover commonalities and to examine the possibilities within the region for support and markets.

Formation of ASEAN

In 1967 the Association for Southeast Asian Nations (ASEAN) was formed by Malaysia, Indonesia, the Philippines, Thailand, and Singapore (Brunei joined in 1985). This group's initial interest was in security, but it has moved cautiously into other fields. It played an important role, for example, in seeking an end to the Vietnam-Cambodia conflict and has sought a solution to the civil strife in Cambodia. In economic affairs it has worked quietly to discuss such matters as duplication of large industrial projects, but, perhaps because the economies of most of its members are quite similar and as yet only par-

tially industrialized, ASEAN has not attempted to build a true economic community. Only since the mid-1980s has ASEAN been taken seriously by major powers, or even sometimes by Southeast Asians themselves. It seems likely, however, that the formerly Soviet-dominated states of Vietnam, Laos, and Cambodia will become part of ASEAN before the end of the 1990s, and Myanmar may be compelled to follow. Such circumstances will undoubtedly open up greater regional markets and give the region as a whole a more imposing world profile. Moreover, modern communications, which have already begun to inform ASEAN populations more closely about each other, cannot help but further this process and draw attention to common strands in an emerging modern culture that is shared, at least to some degree, by all the nations of the region. (W.H.F.)

THE COUNTRIES OF SOUTHEAST ASIA

Brunei

Brunei—officially State of Brunei, Abode of Peace (Malay: Negara Brunei Darussalam)—is a small, independent Islāmic sultanate on the northern coast of the island of Borneo. It has an area of 2,226 square miles (5,765 square kilometres) and is bounded to the north by the South China Sea and on all other sides by the East Malaysian state of Sarawak, which also divides the state into two enclaves of unequal size. The western enclave is the larger of the two and contains the capital city of Bandar Seri Begawan. Brunei achieved independence in 1984, after having been a British protectorate since 1888. It is a member of the Commonwealth and the Association of Southeast Asian Nations (ASEAN).

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief, drainage, and soils.* The narrow coastal plain in the north gives way to rugged hills farther south. Brunei's highest point is Pagon Peak (6,070 feet [1,850 metres]), in the southeast. The country is drained by the Belait, Tutong, and Brunei rivers in the western enclave and by the Pandaruan and Temburong rivers in the east; all flow generally northward to the South China Sea. The Belait is the largest river in the country. The soils of Brunei are deeply weathered and highly leached and generally are infertile. Richer alluvial soils are found along the rivers and in some parts of the coastal floodplain, and these offer the best agricultural potential.

Climate. The climate of Brunei is governed by the equatorial monsoon winds. Daily temperatures average between 76° and 86° F (24° and 30° C). Precipitation averages 110 inches (2,800 millimetres) annually in the coastal areas but can exceed 150 inches farther inland. Rainfall is heaviest during the northeast monsoon (December to March), with lesser amounts falling during the southwest monsoon (May to October).

The monsoons

Plant and animal life. About three-fifths of the country is covered with virgin tropical rain forest, with another one-fifth under second-growth forest. The undisturbed rain forest consists mainly of hardwoods of the Dipterocarpaceae family, most of which are of commercial importance. Large expanses of peat and freshwater swamps are found in the poorly drained lowlands of the Belait and Tutong rivers, while mangrove swamps are common along the lower riverine reaches and sheltered coastal areas. The complex vegetation of the rain forest provides niches for a rich variety of animals, including monkeys, birds, reptiles, and insects.

The people. About two-thirds of the population of Brunei is Malay, and nearly one-fifth is Chinese. The remainder includes such indigenous peoples as the Kadazan (Kedazan), Murut, Bisaya (Bisayah), and Iban (or Sea Dayak), as well as small numbers of Indians and foreigners. The official language is Malay, with English as a major second language. Brunei's population is predominantly Sunnite Muslim, although the Chinese usually are Buddhist, Taoist, or Confucian. Some of the indigenous peoples are Christian, while others in the remote interior are spirit worshipers.

The interior upland areas are sparsely populated by indigenous peoples, who clear areas of the forest for shifting cultivation. In the western enclave, the Iban inhabit the westernmost Belait district, and the Kadazan live in the rural areas of the central Tutong district; the Murut and Bisaya have settled mainly in the eastern enclave. The Malays are distributed in the riverine and coastal villages and towns, and the Chinese are concentrated in the urban areas.

About two-thirds of Brunei's population is found in and around Bandar Seri Begawan, while one-fifth lives in the oil-rich coastal areas of the Belait district. The capital, located on the Brunei River about nine miles from its mouth on Brunei Bay, is the largest urban centre. Adjacent to the modern section of the city is an older part called Kampong Ayer, where Brunei Malays live in houses built on stilts along inlets of the river.

The economy. Brunei's economy is almost totally dependent on the exploitation of its vast reserves of petroleum and natural gas. Oil and gas revenues have allowed the state to give its citizens one of the highest per capita incomes in Asia, but it also has made the country dependent on a single commodity that is subject to market fluctuations. In addition, Brunei must rely exclusively on imports for nearly all of its manufactured goods and most of its food.

Resources. In addition to its reserves of petroleum and natural gas, Brunei has rich—though undeveloped—deposits of white-quartz sand. Oil was first produced in 1929, while the natural gas industry was developed after the discovery in the 1960s of large deposits. Nearly all the oil and natural gas produced in Brunei comes from offshore fields located off the western enclave. All but a small percentage of the production is exported, a small refinery supplying local needs. Oil output peaked in the late 1970s and subsequently was reduced in order to conserve reserves. Brunei's huge deposits of natural gas were intensively developed in the 1970s, including the construction

Hydrocarbon production

of a gas liquefaction plant. As a result, export earnings from liquid natural gas have come to roughly equal those from petroleum.

Agriculture, fishing, and forestry. These three activities—once the mainstays of Brunei's economy—now constitute only a tiny and dwindling fraction of the gross domestic product. The proportion of the workforce practicing agriculture and fishing has fallen, as people have abandoned these occupations in search of better-paying jobs; production in both areas fails to meet local demand. Rubber, once a major crop, is no longer cultivated. The area planted in rice has declined, although the government has tried to reverse that trend by encouraging production. Other crops—mainly sago, coconuts, fruits, and vegetables—are grown on a small scale. The timber industry has been developed to supply the local market exclusively, while the export of timber has been prohibited.

Finance and trade. Brunei's revenues from petroleum and natural gas, which constitute nearly all of its export earnings, have resulted in perennial trade surpluses. Much of the state's financial activity is concerned with managing its substantial foreign investments, and the return on these has become an important source of income. Brunei's principal trading partners are Japan, the members of the European Community, Singapore, and South Korea.

Transportation. Brunei traditionally depended on its rivers and the sea for transportation. Rivers have remained the main means of transport into the interior, but a good and rapidly expanding network of roads has been built in the coastal areas; some roads have been extended into the interior. Per capita car ownership in Brunei is one of the highest in the world. Brunei has two major ports: a large, deepwater harbour at Muara, on Brunei Bay, and a smaller port at Kuala Belait, at the mouth of the Belait River. An international airport is located at Bandar Seri Begawan.

Administration and social conditions. *Government.* In 1959 Brunei became a self-governing state and adopted a constitution, although the British retained jurisdiction over foreign policy, defense, and internal security. Limited attempts at elected, representative government under this constitution were abandoned by 1970. After Brunei attained full independence in 1984, an Islāmic sultanate was established.

Ultimate authority rests with the sultan, who, as prime minister, presides over a Council of Ministers (cabinet) and is advised by several other councils (Religious, Privy, Succession, and Legislative); the members of these bodies are appointed by the sultan. Judicial power is vested in a Supreme Court, composed of a Court of Appeal and a High Court. There also are religious courts that can appeal to the Religious Council. Brunei is divided into four districts for local administration: Belait, Tutong, and Brunei and Muara in the western enclave and Temburong in the east.

Armed forces. The small, well-equipped Royal Brunei Armed Forces consists mainly of an army group, with smaller navy and air force units. These forces are supplemented by a battalion of British Army Gurkhas and by the Royal Brunei Malay Reserve Regiment, formed in 1988.

Health and welfare. Brunei is a welfare state, with well-developed social facilities. Citizens receive free medical service and education. Medical care in rural areas includes a "flying-doctor" service to the villages, outdoor clinics, and traveling dispensaries, while the capital has a large, modern hospital. The literacy rate has improved considerably since the 1960s, with good educational facilities found throughout the state. The University of Brunei Darussalam was founded in 1985.

Education

For statistical data on the land and people of Brunei, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

Brunei's early history is obscure, but it was known to be trading with and paying tribute to China in the 6th century AD. It then came under Hindu influence for a time through allegiance to the Majapahit kingdom in Java. When the ships of Ferdinand Magellan's expedition anchored off Brunei in 1521, the fifth sultan, the great Bolkiah, controlled practically the whole of Borneo, the Sulu Archipelago, and neighbouring islands. Toward the end of the 16th century, Brunei was torn by internal strife. A gradual decline in power continued through the 19th century, notably with the cession of Sarawak to the English adventurer James (later Sir James) Brooke in 1841, the expansion of Sarawak by additional grants to Brooke, the cession to Britain of the island of Labuan in Brunei Bay, and the final loss of what is now Sabah (eastern East Malaysia). Brunei's fortunes began to revive, however, when petroleum was first produced in 1929.

Brunei became a British protectorate in 1888, and in 1906 administration was vested in a British resident, whose advice the sultan was bound to accept. Brunei was occupied (1941–45) by the Japanese during World War II. After the British returned, negotiations began on the eventual independence of Brunei. The first step in this process occurred in 1959, when self-government was achieved and the British resident was replaced by a high commissioner. Britain remained responsible for defense and foreign policy. Brunei adopted a written constitution, and in 1962 a partly elected Legislative Council with limited authority was installed. The conversion to a representative government was interrupted later that year by a revolt, which was suppressed with the help of British forces; the sultan then suspended most provisions of the constitution. New elections were held in 1965, but appointed members still retained their majority in the council.

In 1967 Sultan Omar Ali Saifuddin abdicated in favour of his eldest son, Pengiran Muda Hassanal Bolkiah, although the former sultan continued to exercise influence until his death. Brunei's political life was stable throughout the 1970s in large part because of its flourishing economy and its position as one of the world's wealthiest (on a per capita basis) oil producers. In 1979 the United Kingdom and Brunei signed a treaty whereby Brunei would become fully independent in 1984. Malaysia and Indonesia both gave assurances that they would recognize Brunei's status, thereby allaying the sultan's concern that the state might be incorporated by one of its larger neighbours.

Brunei duly became independent on Jan. 1, 1984, and an Islāmic sultanate was proclaimed. A ministerial form of government was introduced: the sultan became prime minister and held other posts, and he appointed members of his family (including his father as defense minister) to most of the other positions. When his father died in September 1986, the sultan took over the important defense portfolio and enlarged his cabinet. The structure of Brunei's government has been in marked contrast with those of the other ASEAN countries, but Brunei has remained politically stable and economically prosperous.

Independence

(O.J.B.)

For later developments in the history of Brunei, see the BRITANNICA BOOK OF THE YEAR.

Cambodia

Cambodia—officially State of Cambodia (Khmer: Roat Kampuchea)—is a country of Southeast Asia located in the southwestern part of the Indochinese Peninsula. Covering a land area of 70,238 square miles (181,916 square kilometres), it is bordered on the west and northwest by Thailand, on the northeast by Laos, on the east and southeast by Vietnam, and on the southwest by the Gulf of Thailand. The name Cambodia and the French version, Cambodge, are transliterations of the country's traditional name, pronounced Kampuchea in the Khmer, or Cambodian, language.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Cambodia's maximum extent is about 280 miles (450 kilometres) from north to south and 360 miles from east to west. The central region is a low-lying alluvial plain surrounding the Tonle Sap (Great Lake) and the beginnings of the Mekong River delta. Extending outward from this region are transitional plains, thinly forested and with prevailing elevations no higher than several hundred feet above sea level. On the north, along the border with Thailand, the Cambodian

plain abuts a sandstone escarpment that marks the southern limit of the Dangrek (Khmer: Dângrêk) Mountains. A southward-facing cliff, stretching for more than 200 miles from west to east, rises abruptly from the plain to heights ranging from 600 to 1,800 feet (180 to 550 metres), forming a natural frontier boundary. East of the Mekong the transitional plains gradually merge with the eastern highlands, a region of forested mountains and high plateaus that extend into Laos and Vietnam. In southwestern Cambodia two distinct upland blocks, comprising the Krâvanh (Cardamom) Mountains and the Dâmrei (Elephant) Mountains, form another highland region that covers much of the land area between the Tonle Sap and the Gulf of Thailand. In this remote and largely uninhabited area is found Mount Aôral (5,949 feet; 1,813 metres), Cambodia's highest peak. The southern coastal region adjoining the Gulf of Thailand is a narrow lowland strip, heavily wooded and sparsely populated, which is isolated from the central plain by the southwestern highlands.

Drainage and soils. The two most dominant topographical features of Cambodia are the Mekong River and the Tonle Sap. Rising in the Plateau of Tibet and emptying into the South China Sea, the Mekong enters Cambodia from Laos at the Khone Falls and flows generally southward to the border with Vietnam, a distance inside Cambodia of approximately 315 miles. The Tonle Sap, joined to the Mekong by the Sab River, serves as a reservoir for the Mekong. During the rainy season (mid-May to early October), the Mekong's enormous volume of water backs up the connecting river for a distance of 65 miles and flows into the Tonle Sap, expanding the lake's surface area from the dry-season minimum of 1,200 square miles to a rainy-season maximum of more than 3,000 square miles. As the water level of the Mekong falls during the dry season, the process is reversed. Water drains from the Tonle Sap back into the Mekong, reversing its directional flow. As a result of this annual phenomenon, the Tonle Sap is one of the world's richest sources of freshwater fish.

Tonle Sap

Most of Cambodia's soils are sandy and relatively poor in nutrients. The so-called red-soil areas in the eastern part of the country, however, are suitable for such commercial crops as rubber and cotton. The annual flooding of the Mekong during the rainy season deposits a rich alluvial sediment that accounts for the fertility of the central plain.

Climate. Cambodia's climate is governed by the monsoon winds, which define two major seasons. From mid-May to early October, the strong prevailing winds of the southwest monsoon bring heavy rains and high humidity. From early November to mid-March, the lighter and drier winds of the northeast monsoon bring variable cloudiness, infrequent precipitation, and lower humidity. The weather between these seasons is transitional. Maximum temperatures are high throughout the year, ranging from about 82° to 83° F (28° C) in January, the coolest month, to about 95° F (35° C) in April. Annual rainfall varies considerably throughout the country, from more than 200 inches (5,000 millimetres) on the seaward slopes of the southwestern highlands to about 50–55 inches in the central lowland region. Three-fourths of the annual rainfall occurs during the months of the southwest monsoon.

Plant and animal life. Much of Cambodia is heavily forested. The central lowland region is covered with rice paddies, fields of such dry crops as corn (maize) or tobacco, tracts of tall grass and reeds, and thinly wooded areas. Savanna (grassy parkland) is predominant on the transitional plains, with the grasses reaching a height of five feet. In the eastern highlands the high plateaus are covered with deciduous forest and grassland. Broad-leaved evergreen forests grow in the mountainous areas to the north, with trees 100 feet high emerging from thick undergrowths of vines, rattans, palms, bamboos, and assorted woody and herbaceous ground plants. In the southwestern highlands, open forests of pines are found at the higher elevations, while the rain-drenched seaward slopes are blanketed with virgin rain forest growing to heights of 150 feet or more. Vegetation along the coastal strip ranges from evergreen forests to nearly impenetrable mangrove forests.

About three-fourths of Cambodia was forested in 1970. This area has been reduced considerably since then, especially in the provinces bordering Thailand and Vietnam that have been heavily exploited by the local inhabitants and by Thai and Vietnamese entrepreneurs. Unchecked deforestation in northern areas near the Mekong has produced extensive erosion along the river's banks.

The northeastern forests of Cambodia—like the neighbouring areas of Laos and Vietnam—once sheltered large populations of such wild animals as elephants, wild oxen, rhinoceroses, and several species of deer, but the loss of forest cover, combined with warfare and unregulated hunting in the region, has sharply reduced these numbers. Small populations of most species still may be found, along with some tigers, leopards, bears, and many small mammals. Among the more common birds are herons, cranes, grouse, pheasant, peafowl, pelicans, cormorants, egrets, and wild ducks. Four varieties of snakes are especially dangerous: the Indian cobra, the king cobra, the banded krait, and Russell's viper.

Reduction of wildlife

Settlement patterns. Cambodia always has been overwhelmingly a land of villages. Only a small fraction of the total population has ever lived in towns of more than 10,000 inhabitants. Since the 1920s, most of these urban dwellers have been concentrated in Phnom Penh, which is situated at the confluence of the Mekong, Basăk (Bassac), and Sab rivers.

Until the mid-1970s, the vast majority of Cambodia's people inhabited the central lowland region, where the rural village was second only to the family as the basic social unit. The typical Cambodian village in those days was made up of ethnically homogeneous people and had a population of fewer than 300 persons. The village (*phum*) was part of a hamlet or community (*khum*) with which it shared one or more Buddhist temples (*wat*), an elementary school, and several small shops. Cambodian villages usually developed in a linear pattern along waterways and roads, but often houses also were dispersed through the countryside on largely self-contained paddy farms. Houses in Cambodia generally were built on wooden pilings and had thatched roofs, walls of palm matting, and floors of woven bamboo strips resting on bamboo joists. More prosperous houses, while still on pilings, were built of wood and had tile or metal roofs.

Village life

There were a few large landowners in Cambodia, until, under the rulers of Democratic Kampuchea, they were forced off their land and into collectives in 1975 and made to live as ordinary peasants; hardly any reemerged after decollectivization. Before collectivization, the typical villager owned and worked enough land to provide for his family, with a small surplus that could be converted into cash for additional goods or the payment of taxes. Landholdings tended to be small in the crowded south-central regions of the country. During the 1960s the government

A traditional rural settlement on the bank of the Tonle Sap, Cambodia.

of Prince Norodom Sihanouk was successful in colonizing frontier regions, especially in the northwest, with army veterans or poor farmers from more crowded parts of the country. These programs, however, did not significantly alter Cambodian settlement patterns.

Throughout rural Cambodia, lifestyle was closely geared to the agricultural cycle, which was based, in large part, on family-oriented subsistence farming. Family members were awake before dawn, and most of the day's work was accomplished before noon, although minor tasks were performed in the cool of the early evening. Electricity has always been rare in village areas, and country people were generally asleep soon after sunset. During the rice-growing season, all family members worked together in the fields, because the work of planting, transplanting, and harvesting had to be done quickly. Without mechanical assistance, the work of several people was needed to grow enough rice to feed a family for a year. Because of the intensive labour requirements of paddy farming, obligations would build up among families within a village during the agricultural season. Festivals and marriages, celebrated by a whole village, were usually held after the rice had been harvested and money had been obtained from selling the surplus grain.

Urban areas

The urban areas of Cambodia took their present form in the early 20th century, during the French colonial period, as commercial and administrative centres serving their surrounding rural regions. Most of them were located at the intersections of land or river routes and were relatively accessible to the areas they served. Phnom Penh (*phnom* means "hill"; Penh is a woman's name) is Cambodia's single metropolis, and its population fluctuations reflect the country's recent history. Before the outbreak of war in 1970, it held about 500,000 people; its population by 1975, then swollen with refugees, numbered some 2,000,000. People began moving back into the city in 1979, after its official depopulation. Phnom Penh's population has grown rapidly since then, exceeding its 1970 level in the late 1980s.

The people. Cambodia's first national census as an independent nation was taken in 1962, with a resulting total of about 5,700,000. Overall population density has been difficult to determine, because of the enormous losses and movements of people in the years after 1970. Because so much of the country is poorly watered and without inhabitants, the actual density in populated areas is quite high.

Ethnic and linguistic composition. The Khmer (Cambodians) account for the vast majority of the total population. This has produced a homogeneity that is unique in Southeast Asia and has encouraged a strong sense of national identity. Other traditional ethnic groups included the Chinese, Vietnamese, Cham-Malays, various tribal peoples, and Europeans. With the upheavals of the 1970s, the number of European residents declined precipitously, while many Chinese and local Vietnamese survivors emigrated overseas.

The Khmer are concentrated in the lowland regions surrounding the Mekong River and the Tonle Sap, on the transitional plain, and along the coast. They belong to the Mon-Khmer ethnolinguistic group. A product of centuries of intricate cultural and racial blending, the Khmer moved southward before 200 BC into the fertile Mekong delta from the Khorat Plateau of what is now Thailand. They were Indianized by successive waves of Indian influence and in the 8th century AD were exposed to Indo-Malayan influences and perhaps immigration from Java. This was followed by migrations of Tai peoples from the 10th to the 15th century, by a Vietnamese migration beginning in the 17th century, and by Chinese migrations in the 18th and 19th centuries. The typical Khmer family before 1975 consisted of a married couple and their unmarried children. Both sons and daughters usually left the parental home after marriage to establish their own households.

The ethnic minorities

Among the ethnic minorities in Cambodia before 1975, the Chinese were the most important, for they controlled the country's economic life. They were shunted aside in the communist-led revolution of the 1970s and made to become ordinary peasants. Those who did not seek refuge abroad after 1975 and others who subsequently returned regained some of their former influence as urban centres were revived. The Vietnamese minority occupied a somewhat lower status than the Chinese, and most of them fled or were repatriated to Vietnam after 1970. In the 1980s, however, a large number of Vietnamese migrants, many of them former residents of Cambodia, settled in the country. Centuries of mutual dislike and distrust have clouded Vietnamese-Khmer relations, and intermarriage has been infrequent. The next most important minority, the Cham-Malay group known in Cambodia as Khmer Islām, also maintained a high degree of ethnic homogeneity and was discriminated against under the regime of Democratic Kampuchea. Finally, the tribal people of Cambodia, living originally in the forested northeastern part of the country, received slightly better treatment than the Khmer Islām during that period.

Religions. Most ethnic Khmer are Theravāda (Hīnayāna) Buddhists (*i.e.*, belonging to the older and more traditional of the two great schools of Buddhism, the later school being called Mahāyāna). Until 1975 Buddhism was officially recognized as the state religion of Cambodia. Although the social and psychological characteristics often ascribed to the Khmer—individualism, conservatism, patience, gentleness, and lack of concern for material wealth—were often in the eyes of the beholder, they represented Buddhist ideals toward which a large number of Cambodians, especially in rural areas, have continued to aspire. Buddhist precepts, however, do not permeate Cambodian education and ideology as strongly as they did before 1975.

Minority populations were not Theravāda Buddhists. Tribal people were animists, and the ethnic Vietnamese and Chinese were eclectic, following Mahāyāna Buddhism, Taoism, and such syncretic Vietnamese religious movements as the Cao Dai. The Cham were strict Muslims, and a sizable number of Vietnamese were members of the Roman Catholic church.

Demographic trends. In common with many developing countries, Cambodia has a large proportion of children in its population. It should be noted, however, that population trends have been difficult to trace because of the destruction and dislocation since the early 1970s, because of the lack of statistical information available, and because an enormous number of people of childbearing age have died.

The war and social revolution in the 1970s and the political and economic disruption in the country since then have seriously affected the distribution of Cambodia's population. Between 1975 and 1978, hundreds of thousands of urban people were forcibly moved into rural areas to cultivate rice and to dig and maintain extensive irrigation works. With the exception of Phnom Penh and Bătdâmbâng (Battambang), few towns and cities subsequently have regained their pre-1970 population levels. In addition, more than 600,000 people have sought permanent or temporary residence outside Cambodia since 1979. About a third of these have emigrated overseas, while most of the remainder have settled in refugee camps in Thailand along the Cambodian border; the repatriation of these refugees under United Nations auspices was one of the provisions of a peace agreement signed in Paris in 1991.

Emigration

The economy. Even before 1975, Cambodia's economy was one of the least-developed of the Southeast Asian region. It was heavily dependent on two major products—rice and rubber—and consequently was vulnerable to profound annual fluctuations caused by vagaries in the weather and world market prices. Agriculture dominated the economy, with most rural families engaged in rice cultivation. Although the tradition of landownership was strong, family landholdings were relatively small. But, even with small family farms, the rural population was largely self-sufficient. Two and a half acres (one hectare) of rice paddy provided for the needs of a family of five people, and supplementary requirements were traditionally satisfied by fishing, cultivating fruit and vegetables, and raising livestock. Famine was rare in Cambodia, but the self-sufficiency of the rural family produced a conservatism that proved resistant to government efforts before 1975 to modernize the country's primitive agricultural methods.

The collectivization of agriculture under the rulers of Democratic Kampuchea was dismantled after the collapse of that regime, but it remained an ideal of the communist-led government that came to power in 1979. Voluntary cooperative groupings called *krom samaki* subsequently replaced collective farms in many areas, but the vast majority of Cambodian farming continued to be carried out by family units growing crops for subsistence and small surpluses for cash or barter. A law enacted in 1989 permitted Cambodians to buy and sell real estate for the first time. An immediate effect of the law was a speculative boom in urban areas and an increase in investment, particularly in Phnom Penh. In rural areas laws also were implemented that restored traditional rights of land tenure and inheritance.

Resources. Cambodia has few known mineral resources. Some limestone and phosphate deposits are found in Kâmpôt province, and precious stones are mined in Bătdâmbâng province. Cambodia's small quantities of iron and coal have not justified commercial exploitation. Electric power sources are mainly dependent on imported oil. Prospecting for oil and natural gas has been initiated at offshore areas adjacent to sites being exploited by Vietnam.

Agriculture and fisheries. Rice is Cambodia's principal food, its major crop, and, in times of peace, its most important export commodity. Rice is grown on most of the country's total cultivated land area. The principal rice regions surround the Mekong and the Tonle Sap, with cultivation particularly intensive in Bătdâmbâng, Kâmpóng Cham, Takêv, and Prey Vêng provinces. Cambodia traditionally has produced only one rice crop per year because it has lacked the extensive irrigation system needed for double cropping.

Rice production

Under the government of Democratic Kampuchea, great effort was made to build irrigation systems throughout the country. The results occasionally were notable, and in a few parts of the country farmers were able to grow two, and more rarely three, crops of rice per year. In some cases the works were poorly conceived and hastily built and soon collapsed. Most of those that survived were abandoned after 1979.

Under the traditional patterns of agriculture, planting normally begins in July or August, and the harvest period extends from November to January. The amount of rainfall, when there is little irrigation, determines the size and quality of the crop. Other food products include corn (maize), beans, soybeans, and sweet potatoes. The principal fruit crops, all of which are consumed locally, include oranges, bananas, and pineapple; these are supplemented by a variety of other tropical fruits, including breadfruit, mango, mangosteen, and papaya.

Fisheries and livestock are important components of the domestic economy. Fish in its various forms—fresh, dried, smoked, and salted—constitutes the most important source of protein in the Cambodian diet, and subsistence fishing is part of every farmer's activity. The annual freshwater catch includes perch, carp, lungfish, and smelts. Cattle, particularly water buffalo, are used principally as draft animals in the rice paddies and fields. Hog production has also played a large role in agriculture. Efforts to replenish the number of livestock—depleted by years of war—have been hampered by uncertain social conditions and the prevalence of animal diseases.

Industry. Although industrial development remains at a low level, successive governments since independence have made efforts to build a modest industrial base suitable for domestic needs. Equipment installed in the 1950s and '60s in many Cambodian factories has become obsolete, however, and the country has received little foreign investment capital needed for long-term industrial development. Cambodia also has lacked a trained and experienced labour force. Some progress has been made—plants have been established to produce soft drinks, paper, cigarettes, building materials, cement, and cotton textiles—but Cambodia's industrial sector has found it difficult to compete with mass-produced goods from the more economically developed countries of the region. Timber processing and rice milling, which were important before 1975, were revived in the 1980s.

Finance and trade. Foreign trade has been at a standstill since the 1970s, and imports have taken the form of foreign aid. Traditionally, the bulk of Cambodia's exports—consisting almost entirely of rice, rubber, corn, and other agricultural products—went to other Asian nations, while imports came mainly from Japan, the United States, and western Europe.

The civil war of 1970–75 in Cambodia devastated the countryside, sharply reduced foreign trade, and destroyed the country's fragile economic infrastructure. After the communist victory in 1975, the economic policies of the Democratic Kampuchea regime met with mixed results and left the people with few resources with which to fight a full-scale war against Vietnam in 1978–79. The port of Kâmpóng Saôm (formerly Sihanoukville) was used by Democratic Kampuchea and subsequent regimes largely to receive foreign aid. Substantial maritime trade also has developed between Thailand and Cambodia in the Cambodian province of Kaôh Kŏng.

Effects of the civil war

Transportation. Cambodia's inland waterways and road systems constitute the main transportation routes. Each invariably is affected by the floods of the rainy season, which result in heavy accumulations of silt and washouts caused by flash floods. Railroads rank third in significance. Domestic shipping and civil air facilities are limited. Maritime commerce is carried out almost exclusively by foreign vessels.

The road system eventually surpassed the country's inland waterways as the principal means for moving cargo and passengers. The network was originally designed by the French during the protectorate period to link the agricultural hinterland with the port of Saigon (now Ho Chi Minh City, Vietnam). Consequently, the system did not serve Cambodia as a whole. Extensive land tracts in the northern, northeastern, and southwestern parts of the country were without roads. Of the total road network, only a fraction has been paved; other roads have been surfaced with crushed stone, gravel, or laterite or have been simply graded without being paved. The country's longest bridge, traversing the Sab River at Phnom Penh, was destroyed in 1975.

Roads and bridges deteriorated sharply during the Democratic Kampuchea period and in the civil war that followed. Funds and equipment for repairs were not available, and after 1979 most roads were mined or cut by guerrillas hostile to the government in Phnom Penh. Since 1990, repairing Cambodia's road network has been a high priority for the United Nations and has been a focus of foreign-aid efforts in the country.

Cambodia's inland waterways have a collective extent of some 1,200 miles, of which more than 90 percent are part of the Mekong and Tonle Sap systems. Phnom Penh, located about 200 miles from the mouth of the Mekong, can be reached by oceangoing vessels with drafts of less than 13 feet. North of Phnom Penh, the Mekong is navigable to Krâchéh for rivercraft, but rapids and winding channels in the section between Krâchéh and the Laos border generally preclude commercial navigation.

Cambodia's single maritime port is located at Kâmpóng Saôm on the Gulf of Thailand. Completed in 1960, Kâmpóng Saôm can provide unlimited anchorage for oceangoing ships. The port is of strategic importance to Cambodia, and considerable industrial development has taken place in the area. A modern four-lane highway links Kâmpóng Saôm with Phnom Penh.

The railroad system is owned and operated by the Cambodian government. One line, completed prior to World War II, connects Phnom Penh with Paôy Pêt on the Thai frontier and facilitates the movement of milled rice from the western provinces of Bătdâmbâng, Poŭthĭsăt, and Kâmpóng Chhnăng. Another line, completed in 1969, connects Phnom Penh with Kâmpóng Saôm.

Administration and social conditions. *Government.* In 1981 a constitution was promulgated by the Vietnamese-backed government in Phnom Penh controlled by the communist Kampuchean People's Revolutionary Party (transformed in 1992 into the noncommunist Cambodian People's Party). This document (amended in 1989) provided for a legislative National Assembly and a Council

Constitution

of State selected from the assembly, an executive Council of Ministers, and a judiciary. This government was opposed by three major factions: Prince Norodom Sihanouk and his followers, the communist Party of Democratic Kampuchea (commonly called the Khmer Rouge), and the noncommunist Khmer People's National Liberation Front (renamed the Buddhist Liberal Democratic Party in 1992). In 1982 the three opposition groups formed a coalition government-in-exile headed by Sihanouk, but this rival government never gained power in Cambodia and often was racked by internal dissention.

This arrangement, however, accorded the opposition groups international recognition and gave them the opportunity to engage in discussions with the Phnom Penh government. After lengthy negotiations, a series of peace accords were signed in Paris in 1991 by the four political factions. The agreements provided for the reorganization of the national government under the executive control of a Supreme National Council chaired by Sihanouk and composed of members of the four political factions. A United Nations Transitional Authority in Cambodia, established to oversee the implementation of the accords, was given the administration of several key ministries—including those for defense, information, and the interior. Elections for a new government were held in May 1993.

Armed forces. Each of the four political factions has maintained its own military units, with those of the government in Phnom Penh being the largest and best-equipped. Under the 1991 accords, all factions were to reduce by 70 percent the forces under their control.

Education. Cambodia's educational system, as it had developed in the first 70 years of the 20th century, was another casualty of warfare and ideology. During the Democratic Kampuchea period, only primary schools were open; older students attended irregularly scheduled political and technical courses, often held in the communes. After 1979 the government in Phnom Penh gave high priority to primary education, and it also reopened secondary schools and institutions of higher education. Although a large number of young Khmer attend some form of educational institution, schools and colleges have been severely hampered by shortages of funds, books, equipment, and trained staff.

Health and welfare. Throughout Cambodia's history, an acute shortage of medical personnel has been a major obstacle to the implementation of an effective public health program. Even before the civil war, Cambodia had few doctors, hospitals, or medical facilities. The civil war of 1970–75 strained and eroded this fragile structure. The rulers of Democratic Kampuchea moved medical personnel onto collective farms and, as part of its policy of self-reliance, encouraged non-Western medical practices based on the use of local herbs. In the period since 1979, the scarcity of funds, unsettled conditions in the country, a lack of sanitation, and a shortage of medicine have contributed to reports of malaria and hepatitis epidemics. Phnom Penh has the country's best health care facilities and trained medical personnel; most rural areas are served only by a local infirmary.

Cultural life. Before 1970, Cambodian culture and artistic expression were overshadowed by the greatness of the past. Although the Khmer empire owed much to Indian influence, its achievements represented original contributions to Asian civilization. The magnificent architecture and sculpture of the Angkor period (802–1432), as seen in the temple complexes at Angkor Wat and Angkor Thom, marked the apex of Khmer creativity. Following the capture of Angkor by the Thai (15th century) and the crumbling of the empire, the region underwent four centuries of foreign invasions, civil war, and widespread depopulation. It was not until the establishment of the French protectorate in 1863 that internal security was restored, the country's borders were stabilized, and efforts were undertaken to revive traditional Khmer art forms. After Cambodia gained independence from France in 1953, the government placed particular emphasis on accelerating that revival by establishing a national school of music, a national school of ballet and theatre, and a fine arts university. This coincided with the rapid expansion of elementary and secondary school facilities and the emergence of education as the most important factor of social mobility.

Khmer architecture

While Democratic Kampuchea's leadership, inspired by the People's Republic of China, made culture subservient to Marxist-Leninist doctrines, the government in Phnom Penh after 1979 made serious efforts to restore such traditional activities as classical music, ballet, and popular theatre. Foreign aid from India and Poland was used to clean and maintain some of the temples at Angkor, which had suffered from years of vandalism and neglect. These aspects of high culture have had to compete for people's attention with videotapes imported from Hong Kong, Thailand, and elsewhere, and with Western popular music.

Music and dance forms. Music occupied a dominant place in traditional Cambodian culture. It was sung and played everywhere—by children at play, by adults at work, by young men and women while courting—and invariably was part of the many celebrations and festivals that took place throughout the year at Buddhist temples in the rural countryside. Instruments used in full orchestras included xylophones with wooden or metal bars, one- and two-stringed violins, wooden flutes, oboes, and drums of different sizes. The players followed the lead of one instrument, usually the xylophone, and improvised as they wished.

Dancing and drama were also popular forms of artistic expression. The Royal Ballet in Phnom Penh exemplified the classic, highly stylized dance form adapted by the Khmer and Thai from the ancient dances of Angkor. In the countryside, folk drama and folk dances were performed at festivals and weddings by wandering troupes.

Visual arts. The traditional visual arts of Cambodia revealed the essential conservatism of the Khmer. Ancient themes were preferred and rarely was there an effort to improve or adapt. The principal crafts were weaving, working silver and gold, making jewelry, and the sculpture of wood and stone.

Crafts

Literature. In the 1960s and early 1970s, Cambodia's traditionally conservative literature—which was based to a large extent on Thai literary forms—came under Western influence, as did its audience of young, urbanized Cambodian elite. Novels, poetry, visual arts, and films came to reflect international taste. All these forms of expression, however, were banned by the officials of Democratic Kampuchea, and freedom of expression was limited by the government after 1979 through paper shortages and by the regime's use of literature for propaganda.

Press and broadcasting. No daily newspaper is published in Phnom Penh, but there are several weeklies. Television and radio programs are broadcast for only a few hours per day by government-controlled stations.

(L.C.O./D.P.Ch.)

For statistical data on the land and people of Cambodia, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

The importance of Cambodia's contributions to mainland Southeast Asia is out of proportion to its present reduced territory and limited political power. Between the 11th and the 13th century, the Khmer (Cambodian) state included much of the Indochinese Peninsula and incorporated large parts of present-day southern Vietnam, Laos, and eastern Thailand. The cultural influence of Cambodia on other countries, particularly Laos and Thailand, has been enormous.

Early history. It is not known for certain how long people have lived in what is now Cambodia, where they came from, or what languages they spoke before writing was introduced (using a Sanskrit-style alphabet) about the 3rd century AD. Dates based on carbon-14 measurements have established that people able to make pottery inhabited Cambodia as early as 4000 BC. These and subsequent finds have suggested that these early people, like Cambodians today, were of slight to medium build, constructed their houses on wooden piles, consumed a considerable quantity of fish, and raised pigs and water buffalo.

Whether the early inhabitants of Cambodia came originally or primarily from the north, west, or south is still

being debated, as are theories about waves of different peoples moving through the region in prehistoric times. The notion of distinct Asian "races" that was popular until the 1950s has been discredited, and subsequent archaeological finds have suggested that prehistoric mainland Southeast Asia, including Cambodia, had a comparatively sophisticated culture. Some scholars even have attributed the first cultivation of rice and the first casting of bronze to the region.

Indian influences

Funan and Chenla. Indian influences were the most important of Cambodia's early history. They coincided with the first centuries AD, when Chinese and Indian pilgrims and traders stopped along the coasts of present-day Cambodia and Vietnam and exchanged silks and metals for spices, aromatic wood, ivory, and gold. Written sources from about this period are almost entirely in Chinese. A kingdom or group of kingdoms known to Chinese writers as "Funan" flourished in southern Cambodia at this time. Over a period of 300 years between the 3rd and 6th centuries AD, its rulers offered gifts from time to time to Chinese emperors. Chinese writers testified to the extent of Indian influence in the kingdom and cited a local story, dating from the 6th century, that traced its origins to an Indian Brahman named Kaundinya "who changed its institutions to follow Indian models." One early innovation was probably the introduction of large-scale irrigation, which allowed people to raise three or more crops of rice per year in some districts and brought unpromising areas under cultivation. Another was the worship of the Hindu god Śiva (Shiva), who was conceptualized as a tutelary ancestor or spirit of the soil and often was represented by a stone lingam, or phallus. A third was the relatively peaceful coexistence of Hinduism and Buddhism, which characterized Cambodia for more than a thousand years.

The most important legacy of Funan, though it may have been exaggerated by Chinese writers, was a relatively centralized state apparatus, culminating in a theoretically absolute ruler. The ruler presided over the agricultural workforce and commanded agricultural surpluses and off-season labour to sustain his lifestyle, support a priestly caste, and build fortresses, palaces, and temples. In a general way, these social arrangements characterized much of the medieval world, but it would be imprecise to use a term like "feudalism" to characterize Funan and its successor states. Instead, it is probably more fruitful to seek links between ancient and present-day Cambodia than between ancient Cambodia and countries far to the west about which the Khmer would have known nothing.

The appearance of Sanskrit inscriptions in the 6th century—the earliest known Khmer inscription dates from the early 7th century—has made it possible to use indigenous sources to supplement Chinese ones, but they all fail to clarify the confusing political developments that occurred in the Cambodian region between the decline of Funan in the 6th century and the founding of a centralized state in northwestern Cambodia about three centuries later. It has been common practice for modern writers to use "Chenla," the contemporary Chinese term for the region, when referring to Cambodia during this time. Chinese sources suggest that there were at least two kingdoms, known as "Water Chenla" and "Land Chenla," in Cambodia that vied for recognition from China in this period. Whereas the geographic centre for both Funan and Water Chenla lay in the Mekong delta south and east of Phnom Penh and extended into present-day Vietnam, the heartland of Land Chenla appears to have been farther up the Mekong, with an important cult site called Wat Phu located in present-day southern Laos. It seems likely that Water Chenla looked outward and welcomed foreign trade, while Land Chenla was more inward-looking and based its economy on intensive agriculture. Surviving inscriptions in Sanskrit and Khmer testify to a multitude of small kingdoms on Cambodian soil in the 7th, 8th, and 9th centuries. Remarkable sculptures and architectural remains also have survived from this period, displaying a mixture of Indian influence and local inspiration. The appearance of local styles reflected, in part, declining Indian commercial interest in the region beginning in the 7th century.

The Khmer state (Angkor). *Foundation of the kingdom.* In 790 a young Cambodian prince, claiming to be descended from the rulers of Funan, was consecrated in eastern Cambodia under the title Jayavarman II. Part of the ceremony involved breaking ties with "Java," which probably was not a reference to the island of Java but to the kingdom of Śrivijaya on the island of Sumatra. Over the next 10 years, Jayavarman extended his power northward into the Mekong River valley until, in 802, he was reconsecrated as a chakravartin (the ancient Indian conception of world ruler) in northwestern Cambodia. The capital seems to have been located in the Kulén Hills north of the present-day provincial capital of Siĕmréab (Siem Reap), where he died in 835. Despite the high status accorded him by subsequent Angkorean kings, Jayavarman II seems to have left no inscriptions of his own, and the monuments that can be dated to his reign were small and hastily built.

Jayavarman II

Jayavarman's real accomplishment was less tangible and longer-lasting, for he seems to have welded what came to be called Kambuja-desa into a confident, self-aware kingdom that superseded and came to control a range of smaller states. He was Cambodia's first nationally oriented king. Whether smaller states were forced into subservience or volunteered it is uncertain, but, despite the grandeur and apparent continuity of the Angkorean temples that were built over the next four centuries, Jayavarman II's successors were often powerless or were constrained by outside forces. Revolts and usurpations were frequent, as were foreign invasions. Rulers were subject to claims by family members, priests, generals, and bureaucrats. Some kings, especially usurpers, had more freedom of action than others. Those who ruled in periods of peace were also in a better position to undertake building programs and public works. Like their counterparts in medieval Europe, Cambodian kings were far removed from ordinary people. The king was perceived primarily in religious terms, and he assured the fertility of the soil and the well-being of the kingdom through the rituals he performed that were thought to obtain such guarantees. In exchange for his protection, the people were technically enslaved and liable for military service and corvée duty, although they actually spent most of their time growing crops to feed their families.

Toward the end of the 9th century, soon after Jayavarman II's death, the Cambodian capital shifted to the northern shores of the Tonle Sap, near present-day Phumĭ Rôluôs. A king named Indravarman I (ruled 877–*c.* 890) constructed a large reservoir and several temples there, including a pyramidical structure called the Bakong—the first Cambodian temple to be built primarily of stone rather than brick. This so-called "temple mountain" became the model for many larger royal temples at Angkor. These served as monuments to the greatness of their patrons and, subsequently, as their tombs.

Angkorean civilization. Indravarman's son and successor, Yaśovarman I (*c.* 890–*c.* 910), moved the capital again, this time closer to Siĕmréab. This was the foundation of Angkor—a name derived from the Sanskrit word *nagara,* meaning "city"—which has become one of the world's most celebrated archaeological sites, as well as the popular name for Cambodia's medieval civilization. The city that Yaśovarman founded, Yaśodharapura, retained that name and remained Cambodia's capital until it was abandoned in the 15th century. His temple mountain, now called Bakheng (literally, "Mighty Ancestor"), was built on a natural hill that overlooked a teeming city, the more distant rice-growing plain, and the Tonle Sap. The mountain occupied the centre of the city, just as Mount Meru, the mythical home in India of Hindu gods, was said to stand at the centre of the universe. Yaśovarman built a large reservoir nearby. The city wall of Yaśodharapura measured 2.5 miles (4 kilometres) on each side. For such an ambitious building program, the king needed to command a large labour pool. Other evidence suggests that his reign was characterized by tolerance toward a variety of Buddhist and Hindu sects that occasionally blended into local cults honouring ancestral spirits and spirits of the soil. Indeed, for all the apparent absolutism of its kings,

Yaśovarman I

a consistent feature of Angkorean civilization, unmatched in medieval Europe, was religious toleration.

After several decades of warfare, dislocations, and disorder—Yaśodharapura itself was abandoned for nearly 30 years—Rajendravarman II (ruled 944–968) restored the capital and set in motion a period of peace and prosperity that lasted nearly a century. During the reign of his successor, Jayavarman V (968–*c.* 1000), the rose-coloured sandstone shrine of Banteai Srei—arguably the loveliest temple at Angkor—was built on the outskirts of the capital under the patronage of a wealthy priestly family, one of whom had been Jayavarman's teacher. In Yaśodharapura itself, Jayavarman V began work on the imposing temple mountain now called Ta Keo, which was completed under his successor, Suryavarman I (ruled *c.* 1004–*c.*1050). Suryavarman I, an innovative and demanding monarch, was a usurper with links to princely families in what is now northeastern Thailand. His rise to power involved the subjugation of many areas that had become semi-independent under his predecessors and resembled that of Jayavarman II two centuries earlier. Suryavarman extended the Khmer empire westward into present-day Thailand, where he constructed the large mountaintop temple known as Preah Vihear. During his reign, the number of cities ruled from Yaśodharapura jumped from roughly 20 to nearly 50, and foreign trade increased, along with tighter bureaucratic control. His successor consolidated these gains, put down a dangerous rebellion, and was responsible for the temple mountain known today as the Baphuon.

The closing years of the 11th century were ones of turmoil and fragmentation. At different times, two and even three "absolute monarchs" contended, simultaneously, for the title of chakravartin. At the end of the century, however, a new dynasty—which was to last for more than a century—began to rule at Angkor. Its most powerful monarch took the name of Suryavarman II (ruled 1113–*c.* 1150), although he probably was not descended from the earlier king of that name. Like his namesake predecessor, Suryavarman II was a formidable military campaigner. He avenged earlier attacks on Angkor by armies launched from the kingdom of Champa, in what is now south-central Vietnam, and led expeditions into northern and southern Thailand. A campaign against Vietnam, which recently had declared its independence from China, was less successful, although earlier in his reign Suryavarman had renewed diplomatic relations with China.

Angkor Wat

Suryavarman's major accomplishment, from a 20th-century perspective, was his temple complex of Angkor Wat, still the largest religious structure in the world and one of the most beautiful. The temple, which eventually became his tomb and probably was an astronomical observatory as well, was dedicated to the Hindu god Vishnu. Its bás-reliefs, running for nearly a half mile inside its third enclosure, depict events in the well-known Indian epics the *Mahābhārata* and *Rāmāyaṇa*—confirming that these texts were widely known at Angkor—as well as Suryavarman himself holding court. The elegance of these carvings, the hundreds of graceful statues of angelic dancers (*apsaras*) that adorn the temple, and its reflection in the moats that surround it continue to give Angkor Wat an awe-inspiring air; in the 12th century, when its towers were gilded and its moats properly maintained, it must have been even more breathtaking.

Jayavarman VII. Suryavarman II's successor, Yaśovarman II, also reached into earlier history for his royal name, tracing his lineage to the Rôluŏs period. During his reign, several temples begun under Suryavarman were completed. Yaśovarman was overthrown by one of his officials after returning from a military campaign in Thailand. In the aftermath of the coup, a Cambodian prince, later to rule under the name of Jayavarman VII (1181–*c.* 1220), hurried home from Champa—it is uncertain from his inscriptions why he was there—to vie for the Cambodian throne. He arrived too late, and for the next 10 years he bided his time as the usurper lost control and Angkor was invaded and occupied by the Chams. In 1177, heading an army of his own, the prince attacked Angkor and defeated the Cham forces. The battles are vividly depicted in the bas-reliefs of his temple mountain, the Bayon. To forestall further Cham attacks, Jayavarman annexed the Cham capital, and Angkor controlled Champa until Jayavarman's death.

When his campaign against the Chams was over, the future monarch worked to bring Cambodia under his control. An inscription referred to the kingdom as being "shaded by many parasols," a metaphor for a multiplicity of rulers. In 1191, presumably when the process was complete, Jayavarman finally settled in Angkor. He soon embarked on a program of building and public works that was more extensive and grandiose than any in Angkorean history. According to his inscriptions, hundreds of thousands of people were involved in these projects.

Khmer empire *c.* 1200.

Numerous temples, statues, stone bridges, and inscriptions in the Angkor region and elsewhere in Cambodia testify to the vigour of Jayavarman VII's long reign. He rebuilt and refortified the city. He was a fervent Buddhist of the Mahāyāna (Greater Vehicle) school, but, like most other Cambodian kings, he also tolerated and patronized Hinduism and local ancestor cults; several larger-than-life-size statues of the monarch depict him in meditation.

The Bayon

His extraordinary temple, the Bayon, with its multiple towers, each bearing faces of divinities turned in the cardinal directions, is perhaps the most intriguing of the monuments at Angkor. Like Yaśovarman I's Bakheng, the Bayon stood at the centre of the royal city—which had shifted since Yaśovarman's time—and symbolized Mount Meru. Many Hindu gods and the Buddha are depicted in the statuary of the temple, while the bas-reliefs depict scenes of ordinary life, providing a picture of 12th-century Cambodians at work, rest, and play that fails to emerge from the religiously oriented inscriptions or from carvings at other temples. The clothing, tools, houses, and oxcarts in the bas-reliefs closely resemble those in the Cambodian countryside today.

The decline of Angkor. After Jayavarman's death about 1220, few monuments were erected at Angkor, and fewer inscriptions were incised. Little by little, the Khmer empire began to contract. Jayavarman's campaigns neutralized Champa as a threat to Angkor, but, by the early 13th century, vigorous new kingdoms in what is now northern Thailand—centring on the city of Sukhothai—became powerful enough to throw off Angkorean domination, as did some Tai principalities in the south. In the mid-13th century, Tai armies even raided Angkor. For most of the

century, however, Angkor remained a glittering, crowded, and wealthy city. It impressed a Chinese visitor, Chou Ta-kuan, who arrived there in 1296. Chou's account is the longest and most detailed description that has survived of the Khmer capital, supplementing the bas-reliefs of the Bayon. He left a picture of a bustling city in which the king still went forth in great pomp and ceremony.

Chou also observed monks of the Theravāda school of Buddhism at Angkor. This more orthodox and austere school flourished in kingdoms to the west of Cambodia and contrasted sharply with the lavish and elitist rituals associated with Hinduism and Mahāyāna Buddhism. When Chou visited Angkor, Theravāda Buddhism was still one religion among many. Soon afterward, however, it began to benefit from royal patronage, and the conversion of the majority of the population probably followed the conversion of members of the elite. Those disadvantaged by the change included the high-ranking priestly families who had built and maintained the temples and had supported the labourers at Angkor.

Some historians have considered the mass conversion to Theravāda Buddhism as having been responsible for the abandonment of Angkor, which certainly accompanied the conversion in the 14th and 15th centuries. That argument has been undermined by the fact that Theravāda Buddhists from Thailand profited from and even accelerated the collapse by their repeated military attacks, in which hundreds and perhaps thousands of Cambodians were led to captivity in Thailand.

Recorded Tai attacks on Angkor occurred in 1369, 1389, and 1431, after which the Khmer capital was definitely abandoned. There undoubtedly were other attacks as well. In 1351 a Tai kingdom whose court modeled itself culturally on Angkor was founded at Ayutthaya (Ayudhya, or Siam), not far from modern Bangkok. The Tai capital remained at Ayutthaya for the next 400 years. It is tempting to imagine a transfusion of elite culture from Angkor to the more prosperous, more secure Tai court in the 14th and 15th centuries. It is also likely that the Khmer who remained at Angkor were drawn southward to the vicinity of Phnom Penh (said to have been founded in the mid-15th century) by the region's commercial possibilities. In any case, the smaller, outward-looking Khmer kingdom that replaced Angkor in the south earned its wealth primarily from trade rather than from intensive rice cultivation and the mobilization of labour for public works.

Ayutthaya

Tai and Vietnamese hegemony. In the century and a half that followed the abandonment of Angkor, what is known of Khmer history is a confusing mixture of uncertain dates, mythical figures, and complex dynastic rivalries. Cambodian chronicles for this period, composed several centuries afterward, are impossible to verify against inscriptions or other primary sources. Between the mid-14th and the end of the 16th century, all that is known for certain is that Angkor was abandoned, that the Tai court of Ayutthaya absorbed some of its culture and prestige, and that the political centre of Cambodia shifted to the south. Relations between the Tai and the Khmer remained uneasy.

In the late 16th century, a period of Tai weakness following wars with Myanmar (Burma) coincided with a time of Cambodian prosperity; and a Khmer monarch, Chan I (ruled 1516–66), reoccupied the Angkor area briefly, restoring some of the temples, adding some bas-reliefs to those at Angkor Wat, and leaving several new inscriptions. When the Tai recovered their strength in the 1590s, however, they invaded Cambodia in force and sacked the Khmer capital at Lovek, north of Phnom Penh, ushering in a period of Cambodian weakness vis-à-vis its neighbours that has endured to the present day.

Cambodian history from the beginning of the 17th century until the establishment of the French protectorate in 1863 is, indeed, a sorry record of weak kings being undermined by members of their families and forced to seek the protection of their stronger neighbours, Siam (Thailand) and Vietnam. Between 1603 and 1848, 22 monarchs occupied the Cambodian throne. The details of this unstable, humiliating period are perhaps less important than the record that is available of the manner in which Cambodia slowly fell under the suzerainty of its two neighbours. When a Cambodian monarch in the 1620s foolishly declared "independence" from Ayutthaya, for example, he sought assistance from the Nguyen overlords of southern Vietnam. In exchange, he was encouraged to marry a Nguyen princess and also to permit Vietnamese settlers to move into land near present-day Ho Chi Minh City (Saigon), which until then had been under his control. Over the next 200 years, Cambodian kings sought Tai or Vietnamese protection against their rivals in the royal family and against the foreign power temporarily out of favour. The costs in lost territory and diminished autonomy were considerable, but the monarchs had little bargaining power and no freedom to maneuver.

That Cambodia survived at all can be attributed to the fact that in the 18th century the Tai and the Vietnamese had other preoccupations. In the 1750s and '60s, Tai energies were taken up by wars with Myanmar, whose armies sacked and destroyed Ayutthaya in 1767. Soon afterward, the Nguyen rulers of southern Vietnam were engaged in a prolonged campaign to regain power from the usurping Tay Son rebels. Fighting spilled over from Vietnam into Cambodia, and the royal family fled to Thailand. By the end of the century a powerful Tai dynasty had established the kingdom of Siam and had installed itself in its new capital in Bangkok, and at the beginning of the 19th century the Nguyen founded a dynasty that governed all of Vietnam. A confrontation between the two powers in Cambodia was inevitable. In 1794, in exchange for placing a refugee Cambodian prince, Eng, on the Cambodian throne, the Siamese appropriated two Cambodian provinces, Bătdâmbâng (Battambang) and Siĕmréab (Siem Reap)—the latter including the abandoned ruins of Angkor. These provinces remained in Siamese hands until 1907. When Eng died after a short reign, he was replaced by his young son, who ruled as Chan II with Thai protection.

Loss of territory

Chan II's reign confirmed Cambodia's dual vassalage to Thailand and Vietnam. With three rebellious younger brothers and demanding patrons at the Siamese court, he sought assistance from Vietnam; the Siamese supported his brothers, who took refuge in Bangkok. The uneasy calm that ensued, with Chan acknowledging Siamese and Vietnamese suzerainty, ended with Chan's death in 1835. Vietnamese pressure was strong enough to ensure that a powerless princess named Mei was then enthroned, while the Vietnamese controlled most of the country. Not until 1841, when Chan's brother Duong (Duang; ruled 1848–60) returned from exile in Bangkok supported by Siamese troops, were the Cambodians able to exercise a small degree of independence. Fighting between the Siamese and Vietnamese continued in Cambodia for several years. Duong was crowned only after Vietnamese troops agreed to leave the country. Cambodia again became a Siamese protectorate. Duong tried hard to revitalize the kingdom's institutions, but his resources were desperately limited, and his reign was marred by several rebellions. When he died, he was succeeded by his son, Norodom, but conditions were too unstable in the kingdom for Norodom to be crowned.

French rule. *The protectorate.* French control over Cambodia was an offshoot of French involvement in the neighbouring provinces of Vietnam. Their decision to advance into Cambodia came only when they feared that British and Siamese expansion might threaten their access to the largely unmapped Mekong River, which they assumed (incorrectly) would provide them with access to central China. In 1863 French naval officers from Vietnam persuaded Norodom to sign a treaty that gave France control of Cambodia's foreign affairs. The effect of the treaty was to weaken Siamese protection. A French admiral participated in Norodom's coronation, with Siamese acquiescence, in 1864.

For the next 15 years or so, French protection was not especially demanding, and Norodom benefited from French military help in putting down a series of rebellions. By the late 1870s, however, French officials in Cambodia were pressing for greater control over internal affairs. Shocked by what they regarded as the ineptitude and bar-

barity of Norodom's court and anxious to turn a profit in Cambodia, they sought to introduce fiscal and judicial reforms. In doing this, the French knew that Norodom's half brother, Si Votha (Sisowath), who had ambitions for the throne, would cooperate with them. Norodom, however, resisted the reforms, which he correctly perceived as infringements on his power. Exasperated by his intransigence, the French in 1884 forced him at gunpoint to sign a document that virtually transformed Cambodia into a colony. Soon thereafter, provincial officials, feeling threatened, raised guerrilla armies to confront the French.

Anti-French rebellion

The rebellion, which lasted until mid-1886, was the only anti-French movement in the kingdom until after World War II. The French succeeded in suppressing it after agreeing to some concessions to the king, but Norodom's apparent victory was hollow. What the French had been unable to achieve by the convention of 1884, they proceeded to gain through piecemeal action. As Norodom's health declined and as senior Cambodian officials came to see their interests increasingly linked with French power, the way was opened for greater French control. In 1897 the French representative in Phnom Penh assumed executive authority, reducing the king's power to a minimum. Norodom died, embittered and overtaken by events, in 1904.

The first 40 years of the French protectorate—whatever French motives may have been—had guaranteed the survival of the Cambodian state and had saved the kingdom from being divided between its two powerful neighbours. Norodom's successor, Sisowath (ruled 1904–27), was more cooperative with the French and presided benignly over the partial modernization of the kingdom. The northwestern provinces of Bătdâmbâng and Siĕmréab were returned to Cambodia by the Siamese in 1907. By the time Sisowath died 20 years later, hundreds of miles of paved roads had been built, and thousands of acres of rubber plantations had been established by the French. Resistance to their rule, in sharp contrast to what was happening in neighbouring Vietnam, was almost nonexistent.

Sisowath's eldest son, Monivong, who reigned until 1941, was even more of a figurehead than his father had been. During the 1930s, a railway opened between Phnom Penh and the Siamese (Thai) border, while the first Cambodian-language newspaper, *Nagara Vatta* ("Angkor Wat"), affiliated with the Buddhist Institute in Phnom Penh, conveyed a mildly nationalist message to its readers.

World War II and the First Indochina War. When Monivong died in 1941, Japanese forces already had occupied the component states of the Indochinese Peninsula, while leaving the French in nominal control. In these difficult circumstances, the French governor-general, Jean Decoux, placed Monivong's grandson, Prince Norodom Sihanouk, on the Cambodian throne. Decoux was guided by the expectation that Sihanouk, then only 18 years old, could be easily controlled. In the long run, the French underestimated Sihanouk's political skills, but for the remainder of World War II he was a pliable instrument in their hands.

The effect of the Japanese occupation on Cambodia was less profound than it was elsewhere in Southeast Asia, but the overthrow of the French administration by the Japanese in March 1945, when the war was nearing its end, provided Cambodians with opportunities for political development. Pressed by the Japanese to do so, Sihanouk declared his country's independence, and for several months the government was led by Son Ngoc Thanh, a former editor of *Nagara Vatta,* who had been forced into exile in Japan in 1942.

Early postwar period

In October 1945, after the war was over, the French returned to Indochina, arrested Son Ngoc Thanh, and reestablished their control. Cambodia soon became an "autonomous state within the French Union," with its own constitution and a handful of political parties, but real power continued to rest in French hands. Between 1945 and the achievement of complete independence in 1953, however, several significant political developments occurred. The most important was the confrontation between Sihanouk and his advisers and the leaders of the pro-independence Democratic Party, which dominated the National Assembly. Cambodia was poorly prepared for parliamentary democracy, and the French were unwilling to give the National Assembly genuine power. The Democrats, for their part, suffered from internal dissension. The death in 1947 of their leader, Prince Yuthevong, was a severe blow, exacerbated by the assassination of Yuthevong's heir apparent, Ieu Koeuss, in early 1950. Outside Parliament, Son Ngoc Thanh, released from exile in France in 1951, formed a dissident movement, the Khmer Serei ("Free Khmer"), that opposed both Sihanouk and the French.

In June 1952 Sihanouk assumed control of the government. Many Cambodian students in France, among them Saloth Sar (who would become the future communist dictator Pol Pot), objected to Sihanouk's move, but inside Cambodia the king remained extremely popular. His self-styled "Royal Crusade" (a tour of several countries to elicit their support) wrested political independence from the French, anxious to compromise in any case, at the end of 1953. Sihanouk's success discredited the communist-dominated guerrilla movement in Cambodia—associated with the Viet Minh of Vietnam—and Son Ngoc Thanh's anticommunist Khmer Serei.

Independence. At the Geneva Conference convened in 1954 to reach a political settlement to the First Indochina War, Sihanouk's government was recognized as the sole legitimate authority within Cambodia. This decision prevented the Viet Minh from gaining any regional power in Cambodia, as they did in Laos.

While they recognized Sihanouk's role in gaining Cambodia's independence, Democrats and communists alike opposed his increasing authoritarianism. Unable to govern unopposed, Sihanouk abdicated the throne in March 1955 in favour of his father, Norodom Suramarit, and formed a mass political movement, the Sangkum Reastr Niyum ("People's Socialist Community"), whose members were forbidden to belong to other political parties. The effect of the move was to draw thousands of people away from the Democrats, who had expected to win the national elections scheduled for later in the year. When the elections took place, amid widely reported abuses by Sihanouk's police, the Sangkum won every seat in the National Assembly. From then until he was overthrown in 1970, Sihanouk was the central figure in Cambodian politics, sometimes as prime minister and—after his father's death in 1960, when no new monarch was named—as head of state. Overt political life was strictly controlled by the prince, his colleagues, and the police. Cambodian communists, a marginal group of fewer than a thousand members, operated clandestinely and enjoyed little success. In 1963 Saloth Sar, a schoolteacher who also was secretary of the party, fled Phnom Penh and took refuge in the forests along the Vietnamese border; from there he built the organization that later would be known as the Khmer Rouge.

Origin of the Khmer Rouge

Until the mid-1960s, when opposition to his rule intensified, Sihanouk was widely revered in Cambodia. He saw Thailand and what was then South Vietnam as the greatest threats to Cambodia's survival. These two countries were allied with the United States, which the prince distrusted. At the same time, Sihanouk feared the eventual success of the Vietnamese communists in their war against South Vietnam and the United States and was worried by the prospect of a unified Vietnam under communist control. To gain some freedom to maneuver, he proclaimed a policy of neutrality in international affairs. Convinced, however, of American involvement in two South Vietnamese-backed plots against the Cambodian state in 1959 and encouraged in his anti-Americanism by the French president Charles de Gaulle, whom he idolized, Sihanouk broke off relations with the United States in 1965. Soon afterward, he concluded secret agreements with the Vietnamese communists, who were allowed to station troops on Cambodian territory in outlying districts as long as they did not interfere with Cambodian civilians. The secret agreement protected Sihanouk's army from attacks by the Vietnamese but compromised his neutralist policies. After 1965, when the war in Vietnam intensified, he also edged toward an alliance with China.

Cambodia's internal politics after 1965 developed in a complex fashion. Elections in 1966, the first since 1951 not to be stage-managed by the prince, brought in a majority of National Assembly members who owed little or nothing to Sihanouk himself. Although the prince was still a revered figure among the rural populace, he became increasingly unpopular with the educated elite. Conservatives resented his break with the United States and his seemingly procommunist foreign policy, while Cambodian radicals opposed his internal policies, which were economically conservative and intolerant of dissent. A rebellion in Bătdâmbâng province in 1967, manipulated by local communists, convinced the prince that the greatest threat to his regime came from the radical sector, and without hesitation he began using severe measures—including imprisonment without trial, assassinations, and the burning of villages—to impose his will.

By 1969 Sihanouk's grip on Cambodian politics had loosened, and conflict between his army and communist guerrillas, especially in the northeast, had increased. Some anticommunist ministers led by Prince Sirik Matak and General Lon Nol plotted to depose Sihanouk, whose credibility with radicals had evaporated following his renewal of diplomatic relations with the United States. Sihanouk's elaborate policy of juggling major powers against each other had failed. Matak and Lon Nol worked closely with anticommunists in South Vietnam, including Son Ngoc Thanh, whose Khmer Serei movement had gained recruits among the Khmer-speaking minority in Vietnam.

Civil war. In March 1970, while the prince was visiting the Soviet Union, the National Assembly voted to remove him from office as chief of state. Confused and hurt, Sihanouk traveled on to Peking and accepted Chinese advice to resist the coup by taking charge of a united front government-in-exile. This government was to be allied with China and North Vietnam and was to use the Cambodian communist forces led by Saloth Sar, which only a few days before had been fighting against Sihanouk's army.

Lon Nol's government

In Phnom Penh, Lon Nol's new government was initially popular, particularly for his quixotic pledge to rid Cambodia of Vietnamese communist troops. In fact, the confrontation dragged Cambodia fully into the Vietnam conflict. In May 1970 an American and South Vietnamese task force invaded eastern Cambodia, but communist forces already had retreated to the west. Two offensives launched by Lon Nol—named for the semimythical Cambodian kingdom of Chenla—were smashed by the Vietnamese, and thereafter he assumed a defensive stance. North Vietnamese support for the communists diminished in 1973, following the cease-fire agreement reached in Paris with the Americans. The Cambodian communists, however, refused to adhere to the agreements, and in 1973 they were subjected to a massive American aerial bombardment—this occurring despite the fact that the United States and Cambodia were not at war and that no American troops were endangered by Cambodia. The bombing slowed communist attacks on Phnom Penh and wreaked havoc in the heavily populated countryside around the capital. The civil war lasted for two more years, but already by the end of 1973 the Lon Nol government controlled only Phnom Penh, the northwest, and a handful of provincial towns.

In the meantime, Sihanouk declined in importance. By the end of 1973 the Cambodian communists controlled every aspect of the resistance, although they still claimed Sihanouk as a figurehead. Lon Nol's isolated regime in Phnom Penh continued to receive large quantities of American aid, increasing opportunities for corruption.

In April 1975 the Lon Nol government collapsed. Communist forces entered Phnom Penh and immediately ordered its inhabitants to abandon the city and take up life in rural areas. Phnom Penh and other cities and towns throughout the country were emptied in less than a week. Thousands of city dwellers died on the forced marches, but in subsequent years conditions worsened.

Democratic Kampuchea. Over the next six months, following the directives of a still-concealed Communist Party of Kampuchea, Cambodia experienced the most rapid and radical social transformation in its history. Money, markets, and private property were abolished. Schools, hospitals, shops, offices, and monasteries were closed. Nothing was published, no one could travel without permission, and everyone was ordered to wear peasant work clothes. As in Mao Zedong's China, the poorest peasants were favoured at everyone else's expense—an irony that probably escaped the largely bourgeois leaders of the communist movement themselves. A handful of these men and women controlled everything in the country, but they remained in hiding and explained few of their decisions. Instead, they urged everyone to "build and defend" the country. In April 1976 Sihanouk resigned as head of state, soon after a new constitution had renamed the country Democratic Kampuchea. An unknown figure named Pol Pot became prime minister, and more than a year passed before observers outside the country were able to identify him as Saloth Sar.

Khmer Rouge policies

In 1976–77 the new regime, following the lead of Maoist China, sought to achieve the total collectivization of Cambodia, mobilizing its population into an unpaid labour force and seeking to double the average prerevolutionary yields of rice immediately and on a national scale. The human costs of this ill-conceived experiment were enormous. Conservative estimates are that between April 1975 and early 1979, when the regime was overthrown, at least one million Cambodians—about 15 percent of the total population—died from overwork, starvation, disease, or execution. Parallels have been drawn between these events and the fate of European Jews in World War II, Mao's Great Leap Forward in China in the late 1950s, and Josef Stalin's collectivization of Ukrainian agriculture in the Soviet Union in the 1930s. The Soviet and Chinese experiments, rather than the European Holocaust, appear to have been used as models by the Khmer Rouge, although the proportion of the population killed in Cambodia was greater than it had been in China or the Soviet Union. The number of deaths stemmed from the literalism with which plans were carried out, the cruelty of the inexperienced communist cadres, and—as far as executions were concerned—the suspicions of the leadership that the failure of their experiment could be traced to "traitors" in the pay of foreign powers. The Communist Party's interrogation centre in Phnom Penh was the site of more than 20,000 such executions. Those tortured and put to death included many who had served the party faithfully for years—victims of the extreme paranoia of Pol Pot and his colleagues.

Vietnamese intervention. The Khmer Rouge initially had been trained by the Vietnamese, but since the early 1970s they had been resentful and suspicious of Vietnam and Vietnamese intentions. Scattered skirmishes between the two sides in 1975 had escalated into open warfare by the end of 1977. Despite continuing infusions of Chinese aid, the Cambodians were no match for the Vietnamese forces. In December 1978 a large Vietnamese army moved into Cambodia, brushing aside the Democratic Kampuchean forces. Within two weeks the government had fled Phnom Penh for Thailand, and the Vietnamese had installed a puppet regime—the People's Republic of Kampuchea—consisting largely of Cambodian communists who had deserted Pol Pot in 1977–78.

Over the next decade, under the relatively benign tutelage of the Vietnamese, Cambodia struggled back to its feet. Private property was restored, schools and Buddhist practices were reintroduced, cities were repopulated, and, with freedom of movement, trade flourished. At the same time, at least 500,000 Cambodians, some one-fifth of them associated with the communists, fled to Thailand in the aftermath of Democratic Kampuchea's fall and because of the hardship, uncertainty, and disorder that accompanied the installation of the new regime. Of these, perhaps 200,000 people, including most of the surviving members of Cambodia's educated elite, sought refuge in other countries, while the rest came under the control of three resistance groups camped along the Thai-Cambodian border: Norodom Sihanouk and his followers, the Khmer Rouge, and the noncommunists under the leadership of Son Sann (a former prime minister). These groups were supported financially by foreign powers anxious to oppose

Vietnam. Thousands of Cambodians continued to enter Thailand in the 1980s, and by the end of the decade those in refugee camps were thought to exceed 300,000.

Sihanouk's government-in-exile

In 1982 an uneasy alliance was reached among the three groups opposing the Vietnamese-backed regime in Phnom Penh, and a government-in-exile was established with Sihanouk as president and Son Sann as prime minister. This government, despite United Nations recognition, received little support from Cambodians inside the country and was largely ineffectual. The member groups of the coalition continued independently to resist the Phnom Penh regime, with the larger and better-equipped forces of the Khmer Rouge being the most effective.

Cambodia since 1990. The political stalemate that developed among the four groups vying for power was broken in the late 1980s, when international political pressure, an economic boycott of Cambodia led by the United States, and a reduction in aid from the Soviet Union contributed to Vietnam's decision to withdraw its forces from Cambodia (completed in 1989). Freed from Vietnamese tutelage, the Phnom Penh government took two initiatives that increased its popularity: it legalized the ownership of real estate and officially encouraged the practice of Buddhism. The withdrawal of the Vietnamese also allowed the resistance factions to seek through negotiation the political objectives that they had been unable to obtain by military action against the Phnom Penh government; they were encouraged in this endeavour by their foreign patrons.

These negotiations, which had been conducted for some time and which had intensified after 1989, led in 1991 to two significant results. The first was the creation of a largely ceremonial coalition government—the Supreme National Council (SNC)—that contained representatives of all four factions. Although the SNC was recognized by the United Nations, effective control in most of Cambodia remained in the hands of the Phnom Penh regime. The second and more important result was the conclusion of a peace agreement among the factions that also provided for a popularly elected government. The UN Security Council, with the backing of the factions, endorsed this treaty and agreed to establish in the country a peacekeeping operation consisting of both soldiers and civil servants, which would monitor progress toward conducting elections, temporarily run several government ministries, and safeguard human rights. The operation was difficult to implement, notably because of the lack of cooperation by the Khmer Rouge. Free elections, however, were held in 1993, and Sihanouk returned as the country's monarch, heading a coalition government. In the mid-1990s the Khmer Rouge collapsed. In 1998 free elections again produced a coalition government, the country was admitted to ASEAN, and Pol Pot died. Subsequent UN efforts to bring surviving Khmer Rouge leaders before an international tribunal were hampered by the Cambodian government, which included some former Khmer Rouge members. (D.P.Ch.)

For later developments in the history of Cambodia, see the BRITANNICA BOOK OF THE YEAR.

Laos

Laos (in full, Lao People's Democratic Republic; Lao: Sathalanalat Paxathipatai Paxaxôn Lao) is a small, landlocked country constituting the northwestern portion of the Indochinese Peninsula. It is bounded on the north by China, on the northeast and east by Vietnam, on the south by Cambodia, on the west by Thailand, and on the northwest by Myanmar (Burma). Laos extends about 650 miles (1,050 kilometres) from northwest to southeast and has a total area of approximately 91,400 square miles (236,800 square kilometres). The capital is Vientiane (Lao: Viangchan).

PHYSICAL AND HUMAN GEOGRAPHY

Mountains

The land. *Relief.* Dominating the landscape of Laos are its inhospitable, forest-covered mountains, which in the north rise to a maximum elevation of 9,245 feet (2,818 metres) above sea level at Mount Bia and everywhere constitute an impediment to travel. The principal range lies along a northwest-southeast axis and forms part of the Annamese Cordillera (Chaîne Annamitique), but secondary ranges abound. Three notable landscape features of the interior of Laos may be mentioned. In the northern province of Xiangkhoang, the Plain of Jars (Lao: Thông Haihin; the name derived from large prehistoric stone jars discovered there) consists of extensive rolling grasslands rather than a true plain and provides a hub of communications. The central provinces of Bolikhamxay and Khammouan contain karst landscapes of caverns and severely eroded limestone pinnacles. Finally, in the south the Bolovens Plateau, at an elevation of about 3,600 feet, is covered by open woodland and has generally fertile soil. The only extensive lowlands lie along the eastern bank of the Mekong River.

Drainage. The general slope of the land in Laos is downhill from east to west, and all the major rivers—the Tha, Beng, Ou, Ngum, Kading, Bangfai, Banghiang, and Kong—are tributaries of the Mekong (Lao: Mènam Khong). The Mekong flows generally southeast and south along and through western Laos and forms its boundary with Myanmar and most of the border with Thailand. The course of the river itself is severely constricted by gorges in northern Laos, but, by the time it reaches Vientiane, its valley broadens and exposes wide areas to flooding when the river breaches its banks, as it did in August 1960. A few rivers in eastern Laos flow eastward through gaps in the Annamese Cordillera to reach the Gulf of Tonkin; the most important of these is the Ma River, which rises in Xiangkhoang province.

The Ou River at Muang Khoua, northern Laos.

Soils. Soils in the floodplains are formed from alluvium deposited by rivers and are either sandy or sandy clay with light colours or sandy with gray or yellow colours; chemically, these are neutral to slightly acidic. Upland soils derived from crystalline, granitic, schistose, or sandstone parent rocks generally are more acidic and much less fertile. Southern Laos contains areas of laterite (leached and iron-bearing) soils, as well as basaltic soils on the Bolovens Plateau.

Climate. Laos has the typical tropical monsoon climate of the region, though the mountains provide some variations in temperature. During the rainy season (May to October), the winds of the southwest monsoon deposit an average rainfall of between 50 and 90 inches (1,300 and 2,300 millimetres), with totals reaching 160 inches on the Bolovens Plateau. The dry season (November to April) is dominated by the northeast monsoon. Minimum temperatures average between 60° and 70° F (16° and 21° C) in the cool months of December through February, increasing to highs of more than 90° F (32° C) in March and April, just before the start of the rains. In the wet season the average temperature is 80° F (27° C).

Plant and animal life. Laos has tropical rain forests of broad-leaved evergreens in the north and monsoon forests of mixed evergreens and deciduous trees in the south. In the monsoon forest areas the ground is covered with tall, coarse grass called *tranh;* the trees are mostly second growth, with an abundance of bamboo, scrub, and wild banana. The forests support a rich wildlife, including elephants, gaurs (wild oxen), deer, bears, tigers and leopards, monkeys, and a large variety of birds.

Settlement patterns. Laos is predominantly rural and agricultural. The numerous isolated valley communities preserve a variety of different traditions and dialects. Villages usually are located close to rivers and roads that give the people access to itinerant traders as well as to each other. Most villages are laid out around a main street or open area, farmlands being adjacent to the residential areas. Every village, if it can, has a Buddhist temple and supports at least one monk. The temple compound usually includes a public building that serves as a school and a meeting hall. Village leadership is usually divided, the headman having authority in secular matters and the monk in religious.

Typical village layout

The hill peoples usually are organized on tribal lines and live in smaller groupings. They are hunters and gatherers of forest products, as well as farmers, but their practice of shifting cultivation prevents them from establishing permanent villages. Hill peoples living close to the lowland areas tend to acquire the languages and cultures of their neighbours and to engage in limited trade with them; those living at higher elevations remain unacculturated.

Urban life in Laos is limited mainly to the capital, Vientiane, the former royal capital, Louangphrabang, and four or five other large towns. With the exception of Louangphrabang, all are located near the Mekong River in the floodplain area. Their populations are predominantly Lao, with smaller groups of Chinese, Vietnamese, and Indians. Compared with the cities of Thailand, Malaysia, or Vietnam, those of Laos are small and provincial.

The people. *Ethnic and linguistic characteristics.* The peoples of Laos are divided by language, culture, and location. Lao officials distinguish four basic ethnolinguistic groups: the Lao-Lum, or valley Lao; the Lao-Tai, or tribal Tai; the Lao-Theung, better known as the Mon-Khmer; and the Lao-Soung, or Hmong and Man. Mountain people sometimes are called Kha ("Slaves"), a pejorative term.

The Lao-Lum live in the lowlands, on the banks of the Mekong and its tributaries, and in the cities. They speak Laotian Tai, which is closer to the language spoken by the Thai of Thailand than it is to the language of the local Tai-speaking tribes.

The Lao-Tai include such local groups as the Black Tai (Tai Dam) and Red Tai (Tai Deng), both names referring to the dress of the women; the Tai Neua, or Tai of the north; the Tai Phuan of Xiangkhoang province; and the Phu Tai. The Lao-Tai live throughout the country, chiefly in upland areas, and their various dialects are mutually intelligible.

The Lao-Theung (Mon-Khmer) include many groups of people scattered throughout Laos, northeastern Myanmar, northern Thailand, and southern China. They are thought to be descendants of the earliest peoples to inhabit the region. These people do not form a single coherent group but rather include between 25 and 30 distinct groups, some of which are closely related while others are only tenuously identified as being part of this linguistic group.

The Lao-Soung, which include the Hmong (formerly called the Meo, or Miao) and the Man (Yao), are believed to have been coming from southern China since the late 18th century. They are divided into subgroups, and neither constitutes a large proportion of the population of Laos.

Other distinct linguistic groups are few in number. Speakers of Tibeto-Burman dialects, who also came from southern China, live in the north and northwest. Chinese and Vietnamese live primarily in the urban areas. Initially, French was the language of the Lao elite and of the cities, but by the 1970s English had begun to displace it. Under the leadership of the Lao People's Revolutionary Party, Vietnamese has become the third language of the elite.

Prior to the establishment of the Lao People's Democratic Republic (LPDR) in 1975, it was accurate to say that the Lao-Lum peoples had a distinct pattern of culture and dress. They also had a well-defined social structure, differentiating between royalty and commoners. The members of the elite included only a few outsiders who were not descendants of nobility. Most of the elite lived in the cities, drawing their incomes from rural land rents or from urban occupations. After 1975 a new elite emerged representing the victorious leftist forces. Many of this group, however, were of aristocratic origin.

Social and political structure

Traditionally, Lao-Tai society had a stratified social structure and a political hierarchy. The people were organized into groups larger than villages called *muong,* each of which was ruled by a hereditary ruler called the *chao muong.* Within this broad grouping, however, there were ethnic variations. Among the Black Tai, the nobility consisted of two descent groups, the Lo and the Cam, who provided the rulers of the *muong.* The religious leaders came from two other descent groups, the Luong and the Ka. The Black Tai tribal organization had three levels: the village; the commune, which was composed of a number of villages; and the overall *muong.* The latter two were ruled by nobles, while the village headman was selected from among the commoners by the heads of households. The Red Tai had a similar social structure, with the addition of a council of five to aid the *chao muong.* The nobility owned the land and had the right of service from the commoners.

The Mon-Khmer had no political or social structure beyond the village. They were led by a village headman, who was their link to the central government; but his role in the village was not clear.

Among the Lao-Soung, the Hmong maintained the tradition of a king and subchiefs and a large-scale organization, although in practice this usually was limited to the village. The village consisted of several extended families. In some villages, all the heads of households were members of a single clan, and the head of the clan was the headman of the village. Where several clans resided together in a large village there were several headmen, one being the nominal head and the link to the government. The headman had real authority in the village and was aided by a council. The Hmong extended their organization beyond the village for military purposes.

Religion. The predominant religion of Laos is Theravāda Buddhism, which is professed by most Lao and by a small number of other ethnic groups. Most of the rest of the people are animists, or spirit worshipers, especially in the more isolated upland areas. Many see no contradiction in being both, since Buddhism shows the way to enlightenment, while spirit worship helps a person to cope with daily and local problems. Among the hill peoples, especially those who have migrated from southern China, are found groups that mix Confucian ideas with Buddhism and animism. One subgroup of the Mon-Khmer, the Lamet, practices ancestor worship, and the Hmong are both spirit and ancestor worshipers. Roman Catholic and Protestant missionaries were present in the country before 1975, but only a tiny proportion of the population is Christian. The Vietnamese, who live both in the cities and in the northeastern rural areas, practice a mixture of Mahāyāna Buddhism and Confucianism.

Demographic trends. Laos is an underpopulated country. It has the lowest population density of any Southeast Asian nation, and its population is also one the most youthful. A high birthrate is offset by one of the highest infant-mortality rates in the region. About half the people are concentrated in the lowlands, and only about one-fifth are urban dwellers. The Lao-Lum are the largest ethnic group. There has been a considerable out-migration of people from Laos since the mid-1970s, including most of the country's educated and professional elite.

Migration

The economy. Laos is one of the world's poorest countries. The disruption during the civil-war period and the economic policies of the early years of the LPDR—notably the attempt to collectivize agriculture—resulted in economic stagnation in the country. By 1980, however, the government had begun to pursue more pragmatic development policies, and in 1986 it introduced market-oriented

reforms. Subsequently, private enterprise has been allowed to operate on every level, and foreign investment has been encouraged. A number of nongovernmental organizations, including some from the United States, have been assisting the government, mainly in the fields of rural development and public health.

Resources and power. Laos has a number of mineral resources, including coal, iron, copper, lead, gold, tin, gypsum, and precious stones. Tin has been mined commercially since colonial times, and gypsum has become important; the other minerals have been worked only in primitive and unsystematic ways.

Laos has considerable hydroelectric power potential. Electricity produced from a dam on the Ngum River north of Vientiane and sold to Thailand is one of the country's most valuable exports.

Agriculture, forestry, and fishing. The chief occupation of the people is agriculture, with the vast majority engaged in rice farming. In years with normal harvests, Laos is self-sufficient in rice production, a reflection of the success of private landownership and market incentives. In addition to a variety of food crops, modest amounts of such cash crops as sugarcane, tobacco, and coffee are produced. Agricultural production, however, is vulnerable to natural calamities, and Laos is subject to periodic droughts and floods, with both sometimes occurring in the same year. A significant proportion of rice production comes from upland dry rice raised by hill people using shifting-cultivation methods (*i.e.,* fields are cleared and cultivated for a few years before being abandoned and allowed to revert to forest). The government has considered this practice to be a major cause of deforestation and has attempted to resettle hill peoples on plains where they can adopt sedentary agricultural practices.

Another problem for the government has been the illegal cultivation of the opium poppy, mainly by Hmong hill people. Programs to curb production have had limited success because of the profitability of opium production and the inaccessibility of growing areas.

The extensive forests of Laos produce teak and other timber, benzoin (a balsamic resin), cardamom, and stick lac (used to make shellac). Much of the deforestation in the country has been blamed on logging operations and on the cutting of wood for fuel, which are believed to have caused the erosion of hillsides and the silting of rivers that has heightened the severity of droughts and floods. The regulation of logging by the government has been difficult because of poor communications and the high number of illegal operations.

Deforestation

Fishing is important for lowland dwellers, and aquaculture has increased. Livestock raising has grown in importance since 1980.

Industry. The main activities of the country's tiny industrial sector are food processing (rice milling and beverage production), sawmilling, and the manufacture of building materials and a variety of light consumer goods. Handicrafts also are important.

Finance and trade. Until the late 1980s, the government controlled all banking activities. Since then it has fostered the development of a private banking sector. Foreign investment and joint ventures with foreign companies have been officially encouraged.

The chief exports, in terms of value, are timber and other forest products, electricity, coffee, and tin. Major imports include foodstuffs, petroleum products, machinery, and transport equipment. The main trading partners are Thailand, Japan, China, and Hong Kong. Imports always have vastly exceeded exports in value, leaving a gap to be filled by foreign aid.

Transportation. A major obstacle to the economic and social development of Laos has been its poor transportation system. Rivers and roads are the major avenues of communication, supplemented by air transport. The Mekong River is the major north-south commercial artery; all but two sections of it—the Khone Falls and the rapids of Khemmarat (Khemarat)—are navigable for at least part of the year. Large barges ply the deeper sections of the rivers between towns, but most of the water traffic is carried in smaller craft. Some of the mountain people build bamboo rafts and float their goods to market, selling the raft along with the goods. During French rule, a primitive network of roads was created. The main artery joined Saigon (now Ho Chi Minh City, Vietnam) with Louangphrabang, and several lesser roads led eastward through mountain passes into Vietnam. During the Vietnam War, road building and improvement were undertaken by the United States, China, and what was then North Vietnam; the best-known of these works was the Ho Chi Minh Trail, a complex of roads, fords, and ferries in the Annamese Cordillera. Laos itself has no railway system, but Thailand's railways funnel goods and passengers to Laos. Small aircraft came into use during the war, and some inhabitants of Laos flew in airplanes before they had seen an automobile. Vientiane has an international airport.

Administration and social conditions. *Government.* Since its establishment in December 1975, the Lao People's Democratic Republic (LPDR) has been effectively controlled by the communist Lao People's Revolutionary Party. This party, in alliance with the Vietnamese communists, carried out the revolution that ended in its seizure of power and the abolition of the monarchy. Top government positions—beginning with the president, who is head of state, and the prime minister, who is also the party chairman—are held by high-ranking party members, who constitute a Central Committee with a Politburo at the head. A constitution adopted in 1991 provides for a National Assembly, the members of which are elected to five-year terms. The judicial system is headed by the Supreme People's Court.

The country is divided into 16 provinces—roughly from north to south, Phôngsali, Louang Namtha, Bokeo, Oudomxay, Louangphrabang, Houaphan, Xaignabouri, Vientiane, Xiangkhoang, Bolikhamxay, Khammouan, Savannakhét, Saravan, Xékong, Champasak, and Attapu—as well as Vientiane Municipality, the administrations of which are said to have considerable autonomy in economic matters. The provinces are subdivided into districts and villages. At each level of local government there are party committees and administrative committees, which often are headed by the same individuals.

Provinces

Security. Laos maintains a small military force consisting almost entirely of army personnel, with smaller air and naval branches. Internal security measures have been strictly enforced, as the regime fears political opposition linked to a large exile population and sporadic armed resistance within the country.

Education. Education has been reorganized since 1975. The government has set up a number of agricultural schools, sent teachers to provincial villages to provide literacy instruction, and opened new primary, secondary, and teacher-training schools. School enrollment and literacy rates subsequently have increased significantly from levels in the mid-1970s.

Health and welfare. Medical care in general is inadequate and unevenly distributed in Laos, with most of the health care facilities located in urban areas. Infant mortality rates are high, and life expectancy is low. Respiratory diseases, influenza, malaria, and gastroenteritis are the major health problems. The departure of most of the country's physicians after 1975 created a serious problem for the new government. It began to build village infirmaries and dispensaries in most of the provinces and to train medical workers. These village medical workers, often using only traditional medicinal herbs, now provide most of the country's primary health care.

Cultural life. *The arts.* The basis of Laotian culture is religion and tradition. Art, literature, music, and drama draw mainly from these sources. Towns along the Mekong are exposed to Western culture through Thai mass media.

Theravāda Buddhism entered the country in the 14th century. This religion and Hinduism have been major influences on cultural and intellectual life in Laos. The story of the Buddha and Hindu myths are the subjects of the carvings and sculptures found in all religious places. In the south, Khmer influences on the peoples of Laos are strong; in the north, Myanmar and Thai influences are readily apparent. As elsewhere in Southeast Asia, religious symbols, stories, and themes have been modified and lo-

calized. The snake, for example, representations of which adorn religious and royal buildings, symbolizes the benevolent spirit of the water and the protector of the king.

The Laotians have a variety of folk arts, including weaving, basketmaking, wood and ivory carving, and silverwork and goldwork. There are a number of Laotian musical instruments, of which the *khene*, a bamboo wind instrument, is most widely known. Music is not written down but is played from memory.

Dance

Dancing is a profession rather than a form of recreation; the professional dance troupes travel throughout the country performing for religious celebrations or on important holidays. Their main themes are drawn from the Indian epics. All professional dancers are male, the female roles being performed by young men and boys.

Laotian literature is predominantly religious and linked to the Buddhist tradition. There is also a secular literary stream based on themes of the Hindu epic poems, which have been transmuted into popular language; an example of this is the Laotian epic the *Sin Xay*, written between the mid-16th and the late 17th century. The popular poems and songs are often satiric.

Press and broadcasting. The government controls all aspects of the media. The largest-circulating daily newspaper is *Pasason*, published in Vientiane; it is the official organ of the ruling party. Also published in Vientiane is the quarterly journal *Aloun Mai*. The official news agency is Khaosan Pathet Lao (KPL). The National Radio of Laos broadcasts in a number of languages, principally Lao, English, and French. There is also a government-run television station. (J.Si./A.J.D.)

For statistical data on the land and people of Laos, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

The Lao people, the predominant ethnic group in present-day Laos, are a branch of the Tai-speaking peoples who by the 8th century AD had established a powerful kingdom, Nanchao, in southwestern China. From Nanchao, the Tai gradually penetrated southward into the Indochinese Peninsula; their migration was accelerated in the 13th century by the Mongol invasions of southern China by Kublai Khan. The Lao, together with other Tai peoples, gradually supplanted various indigenous tribes (collectively known as Kha, or "Slaves") that from the 5th century on had lived in what is now Laos under the suzerainty of the Khmer empire of Cambodia. During the 12th and 13th centuries, the Tai established the principality of Muong Swa (later Luang Prabang, now Louangphrabang), which was ruled by various Tai leaders and the history of which survives in Laotian legend and myth.

The first Laotian state

Lan Xang. Recorded Laotian history begins with Fa Ngum, the ruler who founded the first Laotian state, Lan Xang ("Kingdom of the Million Elephants"), with the help of the Khmer sovereign at Angkor. Fa Ngum was a great warrior, and between 1353 and 1371 he conquered territories that included all of present-day Laos and much of what is today northern and eastern Thailand. He extended the Indo-Khmer civilization to the upper Mekong River and introduced Theravāda Buddhism, which had been preached by Khmer missionaries from Angkor.

In 1373 Fa Ngum was succeeded by his son Oun Hueun (reign name Sam Sen Thai), who did much to organize the pattern of administration and defense for the kingdom. After his death in 1416, a long period of calm—broken only by a Vietnamese invasion in 1479—allowed his successors to complete the work of organizing Lan Xang. This period of peace and tranquility ended with Photisarath (ruled 1520–48), who involved Lan Xang in a struggle against Myanmar and the Thai kingdom of Ayutthaya (Ayudhya) that lasted two centuries. Photisarath waged three wars against Ayutthaya and succeeded in placing his son Setthathirath on the throne of the Tai state of Chiang Mai (Chiengmai), marking Lan Xang's maximum territorial expansion. On Photisarath's death, Setthathirath returned to rule as Setthathirath I (ruled 1548–71). His reign was marked by the loss of Chiang Mai to the Myanmar, by the transfer of the capital from Luang Prabang to Vien Chan (now Vientiane), and by the repulsion of two Myanmar invasions that took place about 1565 and 1570.

When he died (1571), the Myanmar seized Vien Chan (1574) and ravaged the country, which lapsed into anarchy until Souligna Vongsa ascended the throne in 1637 and restored order. He fixed the frontiers with Vietnam and Siam (Thailand) by means of treaties and led two victorious expeditions against the principality of Chieng Khouang in the south. A defender of Buddhism and a patron of the arts, he embellished Vien Chan and made it a vibrant intellectual centre. His reign is considered by Laotians to be a golden age.

When Souligna Vongsa died in 1694, one of his nephews seized the throne with the help of a Vietnamese army, thus placing Lan Xang under Vietnamese rule and initiating a period of chaos that ended in the partition of the kingdom of Lan Xang. Other members of the royal family refused to accept Vietnamese vassalage. With the northern provinces under their control, they declared themselves independent (1707) and established the separate kingdoms of Luang Prabang and Vien Chan. The south seceded in turn and set itself up as the kingdom of Champassak (1713). Split into three rival kingdoms, Lan Xang ceased to exist.

Under foreign rule. During the 18th century, the three Laotian states, which were continually at loggerheads, tried to maintain their independence from the Myanmar and the Siamese, both of whom were contending for the control of western Indochina. The weakness of these states, resulting from their disunity, inevitably caused them to fall prey to the Siamese.

Siamese control

Vien Chan, which had sided with the Myanmar, was invaded (1778), annexed, and made a state subject to Siam (1782). Luang Prabang, which had supported the Siamese, was invaded by the Myanmar (1752), who imposed their rule upon it until the Siamese supplanted them (1778). In the south, Champassak, which had supported a Myanmar revolt against the Siamese, also was invaded (1778) and transformed into a dependency of Siam. Each of these kingdoms was placed under the control of a Siamese commissioner. The kings of Champassak, Vien Chan, and Luang Prabang were allowed to rule in their respective kingdoms but had to pay tribute to Bangkok. Their appointments to the throne were made in Bangkok.

The last king of Vien Chan, Chao Anou (also called Anouvong; ruled 1805–28), attempted to shake off this yoke. First, he strengthened the bonds of allegiance uniting Vien Chan to Vietnam (1806), whose influence in Indochina had grown to rival that of Siam. Next, he persuaded Bangkok to give his son the governorship of Champassak, thus extending his frontiers as far as the old southern boundaries of Lan Xang. Thinking that the British, who had just defeated the Myanmar, were going to attack Siam, he led three armies against Bangkok (1827). The Siamese, however, regrouped their forces, marched on Vien Chan, and defeated Anou, who fled to Vietnam. Vien Chan was pillaged and destroyed. In 1828 Anou attempted another attack but was again defeated. Vien Chan was made a Siamese province.

For the Siamese, the annexation of Vien Chan was the first step toward the creation of a great empire. They next extended their colonization of the eastern bank of the Mekong to protect themselves from an eventual Vietnamese expansion westward. They therefore garrisoned Champassak (1846) and Luang Prabang (1885) and stationed troops as far as the Annamese Cordillera. Siamese expansion toward the northeast—where the mountain states were placed under the cosuzerainty of Vietnam and Luang Prabang—provoked the protests of the French, who had established a protectorate over Vietnam. France entered into negotiations with Bangkok (1886) to define the Siamese-Vietnamese frontier and won the right to install a vice-consul in Luang Prabang. The office was entrusted to Auguste Pavie, who, owing partly to his popularity with the Laotians, succeeded in winning Luang Prabang over to France. After a number of Franco-Siamese incidents in the Mekong River valley, French ships made a show of strength off Bangkok in 1893. Later that year, on the advice of the British, Siam withdrew from the eastern bank of the Mekong and gave official recognition to the French

protectorate in the evacuated territory. French annexation was completed by treaties with Siam (called Thailand from 1939) in 1904 and 1907.

French protectorate

The French organized this territory as a protectorate, with its administrative centre at Vientiane, and allowed it autonomy in local matters. The kingdom of Luang Prabang survived, but the other provinces were placed under the direct authority of a French official. France paid little attention to Laos until the Japanese invaded the Indochinese Peninsula during World War II; in 1941, under Japanese pressure, the Vichy government restored to Thailand the territories acquired in 1904. In March 1945 the Japanese took outright administrative control of Indochina from the French, and the following month the independence of Laos was proclaimed.

Two movements sprang up at this time. The first was anti-Japanese and was represented by the court of Luang Prabang and Prince Boun Oum of Champassak; the second was anti-French (the Free Laos movement, or Lao Issara), was located in Vientiane, and was led by Prince Phetsarath. These two movements remained in conflict until the return of French troops, which in early 1946 compelled the supporters of the Lao Issara to flee to Thailand. France, in a temporary agreement, recognized the internal autonomy of Laos under the king of Luang Prabang, Sisavang Vong. Finally, after a constitution was promulgated and general elections were held, a Franco-Laotian convention was signed in July 1949 by which Laos was granted limited self-government within the French Union. All important power, however, remained in French hands.

Although many of the Lao Issara leaders were prepared to work with the French under this new arrangement, their decision was opposed by a more radical group led by Kaysone Phomvihan and Prince Souphanouvong. Under Souphanouvong's presidency, a new political movement, the Pathet Lao ("Land of the Lao"), was proclaimed (1950) that joined forces with the Viet Minh of Vietnam in opposing the French. The Pathet Lao remained unreconciled when the French took further steps toward granting independence to Laos in October 1953, while still retaining control of all military matters in the kingdom. Between 1950 and early 1954, the Pathet Lao gained strength in northeastern Laos and had a firm grip on two of the country's provinces when the peace conference in Geneva brought the First Indochina War to an end.

(P.-B.L./M.E.O.)

Laos after the Geneva Conference, 1954–75. The Geneva Accords of 1954 marked the end of French rule on the Indochinese Peninsula. The participating nations (including France, Great Britain, the United States, China, and the Soviet Union) at the Geneva Conference agreed that all of Laos should come under the rule of the royal government and should not undergo partition (as did Vietnam). The agreements, however, did provide for two "regroupment zones" in provinces adjacent to what was then North Vietnam to allow the Pathet Lao forces to assemble. This resulted in the de facto control of these areas by the Laotian communists, while the rest of the country was ruled by the royal government.

The uneasy peace in Laos was short-lived, as hostilities broke out between leftist and rightist factions in 1959. Another conference in Geneva was convened in May 1961, culminating in an agreement in July 1962 that called for the neutralization of the country and the formation of a tripartite government. The new government consisted of factions from the left (the Pathet Lao, who were linked to North Vietnam), the right (linked to Thailand and the United States), and neutrals (led by Prince Souvanna Phouma). Once again, however, the cease-fire was brief. The coalition split apart by 1964, and the larger war centred in Vietnam engulfed Laos. In this expanded war, Laos, like Cambodia, was viewed by the major protagonists as a sideshow.

Tripartite government

The agreement negotiated by the United States and North Vietnam at Paris in 1973 called for a cease-fire in each of the countries of the Indochinese Peninsula, but only in Laos did peace actually occur. In February 1973, just a month following the agreement, the Laotian factions signed the Vientiane Agreement, which provided again for a cease-fire and yet another coalition government composed of factions from the left and right, presided over by Souvanna Phouma. As political control in Vietnam subsequently tipped toward the communists, following the American departure there, the Pathet Lao gained political ascendancy in Laos. When the communists marched into Saigon (now Ho Chi Minh City, Vietnam) and Phnom Penh, Cambodia, the right-wing forces in Laos lost heart and most of their leaders fled, permitting a bloodless takeover by the Laotian communists in mid-1975. The Laotian communists proclaimed an end to the 600-year-old monarchy in December 1975 and established the Lao People's Democratic Republic (LPDR).

The Lao People's Democratic Republic. Guiding the politics of the newly established republic was the Lao People's Revolutionary Party (LPRP), the communist party of Laos. Its politburo was dominated by a small, cohesive band of revolutionaries who had founded the party in 1955 (called the Lao People's Party until 1972) and had engaged in persistent revolutionary activity until their takeover in 1975. These leaders had a long and intimate relationship with their Vietnamese communist allies. Prior to founding the party, they had been members of the Vietnamese-led Indochina Communist Party. Most spoke Vietnamese, and some had family ties with Vietnam. The party's general secretary (until 1992), Kaysone Phomvihan, had a Vietnamese father; second-ranked Nouhak Phoumsavan and third-ranked Prince Souphanouvong had Vietnamese wives. Their worldview had been shaped by their shared revolutionary struggle with Vietnam. Moreover, the Vietnamese had numerous channels—party, military, and economic—through which they directly conveyed their influence. Thus, the new state was intimately linked to Vietnam and closely followed its policy line until the late 1980s.

In the early years of the LPDR, the leadership declared its twin economic goals to be "socialist transformation with socialist construction." Following the Vietnamese communist model, the party leaders attempted to create agricultural collectives in the countryside and to nationalize the limited industry and commerce in the towns. Former members of the Royal Lao Army as well as of the deposed government—perhaps as many as 30,000—were incarcerated in "reeducation" camps. These and other repressive political measures and the grim economic conditions in Laos compelled some 10 percent of the country's population to flee across the Mekong River to Thailand after 1975.

Reforms in the 1980s

Beginning in the early 1980s and continuing with greater conviction after 1986, party leaders introduced significant changes in both domestic and foreign policy. Within Laos, market incentives were adopted, and government economic enterprise was decentralized. Private investment and joint ventures also were encouraged. To the relief of Lao peasants, attempts at collectivization were abandoned in favour of family-operated farms. Although the ruling party retained unchallenged control, as in Vietnam, both political freedom and participation were enlarged. A new constitution was promulgated in 1991. Citizens were permitted to move about their country more freely and even to cross the Mekong River to Thailand with fewer impediments.

The most significant change in foreign affairs was the reduction of Vietnamese political control and military presence. Concurrently, Lao relations with Thailand improved, and there was a warming of relations with China. Border-demarcation agreements were signed with China, Myanmar, and Vietnam. Relations with the United States, which had become strained but were never severed, also improved. After the establishment of the LPDR, the Soviet Union and the countries of eastern Europe became the country's primary trading partners and donors of economic assistance. The dissolution of the Soviet Union and transformation of its European allies, however, has obliged Laos to turn increasingly for aid to Japan, Australia, Sweden, the European Community, and international organizations.

For later developments in the history of Laos, see the BRITANNICA BOOK OF THE YEAR.

Malaysia

The Southeast Asian nation of Malaysia consists of two dissimilar regions: Peninsular, or West, Malaysia on the Malay Peninsula and East Malaysia on the island of Borneo. The capital is Kuala Lumpur, located on the western side of Peninsular Malaysia. Malaysia has a total area of 127,584 square miles (330,442 square kilometres), which includes about 265 square miles of inland water. Of this total, Peninsular Malaysia constitutes about 50,810 square miles and East Malaysia about 76,510 square miles.

Peninsular Malaysia occupies most of the Malay Peninsula south of latitude 6°40′ N. To the north it is bordered by Thailand, with which it shares a land boundary of some 300 miles (480 kilometres). To the south, at the tip of the peninsula, is the island republic of Singapore, with which Malaysia is connected by a causeway. To the southwest, across the Strait of Malacca, is the Indonesian island of Sumatra.

East Malaysia consists of the states of Sarawak and Sabah and is separated from Peninsular Malaysia by some 400 miles of the South China Sea. These two states occupy most of the northwestern coastal part of the large island of Borneo and share a land boundary with the Indonesian portion (Kalimantan) of the island. Within Sarawak is a small coastal enclave containing the sultanate of Brunei.

Malaysia, a member of the Commonwealth, represents the political marriage of territories that were formerly under British rule. When it was established on Sept. 16, 1963, Malaysia was composed of Malaya (now Peninsular Malaysia), Singapore, Sarawak, and Sabah. In August 1965 Singapore seceded from the federation and became an independent republic.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The long, narrow, and rugged Malay Peninsula extends to the south and southwest from Myanmar and Thailand. The Malaysian portion of it is about 500 miles long and—at its broadest east-west axis—about 200 miles wide. About half of Peninsular Malaysia is covered by granite and other igneous rocks, one-third is covered by stratified rocks older than the granite, and the remainder is covered by alluvium. At least half the land area is more than 500 feet (150 metres) above sea level.

Peninsular Malaysia is dominated by its mountainous core, which consists of a number of roughly parallel mountain ranges aligned north-south. The most prominent of these is the Main Range, which is about 300 miles long and has peaks rising to elevations of more than 7,000 feet. Karst landscapes—limestone hills with characteristically steep, whitish gray sides, stunted vegetation, caves created by the dissolving action of water, and subterranean passages—are distinctive landmarks in central and northern Peninsular Malaysia. Bordering the mountainous core are the coastal lowlands, 10 to 50 miles wide along the west coast of the peninsula but narrower and discontinuous along the east coast. Settlement and development have taken place primarily along the west coast.

East Malaysia is an elongated strip of land approximately 700 miles long with a maximum width of about 170 miles. The coastline of 1,400 miles is paralleled inland by a 900-mile land boundary with Kalimantan. For most of its length, the relief consists of three topographic features. The first is the flat coastal plain. In Sarawak, where the coastline is regular, the plain averages 20 to 40 miles in width, while in Sabah, where the coastline is rugged and deeply indented, it is only 10 to 20 miles wide. Inland from the coastal plain is the second topographic feature, the hill-and-valley region. Elevations there generally are less than 1,000 feet, but isolated groups of hills reach heights of 2,500 feet or more. The terrain in this region is usually irregular, with steep-sided hills and narrow valleys. The third topographic feature is the mountainous backbone that forms the divide between East Malaysia and Kalimantan. This region, which is higher and nearer the coast in Sabah than in Sarawak, is composed of an eroded and ill-defined complex of plateaus, ravines, gorges, and mountain ranges. The summits of the ranges are between 4,000 and 7,000 feet. Mount Kinabalu, at 13,455 feet (4,101 metres) the highest peak in Malaysia, towers above this mountain complex.

Features of East Malaysia

Drainage. Peninsular Malaysia is drained by an intricate system of rivers and streams. The longest river—the Pahang—is only 270 miles long. Streams flow year-round because of the constant rains, but the volume of water transported fluctuates with the localized and torrential nature of the rainfall. In the western part of the peninsula such heavy rainfalls may occur at any time of year, but in the eastern part they are more likely to occur during the northeast monsoon (November to March). Prolonged rains often cause floods, especially in areas where the natural regimes of the rivers have been disrupted by uncontrolled mining or agricultural activities.

As in Peninsular Malaysia, the drainage pattern of East Malaysia is set by the interior highlands, which also form the watershed between Malaysia and Indonesia. The rivers, also perennial because of the year-round rainfall, form a dense network covering the entire region. The longest river in Sarawak, the Rajang, is about 350 miles long and is navigable by shallow-draft boats for about 150 miles from its mouth; its counterpart in Sabah, the Kinabatangan, is of comparable length but is navigable for only about 120 miles from its mouth. The rivers are important because they provide a means of communication between the coast and the interior. Settlement also has taken place along the rivers, as it did on the peninsula in an earlier period.

Soils. The soils of both portions of Malaysia have been exposed for a long period of time to intense tropical weathering, with the result that most of their plant nutrients have been leached out. Soils typically are strongly acidic and coarse-textured and have low amounts of organic matter. Any organic matter when exposed to weathering is rapidly oxidized, and the soils consequently become even poorer. Soil erosion is always a danger on sloping ground, where such additional measures as building contour embankments or planting protective cover crops are required.

Only a small proportion of the soils of Peninsular Malaysia are fertile; regular applications of fertilizers are therefore necessary in order to sustain crop yields. Generally, soil conditions in Sarawak and Sabah do not differ greatly from those on the peninsula. Of these three regions, only Sabah has appreciable areas of fertile soils. These are found in particular in the southeastern coastal areas, where the parent material from which the soil is formed is composed of chemically basic volcanic materials.

Climate. Both peninsular and insular Malaysia are in the same latitudes and are influenced by similar airstreams. They consequently have high temperatures and humidities, heavy rainfall, and a climatic year patterned around the northeast and southwest monsoons. The country is influenced by eight or nine major airstreams flowing from the northeast, the south, and the west; the advance and retreat of these airstreams are responsible for the division of the climatic year into four seasons. These are the northeast monsoon (from November or December until March), the first intermonsoonal period (March to April or May), the southwest monsoon (June to September or early October), and the second intermonsoonal period (October to November). The onset and retreat of the two monsoons are not sharply defined.

Seasons

Malaysia has an equatorial climate, but the narrowness and topographic configuration of each portion—central mountainous cores with flat, flanking coastal plains—facilitate the inland penetration of maritime climatic influences. In addition, the monsoons further modify the climate. The northeast monsoon brings heavy rain and rough seas to the exposed coasts of southwestern Sarawak and northern and northeastern Sabah. The southwest monsoon, however, affects mainly the southwestern coastal belt of Sabah. Floods are common, especially along the west coast of Sabah. Neither peninsular nor insular Malaysia is in the typhoon belt, but their coasts occasionally are subject to the heavy rainstorms associated with squalls.

Temperatures are uniformly high throughout the year. On the peninsula, they average 78° to 82° F (25° to 28° C) for most lowland areas. In coastal areas in East Malaysia, minimum temperatures range from 72° to 76° F (22° to 24° C), and maximum temperatures from 88°

to 92° F (31° to 33° C); temperatures are lower in the interior highland regions. The mean annual rainfall on the peninsula is approximately 100 inches (2,540 millimetres); the driest location, Kuala Kelawang (formerly Jelebu), near Kuala Lumpur, receives about 65 inches of rain per year, while the wettest, Maxwell's Hill, northwest of Ipoh, receives some 200 inches annually. Mean annual rainfall in Sabah varies from 80 to 140 inches, while most parts of Sarawak receive 120 inches or more per year.

Plant life. The characteristic vegetation of Malaysia is dense, evergreen rain forest. Rain forest still covers about half of the peninsula and some three-fourths of Sarawak and Sabah; another fraction is under swamp forest. Soil type, location, and altitude produce distinctive vegetation zones: tidal swamp forest on the coast, freshwater- and peat-swamp forest on the ill-drained parts of the coastal plains, lowland rain forest on the well-drained parts of the coastal plains and foothills up to an altitude of about 2,000 feet, and submontane and montane (lower mountain-type) forest above that elevation. The highly leached and sandy soils of parts of central Sarawak and the coast support an open, heathlike forest known locally as *kerangas* forest.

The flora of the Malaysian rain forest is among the richest in the world. There are some 8,000 species of flowering plants, of which at least 2,500 are trees. An acre (0.4 hectare) of forest may have as many as 100 different species of trees, as well as shrubs, herbs, lianas (creepers), and epiphytes (nonparasitic plants that grow on other plants and derive nourishment from the atmosphere). The forest canopy is so dense that little sunlight can penetrate it. As a result, the undergrowth usually is poorly developed and—contrary to popular belief—is not impenetrable. Much of the original rain forest has been destroyed by severe wind and lightning storms, by indigenous peoples clearing it for shifting cultivation, or by clearances made for agricultural or commercial purposes. When such cleared land is subsequently abandoned, coarse grassland, scrub, and secondary forest develop.

Loss of the original forest

Animal life. The forests and scrublands are inhabited by a large variety of animal life. Mammals on the peninsula include the elephant, tiger, seladang (or Malayan gaur, a massive wild ox), Sumatran rhinoceros, tapir (a hoofed and snouted quadruped), wild pig, and many species of deer, including the *pelandok,* or chevrotain (a small, deer-like ruminant). Crocodiles, monitor lizards, and cobras also are indigenous to the country, while the green sea turtle and the giant leathery turtle nest regularly on the beaches of the east coast.

Animal life in East Malaysia is even more varied than it is on the peninsula. In addition to the peninsular species, East Malaysia is also the home of the fast-disappearing orangutan and rhinoceros, the sun bear (also called the honey bear), and the unique proboscis monkey—a reddish tree-living species. There also are vast numbers of cave swifts, whose nests are regularly collected and sold as the main ingredient of bird's nest soup.

Settlement patterns. The people of Malaysia are predominantly rural. Their settlements are similar in appearance and pattern to those of their rural counterparts elsewhere in Southeast Asia. The basic unit in both East and Peninsular Malaysia is the kampong (village, or community of houses), consisting of dwellings on stilts.

The houses of Peninsular Malaysia usually are built of wood, and traditionally they have a thatched roofing called atap that is woven from the leaves of the nipa palm (a species also used for basketry); increasingly common are roofs of corrugated metal. Each house is surrounded by a grove of coconut palms and banana, papaya, and other fruit trees. The four main types of Malay settlement—fishing villages, paddy (wet-rice) villages, cash-crop villages, and mixed-crop villages—despite their variations, conform to the same basic pattern. Most other rural settlements on the peninsula are associated with peoples who have settled in the country since the early 19th century. The earliest of these were the mining camps, which sprang up in the tin fields in the west. Some have since grown into large towns, but others—especially in the Kinta River valley—still remain small. The British introduced the plantation system of agriculture, and the subsequent cultivation of rubber and the oil palm changed the face of rural Peninsular Malaysia. Added to the landscape was the plantation, or estate, settlement, typically a group of buildings consisting of the processing factory and storehouse, the labourers' quarters, and the manager's house.

New Villages represent a type of settlement that is unique to Peninsular Malaysia. These originally were simply groups of buildings that were established as defensive sites near roads between 1948 and 1960, during the Emergency, the formal name for the period when the British administration was engaged in suppressing the communist guerrilla uprising. With the end of the Emergency in 1960, some of the New Villages were abandoned, but most of them became permanent settlements. A more recent and significant government program has involved the resettlement of poor Malays into forest areas, which are cleared and planted in rubber trees and oil palms; since the mid-1950s, more than 100,000 families have been resettled.

Rural resettlement

About three-fourths of the population of East Malaysia is still rural, and it is in the rural areas that the greatest variety of settlement types is encountered. This variety is a direct reflection of the considerable ethnic diversity of the population and of the fact that indigenous as well as immigrant groups are settled in the rural areas. The non-Malay indigenous ethnic groups—including the Iban (Sea Dayak), Bidayuh (Land Dayak), Kenyah, Kayan, and Murut—are thinly scattered in the foothill country and, to some extent, in the coastal lowlands as well. They are primarily shifting cultivators and live in locations on or near riverbanks. Their traditional dwelling is the longhouse, which is more commonly found in Sarawak than in Sabah. Each longhouse is raised on stilts and is composed of a number of rooms, known as *bileks*; each *bilek* houses a family. A longhouse can grow by accretions of related families, and an Iban longhouse may in time reach a length of 40 or more *bileks*. Some groups, such as the Melanau of Sarawak and the Kadazan of Sabah, have abandoned the longhouse settlement form, adopting instead the single-family dwelling of the Malays.

The Malays and Melanau of East Malaysia share many common characteristics with their rural counterparts on the peninsula. They tend to be riverine and coastal peoples, with an economy based on agriculture and fishing. Many live in kampongs set in the midst of coconut palms, mangroves, or other swamp trees. Their houses generally are built on stilts. The Melanau live in the large delta swamp region between Bintulu and Rajang. The rural Chinese in Sarawak have settled in the region between the coast and the uplands, usually in homesteads strung along both sides of the roads, where they grow cash crops in smallholdings. Their houses are commonly built at ground level and thus are easily distinguishable from the stilt-raised dwellings of the indigenous peoples.

The cities and large towns of Peninsular Malaysia were built up during the colonial and postcolonial periods and are distributed mainly in the tin and rubber belt along the west side of the peninsula. The towns are associated with mining, purchasing, processing, distributing, exporting, and administrative functions, and each town usually performs several of these functions. Some towns are located at coastal or riverine sites, emphasizing the early importance of water transport, while more modern towns have been built in inland areas served by road, rail, and air transport.

There is a growing number of satellite towns such as Petaling Jaya (outside Kuala Lumpur), although most of the towns of Peninsular Malaysia are unplanned, having grown up around small nuclei. Urban land use generally is mixed, and buildings are put to multiple uses. Streets, built for a more leisurely era, are narrow and often congested. In the larger centres, such as Kuala Lumpur, Ipoh, and George Town (Pinang, or Penang), distinct central business districts similar to those in Western cities have emerged. These are characterized by heavy population and traffic densities, high land values, and a concentration of shopping, banking, insurance, entertainment, and other facilities.

Urbanization in East Malaysia has proceeded slowly. Only a small percentage of people live in towns. The

largest towns are Kuching, Sibu, and Miri in Sarawak and Sandakan, Kota Kinabalu, and Tawau in Sabah. The large towns invariably are located on coastal or riverine sites. The layout and appearance of these towns are markedly similar: a wharf area, rows of Chinese shop-houses in the central business districts, more substantial buildings in the governmental administrative area, and one or more timber and atap kampongs built on the riverbanks.

The people. The population of Malaysia is unevenly divided between Peninsular and East Malaysia, with the vast majority living in Peninsular Malaysia. The population shows great ethnic, linguistic, cultural, and religious diversity. A significant distinction is made between indigenous peoples (aborigines and Malays, collectively often called *bumiputra*) and immigrants (primarily Chinese and South Asians). In addition, there are important differences among the indigenous peoples themselves and among religious groups.

Peninsular Malaysia

Ethnic composition, languages, and religions. The Malay Peninsula, situated at one of the great maritime crossroads of the world, has long been the meeting place of peoples from other parts of Asia. As a result, the population shows the ethnographic complexity typical of Southeast Asia as a whole. In general, there are four groups of people, given in the order of their appearance on the peninsula: the Orang Asli (aborigines), the Malays, the Chinese, and the South Asians. In addition, there are small numbers of Europeans, Americans, Eurasians, Arabs, and Thai.

The Orang Asli constitute the smallest group and can be divided ethnically into the Jakun, who speak an archaic Malay, and the Semang and Senoi, who speak languages of the Mon-Khmer language family. They are primarily adherents of traditional religions, but a number have been converted to Islām.

The Malays originated in different parts of the peninsula and archipelagic Southeast Asia. They constitute about two-thirds of the population and are politically the most important group. They share with each other a common culture, speak a common Austronesian language—Malay (officially called Bahasa Malaysia), which is the national language—and are overwhelmingly Muslim. Adherence to Islām is regarded as one of the most important factors distinguishing a Malay from a non-Malay, and the number of Malays who are not Muslim is negligible. Minor differences in dialect, culture, and physical characteristics are noticeable among the Malays living in the south in Johor state, on the east coast in the states of Kelantan and Terengganu, and on the west coast in the states of Negeri Sembilan, Perak, Kedah, and Perlis.

The Chinese, who make up about one-third of the peninsular population, originally migrated from southeastern China. They are ethnically homogeneous but are less homogeneous than the Malays in language and religion. Several different dialects are spoken, notably Hokkien, Cantonese, Hakka, and Hainanese. Thus, it may be necessary for two Chinese to converse in Mandarin Chinese, English, or Malay. A minority, the Baba Chinese, speak a Malay patois, although otherwise they remain Chinese in customs, manners, and habit. The Chinese do not have a dominant religion; most of them, while subscribing to Confucian moral precepts, are either Buddhist or Taoist. A small minority is Christian.

The peoples from South Asia—Indians, Pakistanis, and Tamils from Sri Lanka—constitute about 10 percent of the population of Peninsular Malaysia. Linguistically, they can be subdivided into speakers of Dravidian languages (Tamil, Telugu, Malayālam, and others) and speakers of Indo-European languages (Punjābī, Bengali, Pashto, and Sinhalese). Numerically, the Tamil speakers are the largest group. Most of the Indians and Sri Lankans are Hindu, while the Pakistanis are predominantly Muslim. Some Indians have been converted to Christianity. The Sikhs, from the Punjab, adhere to their own religion, Sikhism.

East Malaysia

The population of East Malaysia is ethnographically even more complex than that of Peninsular Malaysia. The government has tended to oversimplify the situation in Sarawak and Sabah, officially recognizing only some of the dozens of ethnolinguistic groups in those two states. The main ethnic groups in Sarawak are the Chinese, various speakers of mutually unintelligible Austronesian languages including the Iban (Sea Dayak), the Malays, the Bidayuh (Land Dayak), and the Melanau.

The Chinese of Sarawak, like those on the peninsula, originally came from southeastern China. The relative size of each dialect group is reversed, however, as speakers of Hakka and Fu-chou (Hokchiu) in Sarawak outnumber those speaking Cantonese and Hokkien. As in Peninsular Malaysia, nearly all the Chinese of Sarawak follow Confucianism and practice Buddhism or Taoism.

The Iban are the largest and most important indigenous group in Sarawak. Their origins are obscure, but traditionally they were headhunters. The Iban are a homogeneous people speaking a language described as a type of pre-Islāmic Sumatran Malay. Most of them live in the interior uplands, where they are longhouse dwellers practicing shifting cultivation. They have a distinctive culture, in which nearly every activity is influenced or governed by their animist religious beliefs.

The Malays of Sarawak are a heterogeneous group of people, among whom only a few are of peninsular origin. Most are the descendants of aboriginal peoples who since the mid-15th century have converted to Islām and adopted the Malay way of life. Although ethnically diverse, they are culturally homogeneous, speaking a common language and practicing Islām.

The Bidayuh live in hill country, most being found in the far western portion of Sarawak. Although all are of the same ethnic group, they speak a number of different but related dialects that to some extent are mutually intelligible. The majority of the Bidayuh practice traditional religions, but Christian missionaries have made some converts among them.

The Melanau differ ethnically from the Sarawak Malays, but their dialects, which are distinct from Malay, do not differ sufficiently to constitute a barrier to communication. The great majority of Melanau are Muslim, with the rest (except for a small number of Christians), following traditional religions. Other indigenous peoples—including the Kenyah, Kayan, Kedayan, Murut, Kelabit, Bisaya (Bisayah), and Punan—contribute much to Sarawak's ethnic and cultural diversity.

Sabah also has a kaleidoscopic mixture of peoples. The largest groups are the Kadazan, Chinese, Bajau, and Murut, while a significant proportion consists of such indigenous peoples as the Kedayan, Orang Sungei, Bisaya, Sulu, and Tidong. Europeans, Eurasians, Malays, Indonesians, Filipinos, and South Asians make up the remainder.

Kadazan society consists of a number of tribes, each speaking a dialect that the others can understand. The great majority of Kadazan are animists, although a significant proportion are Christian and a small number are Muslim. Most of the Chinese are Hakka-speaking, the other important dialects being Cantonese, Hokkien, Teochew, and Hainanese. The Bajau are not a cohesive community, as they are split into two main groups: sedentary agriculturists living on the north coast and those who live by the sea on the east coast. Most are Muslim, but not all of them can communicate with each other. The Murut of Sabah are descended from the same people as the Kadazan and are ethnically different from the Murut of Sarawak. They are shifting cultivators. Although they are divided into subtribes, their languages are mutually intelligible. Most follow traditional religions, with a significant minority being Christian.

Demographic trends. The average life expectancy in Malaysia has increased significantly since the end of World War II. Death rates for all groups are less than half of what they were in the late 1950s, and infant mortality rates also have declined sharply. Mortality rates tend to be lower in towns and cities, where there are better health services; since the Chinese usually are urban dwellers, their death rates are lower than those for the country as a whole. Birth rates have declined significantly since the 1960s, but the rate of natural increase has remained high.

Before World War II, there was a free flow of people to and from both Peninsular and East Malaysia, and the rate of population growth was greatly influenced by a net

surplus from in-migration. A series of laws passed since 1945, and particularly after the political separation from Singapore, now restricts the entry of immigrants from all countries. Thus, immigration is no longer a major cause of population growth.

Population density

The major area of population concentration in Peninsular Malaysia is an axis of economic development on the west side of the peninsula. Much smaller concentrations are found in the Kelantan and Terengganu river deltas in the northeast. The remainder of the peninsula—the interior uplands and most of the east—generally is sparsely populated. Slightly more than half the population of the peninsula's urban centres is Chinese, and about one-third is Malay; Indians and Pakistanis make up most of the remainder.

The population density of East Malaysia is considerably less than that for the peninsula. As in the west, the main concentrations are along the coasts and rivers. In Sarawak the heavy concentration of people in the southwest makes this region the most important in East Malaysia. The population is similarly clustered on the coast in Sabah, but riverine settlements are less important than in Sarawak. As on the peninsula, the urban population is predominantly Chinese.

The economy. Malaysia's economy has been transformed since 1970 from one based primarily on the export of raw materials (rubber and tin) to one that is among the strongest, most diversified, and fastest-growing in Southeast Asia. Primary production remains important: the country is the world's largest producer of rubber and palm oil, exports considerable quantities of petroleum and natural gas, and is one of the world's largest sources of commercial hardwoods. Increasingly, however, Malaysia has emphasized export-oriented manufacturing to fuel its economic growth. Using the comparative advantage of a relatively inexpensive but educated labour force, well-developed infrastructure, political stability, and an undervalued currency, Malaysia has attracted considerable foreign investment, especially from Japan and Taiwan.

The focal point of this growth has been the manufacture of electrical and electronic products and textiles, which together have become one of the most important sources of export earnings. The success of the manufacturing effort has been reflected by the development of a variety of heavy industries, including steelmaking and automobile assembly—the latter implemented through a Malaysian-Japanese joint venture. Peninsular Malaysia, especially the urban area of Kuala Lumpur and the rest of the developed area along the western side of the peninsula, accounts for nearly all of the country's manufacturing output.

The New Economic Policy

Since the early 1970s the Malaysian government has championed a social and economic restructuring strategy, first known as the New Economic Policy (NEP), that seeks to strike a balance between the goals of economic growth and the redistribution of wealth. Traditionally, the Malaysian economy has been dominated by the country's Chinese and South Asian minorities. The goal of the NEP has been to endow the Malays and other indigenous groups with greater economic opportunities and to develop their management and entrepreneurial skills. Official economic policy also has encouraged the private sector to take a greater role in the restructuring process. A major component of this policy has been the privatization of many public-sector activities, including the national railway, airline, automobile manufacturer, and telecommunications company.

Malaysia's systems of public finance—auditing and organization of accounts, parliamentary control, and revenue collection—are generally based on British principles. The primary role of the country's fiscal system is to raise revenue for governmental expenditure, rather than being a mechanism to manipulate the pace of economic activity, the level of employment, or prices. The greater part of government revenues are raised by taxation—roughly equally divided between direct (income) taxes and indirect taxes (*e.g.*, customs and excise duties).

Malaysia's rapid economic expansion has created a great demand for additional labour for the manufacturing and service sectors. The labour shortage has tended to increase wages. Nonetheless, there has been a relatively limited flow of workers from East to Peninsular Malaysia despite the economic incentives, prompting interest in recruiting foreign workers.

Resources. Malaysia is rich in mineral resources. The major metallic ores are tin, bauxite (aluminum), copper, and iron. A host of minor ores found within the country include manganese, antimony, mercury, and gold. The production of tin formed one of the main economic pillars upon which the country's development effort has been built. It is found largely in alluvial deposits along the western slopes of the Main Range in Peninsular Malaysia, with smaller deposits on the east coast of the peninsula. Malaysia's most valuable mineral resources, however, are its reserves of petroleum and natural gas. The major fields are all offshore, off the east coast of the peninsula and off Sarawak. Malaysia also has large reserves of coal, peat, and wood, and it has considerable hydroelectric potential.

Agriculture. Agriculture, forestry, and fishing were the traditional basis of the Malaysian economy. Their contribution to the nation's gross domestic product (GDP) gradually has declined from roughly one-third in 1970 to less than one-fifth. These three activities still engage the largest percentage of the workforce, but the proportion is diminishing.

The main food crop, rice, is grown on small farms. Despite the widespread advances brought about by the introduction of improved plant varieties and chemical fertilizers and pesticides (the so-called Green Revolution), rice production has declined. The main causes of this have been unfavourable weather conditions and the loss of farm labour to urban manufacturing jobs, the latter situation having the effect of reducing the amount of land that can be worked. As a result, the country is not self-sufficient in rice production and must make up the shortfall with imports, chiefly from Thailand. Shifting cultivation is practiced primarily in East Malaysia.

Cash crops

The most important cash crops are palm oil and rubber. Together these account for a significant (though declining) proportion of Malaysia's commodity exports. The production of palm oil and rubber has been subject to considerable fluctuations in the price of these commodities, which has resulted in a decline in the number of plantations. Palm oil has become more important than rubber in terms of value. Also important are cocoa, pepper, and coconuts.

Forestry and fishing. The extensive forests of both Peninsular and East Malaysia are heavily exploited for their timber. The lowland evergreen tropical rain forest is the principal forest formation of commercial importance, being rich in species of the economically valuable Dipterocarpaceae family. Sarawak and Sabah account for the greater part of all timber production. Concern has been raised, however, about the pace of deforestation caused by the combination of shifting agriculture and intensive logging operations in East Malaysia. Attempts have been made to curtail log exports from the region and to substitute wood-based industries, such as the manufacture of plywood and furniture. Logging remains important in Peninsular Malaysia, although much of the easily accessible timber has been cut. The region also has a long history of careful forest management and conservation, and the effects of deforestation there have not been as serious.

Traditionally, most of Malaysia's fish catch has been from the shallow seas off its coasts, where the water's nutrient levels—and hence its productivity—generally have been low. In the 1970s the country's fishing industry was modernized, notably by the addition of trawlers and mechanized fishing boats. This allowed the more abundant offshore fish resources to be tapped, leading to a dramatic increase in catches. Malaysia has become a major fishing nation, even though production peaked in about 1980 and much of the fishing industry has remained confined to the overexploited shallow onshore waters. Aquaculture production also has increased, although the country's potential has remained largely undeveloped.

Mining and power. Extractive industries still contribute significantly to Malaysia's GDP. Tin output has declined dramatically since the 1970s, however, because of the depletion of readily accessible alluvial deposits, rising mining

costs, and fluctuating demand in the world tin market. Petroleum production has increased in importance, as has the production of liquefied natural gas; together they account for a major portion of the country's commodity export earnings. Of some importance are copper, bauxite, and iron, although production of these ores has varied greatly with fluctuations in world markets. Iron output has declined as high-grade deposits have been depleted. Malaysia's bauxite production is centred near Johor at the south end of the peninsula, while the nation's copper comes from western Sabah.

Malaysia's petroleum resources constitute the major energy source for power generation. The country's proven reserves of coal and peat are not economical to mine and have remained largely unexploited. Wood and charcoal were the traditional domestic fuels, but in the urban areas they have been displaced by bottled gas. Hydroelectricity accounts for more than one-fourth of all energy production, but most of this generating power is concentrated on the peninsula; the abundant rainfall and steep gradients of the rivers in the interior highlands offer good opportunities for further exploitation in both portions of the country.

Manufacturing

Industry. Manufacturing has undergone rapid expansion since the 1970s and has become the leading edge of Malaysia's economic growth. It now accounts for the largest share of the country's GDP, although primary activities still employ more workers. Growth has been especially notable in industries assembling electronic equipment, electrical machinery, and appliances and those making chemical products and textiles. The main development goal has been the manufacture of goods for export, with a lesser emphasis on import substitution. One strategy designed to promote manufactured exports has been the establishment of a number of free trade zones, which have provided duty-free access to imported raw materials and semifinished parts and numerous investment and export incentives. Industrial estates also have been established in less-developed parts of the country to stimulate manufacturing and to balance industrial growth, but manufacturing capacity has remained highly concentrated. The country's heavy industries—more important politically than economically—generally have been saddled with excess capacity and high production costs. Increasingly, development strategy has shifted to the promotion of small and medium industries that manufacture their own parts and acquire technology from more economically developed countries, the aim being to move beyond the stage of assembly-only manufacturing.

Finance and trade. Malaysia has an active and growing financial sector, which has been encouraged by government policies that promote foreign investment, market competition, and the privatization of publicly held enterprises. Banking and insurance are regulated by the state-run Bank Negara Malaysia. The state permits a variety of banking activities, including a semipublic bank that operates on Islāmic financial principles. Kuala Lumpur has a commodities exchange and a stock exchange.

Malaysia's export structure has shifted dramatically since 1970, from one dominated by rubber and tin to one in which manufactured goods now account for more than half of all export earnings. Electrical and electronic products constitute the largest proportion of exported manufactures. Commodities exports, however, remain important. Imports are dominated by machinery and other manufactured goods. Malaysia's chief trading partners are Japan, Singapore, and the United States. Such newly industrialized Asian countries as South Korea and Taiwan account for a growing share of trade. Malaysia is a member of the Association of Southeast Asian Nations (ASEAN), and trade with other ASEAN nations (outside of that with member Singapore) also is increasing.

Transportation. Malaysia's transportation systems have been improved considerably since independence, although demand generally has outstripped capacity. In addition, much more attention has been given to developing the infrastructure of Peninsular Malaysia than that of East Malaysia. The peninsula's road network includes high-speed express highways and numerous hard-surfaced secondary roads; it is especially well-developed in the major

Roads

Milt and Joan Mann/Cameramann International

industrial states. The road network in East Malaysia is much less extensive, with fewer paved roads. Malaysia's small railway system, confined primarily to the peninsula, is of much less significance than its roads.

River transport is of great importance in East Malaysia, especially in Sarawak. Malaysia's long and accessible coastlines have long fostered maritime trade. Several ports, notably George Town and Port Kelang on the Strait of Malacca, have become major container-handling facilities. Numerous other ports have been developed, including Kuantan on the eastern coast of the peninsula, Kuching in Sarawak, and Kota Kinabalu in Sabah. Air transport has grown rapidly, with passenger traffic increasing especially on the peninsula. An internal air network connects all Malaysian states, and Kuala Lumpur and Pinang have international airports.

Administration and social conditions. *Government.* Malaysia is a federal constitutional monarchy with a nonpolitical head of state, or *yang di-pertuan agong* ("paramount ruler"), who is elected from among nine state hereditary rulers for a five-year term. The federal legislature consists of the Senate (Dewan Negara) and the House of Representatives (Dewan Rakyat). The federal government also has a prime minister and cabinet, an independent judiciary, and a politically neutral civil service.

The powers of the federal parliament are relatively broad and include the authority to legislate in matters concerning government finances, defense, foreign policy, internal security, the administration of justice, and citizenship. The state legislatures, however, retain responsibility for issues pertaining to Islāmic law and for matters regarding personal and family laws affecting Muslims, as well as for land laws. The constitution also provides that some issues may be addressed either by the federal or by a state legislature.

The House of Representatives functions in a manner similar to that of the British House of Commons. It has a membership of 180, of which 132 are from Peninsular Malaysia, 27 from Sarawak, and 21 from Sabah. Members are elected to office from single-member constituencies by a simple majority to terms of five years. The Senate has a membership of 69; of these, 43 members are appointed by the *yang di-pertuan agong* on the recommendation of the prime minister (including 2 from the federal territory of Kuala Lumpur and 1 from the federal territory of Labuan), and the other 26 are elected—2 from each of the 13 states—by the state legislative assemblies. Voting in either house is by a simple majority, but amendments to the constitution require a two-thirds majority. A bill passed by both houses and sanctioned by the *yang di-pertuan agong* becomes a federal law.

The *yang di-pertuan agong* appoints a prime minister

from the members of the House of Representatives. On the advice of the prime minister, the *yang di-pertuan agong* then appoints the other ministers who make up the cabinet. The number of ministers is not fixed, but all must be members of the federal parliament.

Local rule

Each state of Malaysia has its own written constitution, legislative assembly, and executive council responsible to the legislative assembly and headed by a chief minister. Several Malay states—Johor, Kedah, Kelantan, Pahang, Perak, Selangor, and Terengganu—have hereditary rulers (sultans). The raja (king) is the ruler in Perlis, and the *yang di-pertuan besar* ("chief ruler") in Negeri Sembilan. The heads of state of Melaka, Pulau Pinang (Penang Island), Sarawak, and Sabah—known as *yang di-pertuan negeri*—are appointed to office. The ruler of a state acts on the advice of the state government. The constitution provides for parliamentary elections and for elections to state legislatures, to be held at least every five years.

Political parties. Malaysia has a multiparty political system, and since about 1970 it has held free elections and changed prime ministers peacefully. Party affiliation generally is based on ethnicity, though less so than at independence. Malaysian political life is dominated by the National Front (Barisan Nasional), a broad coalition of ethnically oriented parties that long has been controlled by the United Malays National Organization. The main opposition parties are the Democratic Action Party (consisting primarily of Chinese), the Muslim Unity Movement (a coalition of pro-Islāmic parties), and the Sabah People's Union. The Communist Party of Malaya and the offshoot Malaysian Communist Party are illegal opposition parties.

Justice. The constitution of Malaysia, which is the supreme law of the country, provides that the judicial power of the federation shall be vested in two High Courts, one in Peninsular Malaysia and the other in East Malaysia, and also in subordinate courts. Above the High Courts is the Supreme Court (Mahkamah Agung), with jurisdiction to hear and determine appeals from decisions by any High Court. The supreme head of the judiciary is the lord president of the Supreme Court.

Each High Court consists of a chief justice and a number of other judges—up to 33 in Peninsular Malaysia and up to 8 in East Malaysia. The High Court has unlimited criminal and civil jurisdiction and may pass any sentence allowed by law. Below the High Court are the subordinate courts, which consist of the Sessions Courts and the Magistrates' Courts. Both these lower courts have criminal and civil jurisdiction—criminal cases coming before one or the other court depending on the seriousness of the offense and civil cases depending on the sum involved. In addition, there are religious courts in those Malay states that are established under Islāmic law. These courts are governed by state—not federal—legislation.

Armed forces. The Malaysian armed forces have increased in strength and capability since the formation of Malaysia in 1963. After the withdrawal of British military forces from Malaysia and Singapore at the end of 1971, a five-nation agreement between Malaysia, Singapore, New Zealand, Australia, and Great Britain was concluded to ensure defense against external aggression. The ASEAN also provides additional regional security.

The armed forces consist of an army, navy, and air force. The army is the most experienced and the largest of the three, constituting about four-fifths of all military personnel. The Royal Malaysian Navy concentrates mainly on defending the long indented coastlines and narrow waters of the country. The Royal Malaysian Air Force has combat aircraft, as well as many transport aircraft and helicopters.

The states of Malaysia inherited from their common colonial past an internal security system based on the British model. The police force is well trained and combats not only crime but also armed insurrections.

Education. The federal government provides free, noncompulsory primary and secondary education. Primary-school enrollment is nearly universal on the peninsula but is lower in Sabah and Sarawak. The number of students advancing to the secondary level has increased considerably. Institutions of higher learning include the University of Malaya in Kuala Lumpur, the University of Science, Malaysia, in Pinang, the National University of Malaysia in Bangi, and the International Islāmic University in Petaling Jaya. Enrollment in higher education also has increased, and many Malaysian students have studied abroad.

Universities

Health and welfare. The general level of health has improved considerably since World War II, which has contributed significantly to the decline in death and infant-mortality rates. The country is free from many of the diseases that plague tropical countries, although such diseases as malaria are still a problem in rural areas. Health conditions and health facilities vary among the component states, being better in Peninsular Malaysia than in Sabah and Sarawak. Health services generally are better in the towns and cities than in the rural areas. Segments of the rural population continue to rely on traditional rather than modern medicine for treatment. Most of the modern health services are provided by the government. Welfare services, however, are provided by both government and private agencies and include relief programs for poor, elderly, and handicapped individuals.

The multicultural character of the population of Malaysia is visibly reflected in the wide variety of houses, which range from the traditional longhouses and stilt houses of the rural peoples to examples of modern high-rise architecture in the cities. Housing shortages are rare in rural areas, but squatter settlements are common in the larger towns and cities. A governmental housing authority has had success in establishing low-cost housing in urban areas.

Certain groups of people, especially in Sarawak and Sabah, live by hunting, gathering, fishing, and simple farming, thereby reducing somewhat the number of wage earners in the total economically active population. Because of the increasing pressure of population on the land, however, there is a growing tendency for young people to seek employment in manufacturing. Since wages in the manufacturing sector are significantly higher than those in agriculture, labour shortages continue to prevail in the rural economy. Industrialization has drawn increasing numbers of workers from the countryside to the cities and has created a greater demand for skilled workers.

Cultural life. Malaysia is a melting pot of several major cultural traditions that stem from archipelagic Southeast Asia as well as from China, South Asia, the Middle East, and the West. Malay culture and Bornean culture are indigenous to the area. In the first one and a half millennia AD, indigenous Malay culture in the Malay Peninsula and in other parts of Southeast Asia was strongly marked by pre-Islāmic Indian and early Islāmic influences. Indian contact with the Malay Peninsula extended from about the 2nd or 3rd to the late 14th century, exerting a profound influence on religion (Hinduism and Buddhism), art, and literature. Islām, introduced to Malacca (now Melaka) in the 15th century, soon became the dominant religion of the Malays. The introduction of Western cultural influences in the 19th century affected many aspects of Malay life, especially in technology, law, social organization, and economics. Contemporary Malay culture is thus multifaceted, consisting of many strands—animistic, early Hindu, early and modern Islāmic, and, especially in the cities, Western—and the collective pattern is distinct from other cultures and recognizably Malay.

Outside influences

Unlike the early Chinese traders who settled in Malacca and George Town (now Pinang) and were partially assimilated (at least to the extent of adopting the Malay language), the Chinese who emigrated in large numbers to the Malay Peninsula in the late 19th and early 20th centuries were usually transients who established self-contained communities. Chinese cultural influence has consequently been minimal. The Chinese immigrants themselves, moreover, did not form a homogeneous group. Their culture in Malaysia has its roots in the culture and civilization of prerevolutionary China, with modifications brought about by local circumstances and environment.

Most of the Indians and Pakistanis originally came as labourers to work in the coffee and rubber plantations. Like the Chinese, they also were mainly transients (until World War II), living in closed communities and remaining virtually unassimilated.

The communities of Malaysia have been affected by British colonial rule and Western cultural influences, especially in education and institutional forms. Traditions and cultural institutions have been least affected in the rural areas—in eastern Peninsular Malaysia and in the interior of East Malaysia—while the cities have been the focus of the most rapid cultural changes.

The arts. External cultural influences have made the least impact in music, dancing, literature, and the decorative arts. In East Malaysia the indigenous cultural background includes no written history or literature. Architecture is little developed, and the principal art forms are dancing and handicrafts, represented notably by the textiles handwoven by the Punan tribe, cloth made by the Bajau people, patterned rattan mats and basketwork, and wood carvings. Particularly on the peninsula, the artistic manifestations of Malay culture are mainly in literature, music, dancing, and the decorative arts. Painting and sculpture are poorly developed, primarily because Islām does not encourage the representation of the human form. Examples of Malay decorative arts include batik cloth (cloth hand-dyed by using a special technique), silverware, the handmade kris (a short sword or heavy dagger with a wavy blade), wood carving, and basketwork. Malaysian Chinese culture is derived from Chinese civilization and is represented by literature, drama, music, painting, and architecture. Some Malaysian artists—of Malay, Chinese, and Indian origin—also have begun to produce new, synthesized, and distinctively Malaysian art forms, especially in painting and architecture.

Press and broadcasting. The newspapers are all privately owned (many by political parties) and vary greatly in circulation, quality of reporting, and news coverage. Among the educated groups, the press is the principal source of information. The radio is relied on in remote rural areas. Television, however, is the most popular medium among all language groups. (O.J.B./T.R.L.)

Radio and television

HISTORY

Because the Malay Peninsula links mainland and archipelagic Southeast Asia and because Malaysia is characterized by a geographic division, the history of the present-day country can be understood only within a regional framework and as part of the wider context of the western archipelago zone. The Strait of Malacca (Melaka) bisects this realm and long has constituted a crossroads for peoples, cultures, and trade passing through or taking root in the area. Influences from China, India, the Middle East, and, later, Europe followed the maritime trade. Malaya (Peninsular Malaysia) and Sarawak and Sabah (East Malaysia) have shared many historical patterns, but each region also has developed in unique ways.

The rise of Indianized states. Malaysia's prehistory remains insufficiently studied, but bone and artifact discoveries at the Niah Caves site in northern Sarawak confirm modern human habitation in the region that may date to 40,000 years ago. The vast cave complex contains an almost unbroken succession of human frequentations and occupations, including a unique sequence of the evolution of stone tools that persisted until some 1,300 years ago. Malaya has been inhabited for at least 6,000 to 8,000 years, archaeologists having unearthed evidence of Stone Age and early Bronze Age civilizations; Neolithic culture was apparently well-established by 2500 to 1500 BC. Traditional historiography postulated that successive waves of peoples, who now are the modern Malays, migrated into the region from China and Tibet during the 1st millennium BC, pushing earlier inhabitants into the western Pacific or remote mountain enclaves. More recently it has been suggested that instead the southward migration consisted of small groups who imposed their culture and language and created new ethnic fusions.

Small Malayan kingdoms appeared in the 2nd or 3rd century AD, a time when Indian traders and priests began traveling the maritime routes and brought with them Indian concepts of religion, government, and the arts. Over many centuries the peoples of the region, especially the royal courts, synthesized Indian and indigenous ideas, making brilliant and selective use of Indian models—including Hinduism and Mahāyāna Buddhism—in shaping their political and cultural patterns. The most significant complex of Indianized temple ruins has been found around Kedah Peak in northwestern Malaya. The peninsula and northern Borneo both lacked broad, fertile plains and were unable to support the pattern of densely populated classical Southeast Asian civilizations that flourished in Cambodia and Java. Although knowledge is scant and is based chiefly on Chinese written sources, it does appear that perhaps 30 small Indianized states rose and fell in Malaya, mostly along the east coast, during the 1st millennium AD. The most important of these states, Langkasuka, controlled much of northern Malaya. Malaya developed an international reputation as a source of gold and tin, populated by renowned seafarers. Between the 7th and 13th centuries many of these small, often prosperous peninsular maritime trading states may have come under the loose control of Śrīvijaya, the great Sumatra-based empire. At various times the Cambodian Angkor and Javanese Majapahit empires and the Tai Ayutthaya (Ayudhia) kingdom also claimed suzerainty in the region. The early states left a living legacy, traces of which can still be found in the political ideas, social structures, rituals, language, arts, and cultural practices of Malay Muslims.

Langkasuka

Although development was slower in more remote, less fertile northern Borneo, Sarawak had entered the Iron Age by AD 600. Archaeological excavations in the Sarawak River delta reveal many ancient sites containing evidence of both ironworking and an enormous trade with China and the Southeast Asian mainland. The local peoples exchanged edible bird's nests, rhinoceros horns, hornbill ivory, camphor, spices, wood, and other goods for Chinese ceramics, metal, and probably clothing. Neolithic boatbuilders along the east coast of Sabah already were involved in extensive interregional trade at about the same time; the maritime peoples of the area called the territory the "land below the wind" because it lay south of the typhoon belt.

The advent of Islām. By the late classical period a new religion, Islām, was filtering quietly into the region from outside, carried chiefly by Arab and Indian merchants. From the 13th through 17th century Sunnite Islām spread widely, coming from the Middle East via India. It offered an egalitarian message that challenged the power of the traditional elites and a complex theology that held much appeal for peasants and merchants in the coastal regions. The spread of Islām was intimately linked to the florescence of the great Indian Ocean maritime trading routes that connected China through the Strait of Malacca to India, the Middle East, and East Africa. Over these routes Indonesian spices, Malayan gold, and Chinese silks and tea traveled to Europe, sparking interest there in reaching the sources of these riches.

The arrival of Islām coincided with the rise of the great port of Malacca (now Melaka), established on Malaya's southwest coast by Sumatran exiles about 1400. The Indianized king—who sensibly and successfully sought a tributary relationship with powerful China—converted to Islām, becoming a "sultan" and hence attracting Muslim merchants. Soon Malacca became Southeast Asia's major trading entrepôt, while at the same time it gained suzerainty over much of coastal Malaya and eastern Sumatra. Malacca served as the main centre for the propagation of Islām as well as the eastern terminus of the Indian Ocean trading network. At its height in the late 15th century, Malacca hosted some 15,000 merchants from many countries, including Chinese, Arabs, Persians, and Indians; there were said to be more ships in the harbour than in any other port in the known world, attracted by a stable government and a policy of free trade. The Chinese admiral Cheng Ho called at the port several times in the first decades of the 15th century as part of the great Ming naval expeditions to the western Indian Ocean. Malacca's political and religious influence reached its height under Tun Perak, who served as prime minister (1456–98) after defeating the expanding Thai in a fierce naval

Malacca

Malacca empire in 1500.

battle; during his service Islām became well-entrenched in such districts (and subsidiary sultanates) as Johor, Kedah, Perak, Pahang, and Terengganu.

The mostly Islāmicized people of the Malacca area began calling themselves "Malays" (a likely elite reference to earlier Śrīvijayan origins). Thereafter, the term Malay applied to those who practiced Islām and spoke a version of the Malay language; identity and behaviour, rather than descent, became the criteria for being Malay, so that previously animist and Hindu-Buddhist peoples of various origins could identify themselves (and even merge) with the prestigious Malays. Over time a loose cultural designation became a coherent ethnic group spread throughout Malaya, northern and western Borneo, eastern Sumatra, and the smaller islands in between, a region that can be termed the "Malay world." Islām, however, came to overlay the earlier beliefs, so that, before the rise of religious reform movements in the 19th century, few Malays were orthodox Muslims. Hindu-influenced ritual remained important for the elite, and animist spirits were richly incorporated into Islāmic folk beliefs.

Early European intrusions. The fame of Malacca as the crossroads of Asian commerce had reached Europe by the beginning of the 16th century. The Portuguese, who for a century had been seeking a sea route to the Orient, finally arrived at Malacca in 1509, inaugurating a new era of European activity in Southeast Asian history. Although many Southeast Asians, including the inhabitants of northern Borneo, experienced little Western impact before the 19th century, Malaya was one of the first regions disrupted. In 1511 a Portuguese fleet led by Afonso de Albuquerque captured Malacca. Since fewer merchants chose to endure the high taxes and the conquerors' intolerance of Islām, Malacca languished under Portuguese control. Indeed, the undermanned Portuguese barely repulsed repeated assaults by the dynamic sultanate of Aceh (Acheh) of northern Sumatra. Aceh had leaped into the political vacuum created by Malacca's downfall; during the 16th and early 17th centuries Aceh was deeply involved in peninsular affairs, warring against various sultanates and at times controlling some or most of them. The Dutch, who replaced the Portuguese as the dominant European power in Southeast Asia, seized Malacca in 1641; they tried to revive trade, but the city never recovered its earlier glory.

Aceh

An emphasis on the often complex politics of the peninsula in the post-Malacca years obscures other significant developments. Sultanates continued to be created throughout the Malay world. Usually they were situated at the mouth of a major river and sought to control trade to and from the interior, which often was populated by seminomadic peoples such as the aboriginal Orang Asli of Malaya and the various indigenous peoples of Borneo. Newer, dynamic sultanates—such as Riau-Johor, Kedah, and Brunei (on Borneo's northwest coast)—took over some of the trading functions of Malacca and flourished for several centuries. Islām reached Sarawak and Sabah in the 15th and 16th centuries; many coastal peoples converted, but the interior remained largely animist until the 20th century. Malay political control spread, with the Brunei sultans laying claim to much of what is today Sarawak and Sabah—although their actual power seldom reached much beyond the coastal zone. Attempts by Brunei to control the interior often failed, especially after the aggressive, head-hunting Iban people commenced their migrations into Sarawak from western Borneo (16th through 18th centuries). The Siamese came to control some of the northern Malay sultanates, and the southernmost part of present-day Thailand still has a predominantly Malay Muslim population. The Malay sultanates included many, often feuding chiefdoms, and wars between—or within—sultanates occasionally erupted. Europeans considered the sultanate system politically unstable, but it reflected a chronic situation in which states constituted hierarchical but fluctuating spheres of influence that ruled over mobile populations.

During the 17th century many Minangkabau people migrated from western Sumatra into southwestern Malaya, bringing with them a matrilineal sociocultural system by which property and authority descended through the female side. They elected their chiefs from among eligible aristocratic candidates, a model that has been incorporated into contemporary Malaysia's selection of a king. Later the Minangkabau formed a confederation of nine small states (Negeri Sembilan). The political pluralism of Malaya in the 18th century also facilitated large-scale penetration of the peninsula by the Buginese, a people from southwestern Celebes (Sulawesi) with a well-earned reputation as maritime traders. Buginese immigrants established the sultanate of Selangor in the mid-1700s and also gained dominance in the vigorous sultanate of Johor, at the southern tip of the peninsula, a prosperous trading entrepôt that attracted Asian and European merchants. Despite continuous movement of peoples from the archipelago into the area, Malaya and northern Borneo remained sparsely populated into the early 19th century. Many present-day Malays are descendants of immigrants from elsewhere in archipelagic Southeast Asia who arrived after 1800. Indeed, immigrants from Java, Celebes, and Sumatra demonstrated a tendency to merge with the existing Malay community over time, a process that steadily accelerated with the rise of Malay nationalism and vernacular education in the 1930s. Some of the customs brought by Minangkabau, Javanese, and other immigrants are still practiced in districts where they settled, contributing to the many regional variations of Malay culture and language.

Origins of the modern Malays

The colonization of Malaysia. *Malaya.* Except for Malacca, there was little Western influence in Malaya and northern Borneo until the late 18th century, when Britain became interested in the area. The British sought a source for goods to be sold in China, and in 1786 the English East India Company acquired Penang (or Pinang) Island, off Malaya's northwest coast, from the sultan of Kedah. The island soon became a major trading entrepôt with a chiefly Chinese population. British representative Sir Stamford Raffles occupied Singapore Island off the southern tip of the peninsula in 1819, acquiring trading rights in 1824; a strategic location at the southern end of the Strait of Malacca and a fine harbour made Singapore the centre for Britain's economic and political thrust in the peninsula. The British attracted Chinese immigrants to the sparsely populated island, and soon the mainly Chinese port became the region's dominant city and a major base for Chinese economic activity in Southeast Asia. By then the major industrial capitalist power in Europe, Britain next obtained Malacca from the Dutch in 1824 and thereafter governed the three major ports of the Strait of Malacca, which collectively were named the Straits Settlements. The British Colonial Office took direct control in 1867.

With the opening of the Suez Canal in 1869, the full effect of European technological superiority swept over Southeast Asia. The feuding Malay states were little prepared, with the exception of Johor, which was led by the

modernizing sultan Abu Bakar. The other state administrations generally were weak and failed to cope with their mounting problems, including the steady immigration of Chinese. By the early 19th century, the Chinese—who were being driven to emigrate by increasing poverty and instability in their homeland—began settling in large numbers in the sultanates along the peninsula's west coast, where they cooperated with local Malay rulers to mine tin. The Chinese organized themselves into tightly knit communities and formed alliances with competing Malay chiefs, and Chinese factions fought wars with each other for control of minerals. Chinese settlers also established towns like Kuala Lumpur and Ipoh, which later grew into major cities. The Chinese and Malays increasingly became leading elements in an inadequately integrated sociopolitical structure, a framework that produced chronic communal friction.

British intervention

British investors were soon attracted to Malaya's potential mineral wealth, but they were concerned about the political unrest. As a result, local British officials began intervening in various Malayan sultanates by the 1870s, establishing political influence (sometimes employing force or the threat of force) through a system of British residents (advisers). Initial intervention into Malayan internal affairs was crude and incompetent; the first British resident to Perak was murdered by Malays outraged at his assertive actions. Gradually, the British refined their techniques and appointed more able representatives; notable among these was Sir Frank Swettenham, who in 1896 became the first resident-general of a Malay federation of Perak, Selangor, Negeri Sembilan, and Pahang, with Kuala Lumpur as the capital. By 1909 the British had pressured Siam into transferring sovereignty over the northern Malay states of Kedah, Terengganu, Kelantan, and Perlis. Johor was compelled to accept a British resident in 1914. These sultanates remained outside the federation. Britain had now achieved formal or informal colonial control over nine sultanates, but it pledged not to interfere in matters of religion, customs, and the symbolic political role of the sultans. The various states kept their separate identities but were increasingly integrated to form British Malaya.

Sarawak. Sarawak's history also entered a new stage when the English adventurer James (later Sir James) Brooke intervened in a revolt against Brunei control and was appointed raja (governor) of the Sarawak River basin in 1841 by the Brunei sultan. Brooke inaugurated a century of rule by a remarkable English family and a new form of imperial endeavour. Simultaneously traditional Bornean potentates, benevolent autocrats, and cautious modernizers, the Brookes viewed themselves as protectors of Sarawak's people. Brooke spent his final years consolidating his control of surrounding districts and defending his government against various challenges. Although the first raja's political and financial position was often precarious, Sarawak eventually acquired the status of an independent state under British protection. Relations with Britain, however, were often strained, chiefly because of a consistent Brooke policy of incorporating territory at the expense of the declining Brunei sultanate. The present boundaries of Sarawak were achieved by 1906, but by then the once-powerful Brunei also had become a British protectorate.

Sabah. Sabah (North Borneo) was the last region to be brought under British control. In the early 1700s Brunei transferred its claims over much of Sabah to the sultan of Sulu, but, except in the northeast, actual Sulu power remained limited. Occasional resistance to Brunei or Sulu influence, as well as extensive coastal raiding and confusion of suzerainty, invited Western interest beginning in the 18th century. Despite short-lived American activity in the 1860s, British power proved most decisive. Britain had already acquired the offshore island of Labuan from Brunei by 1846. They gained a toehold in Sabah proper in 1872 when a British merchant, William Cowie, founded an east-coast settlement at Sandakan on lease from Sulu.

British North Borneo Company

By 1881 the British had obtained rights to much of Sabah and launched the British North Borneo Company, which, based in Sandakan, ruled the British protectorate from 1881 to 1941. The company operated the state in the interest of its shareholders but was only moderately prosperous, because of high overhead and poor management; its 60 years of rule, however, established the economic, administrative, and political framework of modern Sabah.

The impact of colonialism. The British presence in the region reflected several patterns: direct colonial rule in the Straits Settlements, more indirect control in some of the east-coast Malay sultanates, and family or corporate control in Borneo. Regardless of the political form, however, British rule brought profound changes, transforming the various states socially and economically. The Brookes and the North Borneo Company faced prolonged resistance before they consolidated their control, while occasional local revolts punctuated British rule in Malaya as well. In Sarawak in 1857, for example, interior Chinese gold-mining communities nearly succeeded in toppling the intrusive James Brooke before being crushed, while Muslim chief Mat Salleh fought expanding British power in Sabah from 1895 to 1900. The Brookes mounted bloody military campaigns to suppress head-hunting and to forcibly incorporate the autonomy-loving Iban, and similar "pacification" campaigns were carried out in Sabah. Those who resisted British annexation or policies were portrayed by colonialists as treacherous, reactionary rebels; but many of them are now hailed in Malaysia as nationalist heroes.

British administration eventually achieved peace and security. In Malaya the Malay sultans retained their symbolic status at the apex of an aristocratic social system, although they lost some of their political authority and independence. British officials believed that the Malay peasants needed to be protected from economic and cultural change and that traditional class divisions should be maintained. Hence, most economic development was left to Chinese and Indian immigrants, as long as it served long-term colonial interests. The Malay elite enjoyed a place in the new colonial order as civil servants. Many Malayan and Bornean villagers were affected by colonial taxes, however, and were forced to shift from subsistence to cash-crop farming; their economic well-being became subject to fluctuations in world commodity prices. Much economic growth occurred; British policies promoted the planting of pepper, gambier (a plant producing a resin used for tanning and dyeing), tobacco, oil palm, and especially rubber, which along with tin became the region's major exports. Malaya and British North Borneo developed classic extractive, plantation-based economies oriented to the resource and market needs of the industrializing West.

British authorities in Malaya devoted much effort to constructing a transportation infrastructure, in which railways and road networks linked the tin fields to the coast; port facilities also were improved to facilitate resource exports. These developments stimulated growth in the tin and rubber industries to meet world demand. The tin industry remained chiefly in immigrant Chinese hands through the 19th century, but more highly capitalized, technologically sophisticated British firms took over much of the tin production and export by World War II. The rubber tree was first introduced from Brazil in the 1870s, but rubber did not supersede the earlier coffee and gambier plantings until near the end of the century. By the early 20th century thousands of acres of forest had been cleared for rubber growing, much of it on plantations but some farmed by smallholders. Malaya became the world's greatest exporter of natural rubber, with rubber and tin providing the bulk of colonial tax revenues.

Introduction of rubber

The British also improved public health facilities, reducing the incidence of some tropical diseases, and they facilitated the establishment of government Malay and Christian mission (mostly English-language) schools; the Chinese generally had to develop their own schools. These separate school systems, however, helped perpetuate the pluralistic society. Some Chinese, Malays, and Indians benefited from British economic policies, while others enjoyed no improvement or saw living standards drop. Government-sanctioned opium and alcohol use provided a major revenue source in some areas.

Between 1800 and 1941 several million Chinese entered Malaya (especially the west-coast states), Sarawak, and British North Borneo to work as labourers, miners,

planters, and merchants. South Indian Tamils were imported as the workforce in Malayan rubber estates. Malays accounted for 90 percent of Malaya's population in 1800, but by 1911 they constituted only about 60 percent. A pluralistic society was developing, with most Malays in villages, Chinese in towns, and Indians on plantations. Colonial authorities skillfully utilized "divide and rule" tactics to maintain their control. Through enterprise, organization, and cooperation, many Chinese became part of a prosperous, urban middle class that controlled retail trade. The various ethnic groups generally lived in their own neighbourhoods, followed different occupations, practiced their own religions, spoke their own languages, operated their own schools, and later formed their own political organizations. Some mostly ethnically oriented nationalist currents stirred in Malaya, Singapore, and Sarawak by the 1930s. Malay groups either pursued Islāmic revitalization and reform or debated the future of the Malays in a plural society, while Chinese organizations were oriented toward political trends in China.

The Borneo states experienced many of the same changes. Sir Charles Brooke, who governed Sarawak from 1868 to 1917, succeeded his uncle, passing the state on to his son, Charles Vyner de Windt Brooke (ruled 1917–46); they furthered the Brooke pattern of personal rule. Chinese immigrants came in response to economic incentives, and by 1939 they accounted for a quarter of the state population. The Brookes involved the Malay elite in government. Sarawak society came to be characterized by a three-way division: most Malays in government or fishing; most Chinese in trade, labour, and cash-crop farming; and most Iban in the police force or shifting cultivation. Gambier and pepper were planted, with Sarawak becoming the major world supplier of the latter crop. Later, rubber became dominant, and an oil industry developed. Most cash-crop agriculture remained in smallholdings rather than following the plantation pattern characteristic elsewhere. Christian missionary activity and church, Chinese, and Malay schools generated sociocultural change. In the 1930s both the Chinese and Malay communities experienced rising ethnic consciousness as personal rule began to erode.

The North Borneo Company in Sabah contrasted with the Brookes. It concentrated on developing an extractive economy for the benefit of its shareholders, based mostly on Western-owned tobacco and rubber estates and forest exploitation. Christian missions facilitated change among non-Muslims. Immigrant Chinese and Indonesians provided a plantation workforce. Both the Brookes and the company created single states out of many local societies, but they tolerated little open political activity.

Japanese occupation of Malaya

Political transformation. The occupation of Malaya and Borneo by Japan (1942–45) during World War II generated tremendous changes in those territories. Their economies were disrupted, and communal tensions were exacerbated because Malays and Chinese reacted differently to Japanese control. The Japanese desperately needed access to the natural resources of Southeast Asia; they invaded Malaya in December 1941, having neutralized American military power in Hawaii (Pearl Harbor) and the Philippines, and shortly controlled the peninsula, Singapore, and Borneo. Pro-communist, predominantly Chinese guerrillas waged resistance in Malaya, and a brief Chinese-led revolt also erupted in North Borneo. In many places increasing politicization and conflict within and among ethnic groups developed as a result of economic hardship and selective repression; the rule of the Brookes and of the North Borneo Company was permanently undermined, while in Malaya some Chinese and Malays saw that British domination was not inevitable. Nonetheless, most people welcomed the Japanese defeat in 1945.

After the end of the war, Sarawak and North Borneo became British crown colonies, but Sarawak faced a turbulent political situation. Many Malays opposed the termination of Brooke rule and Sarawak's cession to Britain; the resulting sociopolitical divisions persisted for years. With the establishment of the British North Borneo colony, the capital was moved to Jesselton (now Kota Kinabalu). Some local self-government was introduced in Malaya. The major generator of political organizing, however, was a British proposal to form a single Malayan Union, incorporating all the Malayan territories except Singapore, that would diminish state autonomy and accord equal political and citizenship rights to non-Malays. A tremendous upsurge of Malay political feeling against this plan, led by Dato Onn bin Ja'afar, resulted in the creation in 1946 of the United Malays National Organization (UMNO) as a vehicle for Malay nationalism and political assertiveness. Strikes, demonstrations, and boycotts doomed the scheme, and the British began to negotiate with the UMNO about the Malayan future.

The negotiations resulted in the creation of the Federation of Malaya in 1948, which unified the territories but provided special guarantees of Malay rights, including the position of the sultans. These developments alarmed the more radical and impoverished sectors of the Chinese community. In 1948 the Communist Party of Malaya—a mostly Chinese movement formed in 1930 that had provided the backbone of the anti-Japanese resistance—went into the jungles and began a guerrilla insurgency to defeat the colonial government, sparking a 12-year period of unrest known as the Emergency. The communists waged a violent and ultimately unsuccessful struggle supported by only a minority of the Chinese community. The British struggled to suppress the insurgency by military means, including an unpopular strategy that forcibly moved many rural Chinese into tightly controlled New Villages. Although this policy isolated villagers from guerrillas, it also increased the government's unpopularity. The British finally achieved success when, under the leadership of British high commissioner Sir Gerald Templer, they began addressing political and economic grievances as well, increasingly isolating the rebels. Promising independence, British officials began negotiating with the various ethnic leaders, including the UMNO and the Malayan Chinese Association (MCA), formed in 1949 by wealthy Chinese businessmen. A coalition consisting of the UMNO (led by the aristocratic moderate Tunku Abdul Rahman), the MCA, and the Malayan Indian Congress contested the national legislative elections held in 1955 and won all but one seat; this established a permanent political pattern of a ruling coalition—known first as the Alliance Party and later as the National Front—that united ethnically based, mostly elite-led parties of moderate to conservative political leanings, with the UMNO as the major force.

The Emergency

On Aug. 31, 1957, the Federation of Malaya achieved independence (*merdeka*) under an Alliance government headed by Tunku Abdul Rahman as prime minister. Singapore, with its predominantly Chinese population, remained outside the federation as a British crown colony. The arrangement tended to favour the Malays politically, with UMNO leaders holding most federal and state offices and the kingship (*yang di-pertuan agong*) rotating among the various Malay sultans, but the Chinese were granted liberal citizenship rights and maintained strong economic power. Kuala Lumpur became the federal capital.

New currents also were emerging in Borneo. Colonial rule succeeded in rebuilding and expanding the economies of the two colonies, with rubber and timber providing the basis for postwar economic growth. Health and education facilities only slowly permeated outside the towns. Political consciousness began to spread, however, as elections were held for local councils. During the 1950s the development of radio broadcasting and newspapers particularly stimulated the Kadazan community to become involved in Sabah politics, while, in Sarawak, Chinese and Malay leaders formed the first political parties there—some espousing multiethnic identities—in expectation of independence. Political activity accelerated with the mooting of the proposal for a federated Malaysian state by Malayan and British officials in 1961, and new parties formed in Sabah representing the Kadazan, Chinese, and Muslim communities. Statewide elections were held in Sabah and Sarawak, with most of the parties accepting independence through merger with Malaysia; that sentiment increased after the Philippines claimed Sabah, based on former Sulu suzerainty.

British leaders proposed a Malaysian federation as a way of terminating their now burdensome colonial rule over

Singapore, Sarawak, and Sabah, even though these states were historically and ethnically distinct from Malaya and from each other. It was in many ways to be a marriage of convenience. Malaya was closely linked economically with bustling Singapore, and the Malays felt a kinship to the various Muslim groups in Borneo. Tunku Abdul Rahman believed the federation could defuse potential leftist Chinese activity while balancing the Chinese majority in Singapore with the non-Chinese majorities of the Borneo states. Malaya already contained a Chinese minority of nearly 40 percent, with Malays barely in the majority there.

Formation of the federation

Hence, on Sept. 16, 1963, the Federation of Malaysia was formed, with Sarawak and Sabah (East Malaysia) shifting from a Bornean to a peninsular orientation. Brunei, which had been invited to join, chose to remain a British protectorate and later became independent as a small, oil-rich Malay sultanate.

Malaysia. The new, hurriedly formed nation faced many political problems, including a period of Indonesian military opposition that ended in 1966, sporadic communist insurgency in Sarawak, periodic East Malaysian disenchantment over Malayan domination and federal policies, and the secession of Singapore from the Federation (at Malaysia's urging) in 1965. The latter event resulted from increasing friction between the mostly Malay federal leaders and the mostly Chinese state leaders, especially Singapore's independent-minded chief minister, Lee Kuan Yew, who disagreed on national goals. Under Lee's autocratic direction and freewheeling economic policies, Singapore became a highly prosperous but tightly controlled city-state, and relations with Malaysia gradually improved. Both countries became founding members of the Association of Southeast Asian Nations (ASEAN) in 1967.

The secession of Singapore allowed the UMNO to exercise more influence over federal policies, even if it did not end political uncertainties. Communal tensions on the peninsula following a heated election generated riots and a nationwide state of emergency in 1969–70. Many non-Malays resented the government's attempts to build national unity and identity, such as increasing the use of the Malay language in education and public life. Government policies aimed at redistributing more wealth to Malays, as well as a growing Islāmic revival, particularly worried the Chinese. The New Economic Policy, launched in 1971 and renewed as the New Development Policy in 1991, was designed to greatly increase Malay wealth and economic potential. Beginning in the late 1970s, the Islāmic fundamentalist revival, or *dakwah* movement, increasingly attracted the support of young Malays who had become alienated by the growth of a Westernized, materialistic society, and this generated divisions within Malay society. Rural development policies reduced poverty rates, but large pockets of urban and especially rural poverty persisted, with many regional and ethnic inequities in the distribution of wealth. Radical critics of the government (including communists, socialists, Islāmic militants, and progressive intellectuals) were politically marginalized or sometimes detained.

For Sarawak and Sabah, politics within Malaysia has proved a turbulent experience. The decision to join was made in haste, and many people continued to resent the loss of their autonomy, especially control over growing petroleum revenues. Political crises have occurred periodically in Sarawak, although it has been governed since 1970 by a Malay-dominated, pro-federal but multiethnic coalition that represented a triumph of peninsular alliance-style politics. By the mid-1980s, however, some Iban leaders had challenged the coalition for being too accommodating to wealthy Malay and Chinese interests. The government encouraged the assimilation of Sarawak society with that of the peninsula and dramatically increased the exploitation of timber resources, sometimes at the expense of powerless interior peoples. Sabah politics also have proved to be contentious, with chronic tensions between Muslim and non-Muslim groups. Between 1967 and 1975 Chief Minister Tun Mustapha ruled the state with an iron hand, co-opting or repressing opponents, promoting Islām, and challenging federal policies. The multiethnic coalition that replaced Mustapha continued to preside over rapid economic growth purchased by the exploitation of Sabah's bountiful natural resources. Communal tensions surfaced again in 1987, when a Christian Kadazan-led party swept into power and followed policies opposed by federal leaders. Although peninsular sociopolitical patterns increasingly influenced Sabah and Sarawak, the states remained unique within the Malaysian system.

Politics in Sabah

Since 1963 Malaysia has maintained a quasi-democratic parliamentary political system that includes regular elections and moderate political diversity but also some restrictions on civil liberties, including a ban on public discussion of "sensitive" issues. Tunku Abdul Rahman was succeeded as prime minister by Tun Abdul Razak in 1970. On Abdul Razak's death in 1976 another UMNO leader, Datuk Hussein Onn, replaced him. In 1981 Mahathir bin Muhammed became prime minister, the first nonaristocrat to hold that office. Mahathir's assertive style and controversial policies generated a major split in the UMNO; in 1988 Mahathir outmaneuvered his opponents, dissolving the UMNO and forming a new Malay party, UMNO Baru (New UMNO). Government and business leaders have managed to develop a prosperous, diversified economy, although commodity exports have remained important and certain areas have experienced severe environmental problems. Malaysia's literacy rates have risen dramatically, and the government has constructed an extensive public education system. The large and expanding urban middle class has become increasingly multiethnic, with a growing percentage of non-Malays fluent in the national language. Although development policies have been criticized as lacking ethnic and regional balance, Malaysia nonetheless has achieved considerable success at creating national unity and sociopolitical stability out of deep regional and ethnic divisions. (C.A.Lo.)

For later developments in the history of Malaysia, see the BRITANNICA BOOK OF THE YEAR.

Myanmar

Myanmar is an independent country in the western portion of mainland Southeast Asia, with an area of 261,228 square miles (676,577 square kilometres). It is bordered by China to the north and northeast, Laos to the east, Thailand to the southeast, the Andaman Sea and Bay of Bengal to the south and southwest, Bangladesh to the west, and India to the northwest.

In 1989 the country's official English name was changed from the Union of Burma to the Union of Myanmar (Burmese: Pyidaungzu Myanma Naingngandaw); in the Burmese language the country has been known as Myanma (or, more precisely, Mranma Prañ) since the 13th century. Also in 1989, the English name of the capital, Rangoon, was dropped in favour of the common Burmese name, Yangôn. In this discussion, the name Burma is used for the country during the period of British rule (1885–1948) and during the subsequent period of independence until 1989; the name Myanmar is used in all other contexts.

Myanmar stretches from latitude 10° N to about 28° 30′ N. It is thus the northernmost of the Southeast Asian countries, with considerable territory situated outside the tropics. The country is shaped like a kite with a long tail that runs south along the Malay Peninsula. Its total length from north to south is about 1,275 miles (2,050 kilometres), and its width at the widest part, across the centre of the country at about the latitude of Mandalay, is approximately 580 miles from east to west.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Myanmar slopes from north to south, from an elevation of 19,296 feet (5,881 metres) at Mount Hkakabo (the country's highest peak) in the extreme north to sea level at the Irrawaddy (Ayeyarwady) and Sittang (Sittoung) river deltas. The mountain ranges generally run from north to south. The country as a whole can be divided into five physiographic regions—the northern mountains, the western ranges, the eastern plateau, the central basin and lowlands, and the coastal plains.

Five physiographic regions

The northern mountains consist of a series of ranges that form a complex knot at Mount Hkakabo. Geologically,

this knot marks the northeastern limit of the encroaching Indian-Australian Plate, which has been colliding with the southern edge of the Eurasian Plate for roughly the past 50 million years and thrusting up the mountain ranges of Myanmar and beyond. This region contains the sources of several of Asia's great rivers: the Irrawaddy, which rises and flows wholly within Myanmar, and the Salween (Thanlwin), Mekong, and Yangtze, which rise to the north in China. The upper courses of these rivers all flow through deep gorges within a short distance of each other, separated by steep, sheer peaks.

The western ranges traverse the entire western side of Myanmar from the northern mountains to the southern tip of the Arakan (Rakhine) Peninsula, where they run under the sea and reappear as the Andaman and Nicobar islands. Their average height is about 6,000 feet, although some peaks rise to 10,000 feet and higher. The mountains consist of old crystalline rocks surrounded by hard, tightly folded sedimentary rocks on either side. From north to south, the Pātkai Range, Nāga Hills, and Chin Hills form the border between India and Myanmar. To the south of these are the Arakan Mountains, which lie entirely within Myanmar and separate the coastal strip from the central basin.

The Shan Plateau in the east rises abruptly from the central basin, often in a single step of 2,000 feet. Occupying the eastern half of the country, it is deeply dissected, with an average height of 3,000 feet. The plateau was formed during the Mesozoic Era (245 to 66.4 million years ago) and thus is a much older feature than the western mountains, but the plateau also shows more recent and intensive folding, with north-south longitudinal ranges reaching elevations of 6,000 to 8,600 feet rising abruptly from the plateau surface. Northward, the plateau merges into the northern mountains, and southward it continues into the Dawna Range and the peninsular Tenasserim Mountains, each a series of parallel ranges with narrow valleys.

The central basin and lowlands, lying between the Arakan Mountains and the Shan Plateau, are structurally connected with the folding of the western ranges. The basin was deeply excavated by the predecessors of the Irrawaddy, Chindwin (Chindwinn), and Sittang rivers; the ancient valleys are now occupied by these rivers, which cover the ancient soft sandstones, shales, and clays with their more recent alluvial deposits. In the deltaic regions formed by the Irrawaddy and Sittang rivers, the landscape is absolutely flat, and the monotony is relieved by only a few blocks of erosion-resistant rocks that are never more than 60 feet high. The basin is divided into two unequal parts, the larger Irrawaddy valley and the smaller Sittang valley, by the Pegu Mountains. In the centre of the basin and structurally connected with the Pegu Mountains and its northern extension is a line of extinct volcanoes with small crater lakes and eroded cones, the largest being Mount Popa, at 4,981 feet.

The coastal areas consist of the narrow Arakan and Tenasserim coastal plains, which are backed by the high ranges of the Arakan and Tenasserim mountains and are fringed with numerous islands of varying sizes.

Drainage and soils. Like the mountains, Myanmar's main rivers run from north to south. About three-fifths of Myanmar's surface is drained by the Irrawaddy and its tributaries. Flowing entirely through Myanmar, it is navigable for nearly 1,000 miles. At the apex of its delta, the Irrawaddy breaks up into a vast network of streams and empties into the Andaman Sea through nine mouths. Its great tributary, the Chindwin, drains the western region. The Bassein River drains the southern Arakan Mountains, and the Yangôn (Rangoon) River drains the Pegu Mountains, both entering the Irrawaddy at the delta. The Sittang flows into the Gulf of Martaban of the Andaman Sea and, in spite of its comparative shortness, has a relatively large valley and delta. The Shan Plateau is drained by the Salween River, which enters Myanmar from southern China and empties into the Gulf of Martaban southeast of the Sittang. It is deeply entrenched and crosses the plateau in a series of deep gorges. Many of its tributaries are more than 300 miles long and join the Salween in cascades. The Arakan coastal plains are drained by short, rapid streams, which, after forming broad deltas, flow into the Bay of Bengal. The Tenasserim plains also are drained by short and rapid rivers, which enter the Gulf of Martaban.

Rivers

The highland regions of Myanmar are covered with highly leached dark red and reddish brown latosols. When protected by forest cover, these soils absorb the region's heavy rain, but they erode quickly once the forest is cleared. The lowland regions are covered with alluvial soils—mainly silt and clay. Low in nutrients and organic matter, they are improved by fertilizers. In the central-region dry belt are found red-brown soils rich in calcium and magnesium. In the same region, however, when the soil has a low clay content, it becomes saline under high evaporation and is recognizable by its yellow or brown colour.

Climate. Although Myanmar is located in the monsoon region of Asia, its climate is greatly modified by its geographic position and its relief. The cold air masses of Central Asia bring snow to the northern mountains for two months of the year, but this mountain wall prevents the cold air from moving farther south, so that Myanmar lies primarily under the influence of the monsoon winds. The north-south alignment of ranges and valleys creates a pattern of alternate zones of heavy and scanty rainfall during both the northeast and southwest monsoons. Most of the precipitation, however, comes from the southwest monsoon. The west coast is subject to occasional tropical storms called cyclones.

Myanmar has three seasons: the cool, relatively dry northeast monsoon (late October to mid-February), the hot, dry intermonsoonal season (mid-February to mid-May), and the rainy southwest monsoon (late May to late October). The coastal regions and the western and southeastern ranges receive more than 200 inches (5,100 millimetres) of precipitation annually, while the delta regions receive about 100 inches. The central region is not only away from the sea but also in the rain shadow of the Arakan Mountains. Rainfall gradually decreases northward until in the dry zone it is only between 20 and 40 inches. The Shan Plateau, because of its elevation, receives between 75 and 80 inches.

Elevation and distance from the sea affect temperature as well. Although Myanmar generally is a tropical country, temperatures are not uniformly high throughout the year. The daily temperature range is greater than in nearly all other parts of Southeast Asia, but no locality has a continental type of climate (*i.e.*, one characterized by large seasonal differences in average temperature). Mandalay, in the centre of the dry zone, has some of the greatest daily temperature ranges, which average about 22° F (12° C) annually. The average daily temperature at Mandalay is 82° F (28° C), compared to 81° F (27° C) at Yangôn near the coast, 79° F (26° C) at Sittwe (Akyab) in Arakan (Rakhine) state, and 71° F (22° C) at Lashio on the Shan Plateau.

Temperatures

Plant and animal life. Even after centuries of rice cultivation involving clearing large areas of forest, about half of Myanmar is covered with forests of various types, depending on elevation and the amount of precipitation. Subtropical and temperate forests of oak and pine are found at elevations above 3,000 feet. In the northern mountains, above 6,000 feet, are forests of rhododendrons. Tropical, evergreen rain forests of hardwood trees occur in areas receiving more than 80 inches of rain annually. In regions where the rainfall is between 40 and 80 inches are found broad-leaved, tropical-deciduous "monsoon" forests, the trees of which shed their leaves during the hot season. They produce valuable woods, notably teak. Where rainfall is less than 40 inches, the forests gradually open into scrubland. There are no true grasslands in Myanmar, but bamboo, bracken, and coarse grass grow in areas where the forest has been cleared and then abandoned. In the Irrawaddy and Sittang deltas are found tidal forests of mangrove trees that grow as high as 100 feet and supply firewood and bark for tanning.

The jungles of Myanmar are home to a profusion of birdlife, including pheasants, parrots, peafowl and other wild fowl, and grouse. The Asiatic two-horned rhinoceros, wild buffalo, gaur (wild bison), and various kinds of deer were once plentiful but are now reduced in number and

protected. Elephants are numerous, and many are trained for work. Tigers, leopards, and wildcats are still common. Bears are found in hilly regions, and gibbons and monkeys of various kinds inhabit the thicker parts of the forests. Snakes include pythons, cobras, and vipers, and crocodiles are found in the deltas. Turtles live in coastal regions, and edible fishes abound in every stream.

Traditional regions. Speakers of Burmese and Mon historically have lived in the plains, while speakers of a dialect of Burmese retaining archaic features occupied the Arakan and Tenasserim coastal plains. The hills were inhabited by those speaking Shan, Kachin, Chin, and numerous other languages. In the plains the division between northern and southern Myanmar (Upper and Lower Burma, respectively) dates from early history, not only because of differences in the geography but also because the Mon (now a small minority) lived in southern Myanmar. The northern dry zone, where the majority Burman population lived, was the cultural, political, and economic heartland of Myanmar. The division became more marked during the period 1852–85, when southern Myanmar became British Burma.

Villages

Settlement patterns. Myanmar is a land of villages. Except for a few large cities—notably Yangôn, Mandalay, and Moulmein (Mawlamyine)—the towns essentially are large villages. The hill peoples, although practicing shifting agriculture, have settled in upland villages at some distance from the fields. On the Shan Plateau and in the neighbouring river valleys, the fields adjoin the villages. Older villages are circular in shape, but along the banks of the delta streams and along railways the villages are rectangular. Houses are built of timber and bamboo, the roofs being thatched or tiled. In the past, houses typically were built on piles, the original purpose being protection from wild animals or floods. The style persists in many villages, especially those on the hills, and farm animals are kept under the houses at night. In small towns the piles have given way to a supporting brick structure with concrete flooring, the upper story still being made of timber. Houses entirely of brick were few in number before 1942, but many later sprang up in Yangôn, Mandalay, and larger towns on the rubble of buildings destroyed during World War II. Life in villages is still communal because of custom, the influence of Buddhism, and the "redistributive" and reciprocal nature of agrarian society.

The people. *Linguistic groups.* Several indigenous languages—as distinct from mere dialects—are spoken in Myanmar. The official language is Burmese, spoken by the people of both the plains and the hills. These languages belong to three language families. The Burmese language itself, and most of the other languages, belong to the Tibeto-Burman subfamily of the Sino-Tibetan family. The Shan language belongs to the Tai family. Languages spoken by the Mon of southern Myanmar and by the Wa and Palaung of the Shan Plateau are members of the Mon-Khmer subfamily of the Austro-Asiatic family.

Until colonial times, only Pyu, Burmese, Mon, and Shan were written; writing systems for Karen, Kachin, and Chin were developed later. The Burmese spoken in Arakan state and Tenasserim (Taninthary) division suggests that it has preserved the language's ancient pronunciations. For the majority of the hill peoples, Burmese is a second language.

During the colonial period, English became the official language, but Burmese continued as the primary language in all other settings. Both English and Burmese were made compulsory subjects in schools and colleges. Since a knowledge of English became an asset, many learned to speak it, and a small English-speaking elite emerged. Burmese, Chinese, and Hindi were the languages of commerce. After independence, English ceased to be the official language and, after the military coup of 1962, lost its importance in schools and colleges; an elementary knowledge of English, however, is still required, and its instruction is again being encouraged.

Ethnic groups. The original home of the Burmans in the dry zone established the ethnic character of the entire Irrawaddy valley and the coastal strips. These areas hold the majority of the population.

The Irrawaddy and Sittang deltas were once peopled by the Mon, who may have entered the country from their kingdoms in the Chao Phraya River valley in Thailand. They were conquered in the 11th century by the Burmans, a more martial and less cultured group at the time. The Mon attempted twice to throw off Burman control, but by the end of the 18th century they had been largely absorbed by the Burmans, by intermarriage as well as by suppression. A sizable number still remain in the Sittang valley and in Tenasserim; although they continue to call themselves Mon, most of them have been integrated into Burman culture and no longer speak their original language.

Tribal peoples

In the western hills and the Chindwin River valley are various groups called by the comprehensive name of Chin. The upper Irrawaddy valley and the northern hills are occupied by groups under the comprehensive name of Kachin. These peoples have had a long association with the Burmans.

The Shan of the Shan Plateau have little ethno-linguistic affinity with the Burmans, and their society, unlike that of the plains peoples, was less elaborately structured. The Wa and the Palaung are Mon-Khmer speakers, but, because of the smallness of their numbers and their long residency on the plateau, they are sometimes confused with the Shan. In the same way, the Nāga on the Myanmar side of the frontier with India are mistakenly placed with the Chin, and the Lolo-Muhso in northeastern Myanmar are grouped with the Kachin.

The Karen are the only hill people who have settled in significant numbers in the plains. Although ethnically and linguistically Tibeto-Burman, they share territory and much vocabulary with the Mon. They are found in the deltas among the Burmans, in the Pegu Mountains, and along both sides of the lower Salween River. The Kayah, who live on the southern edge of the Shan Plateau, were known as Red Karens, or Karenni, apparently from their red robes. Although ethnically and linguistically Karen, they tend to have their own identity.

During the period of British colonial rule, there were sizable communities of South Asians and Chinese, but many of these people left at the outbreak of World War II. A second exodus took place in 1963, when commerce and industry were nationalized.

Religious groups. The vast majority of the population is Theravāda Buddhist. The Burmans are Buddhists except for minimal numbers of Christians and Muslims; the Shan also are Buddhists. Among the Karen, there are many more Buddhists than Christians. The other hill peoples are animists except for a small number of Kayah Buddhists and Kachin and Chin Christians, and even they practice animism to some degree.

Demographic trends. The population density in each region is related to agricultural production, particularly of rice. Thus, the most populous regions are the Irrawaddy delta and the dry zone, with the highest densities found in the upper delta, between Yangôn and Henzada. The populations of the Sittang delta, the sedimented hinterland of Sittwe, and the regions of both sides of the lower Chindwin River are moderately dense. Arakan (except the Sittwe region), the west bank of the Irrawaddy at the base of the Arakan Mountains, Tenasserim, and the more inaccessible parts of the western and northern mountains and the Shan Plateau are sparsely inhabited.

The economy. Myanmar's economy is one of the least developed of the region and is basically agricultural; more than two-thirds of the people derive their livelihoods directly from agricultural pursuits. Of the nonagricultural workers who are employed in the other sectors of the economy, many are indirectly involved in agriculture through such activities as transporting, processing, marketing, and exporting agricultural goods.

Government policies

Nearly half of Myanmar's economic output—notably all large industrial enterprises, the banking system, insurance, foreign trade, domestic wholesale trade, and nearly all the retail trade—was nationalized in 1962–63. Small-scale industry (consisting mainly of food and beverage processing, miscellaneous manufacturing, and cottage industries), agriculture, and fishing were left in the private sector. In 1975–76, however, the government placed nationalized

corporations on a commercial basis and instituted a bonus system for workers. The overall economic objectives of self-sufficiency and the exclusion of foreign investment also were revised. Foreign investment was permitted to resume in 1973 and was further liberalized in the late 1980s.

Enterprises remaining in the private sector after nationalization account for only a small fraction of the nation's tax income. The balance is collected from the public sector. The principal sources of revenue are taxes (income, commercial, and customs) and receipts from state enterprises.

Myanmar also has an informal economy. Considerable quantities of consumer goods are smuggled into the country, and teak and gems are exported both legally and illegally. In addition, northern Myanmar is one of the largest producers of opium in the region.

Agriculture. Myanmar may be divided into three agricultural regions: the delta, where rice cultivation predominates; the dry zone, an area largely of rice production but also where a wide variety of other crops are raised; and the hill and plateau regions, where forestry and shifting agriculture are the most important.

Although the dry zone was Myanmar's most important agricultural region in the past, the rice production of the Irrawaddy delta now provides much of the country's export earnings and the staple diet of the country's people. About half of all agricultural land in Myanmar is devoted to rice, and, despite a climate that permits much more extensive double-cropping, only a small proportion of the land is actually so managed. The delta's traditional agriculture consisted primarily of rice in normal years, with the substitution of millet in drier years when there was insufficient moisture for rice; both grains yielded good returns on the alluvial soils. After Burma was officially annexed to British India in 1886, however, colonial policy called for a more commercially oriented and extensive cultivation of rice. Since the indigenous labour force was thought to be insufficient to support the colonial export economy, the immigration of Indian and Chinese labourers was officially encouraged during the early decades of the 20th century. By 1942, first-generation immigrants made up about 13 percent of the total population. Despite relatively low growth in rice production after World War II, rice remained both the basic food and the basic export of Myanmar.

Crops raised in the dry zone, in addition to rice, include wheat, millet, corn (maize), peanuts (groundnuts), sesame, legumes, tea, and rubber. To cultivate much of this land successfully, however, irrigation is required. The earliest known irrigation works were constructed in the 1st century and greatly improved in the 11th century; though their maintenance has lapsed somewhat since the fall of the monarchy, many are still in active service. As in the delta, the arrival of the British in the dry zone led to increased commercial and public-works activities. British authorities repaired and extended parts of these ancient systems during the early 20th century. Most of Myanmar's irrigated land is in the dry zone, and almost all of it is planted in rice. The portions of the dry zone that are not irrigated are utilized for the production of crops that are less sensitive to the seasonality or irregularity of rainfall than rice. In addition to the crops mentioned above, cotton and sugarcane are cultivated, although neither is of considerable significance. Cattle also are raised there.

Irrigation

The third agricultural zone, the hill and plateau country, occupies perhaps two-thirds of the area of Myanmar. Although this land has less economic significance than the other two zones, it is the home of many of the country's non-Burman ethnic groups. They generally continue to practice shifting cultivation (called *taungya* in Burmese), although more sedentary modes also exist and others are imposed with the advance of agricultural technology and central planning. Outside the forest areas of these highlands, the principal crops raised are rice, yams, and millet, and large numbers of pigs and poultry are kept. Bullocks and buffalo are used as beasts of burden, and goats, pigs, and poultry are raised for food in all parts of the country.

Fisheries and forestry. The second most important element in the diet after rice is fish—fresh or in the form of *ngapi,* a sort of paste that is prepared in a variety of ways and eaten as a condiment. Marine fisheries are not well-developed, although the reported commercial catch is more than three times as great as the reported catch from inland waters. Much private, noncommercial fishing is provided, however, in virtually every type of permanent, seasonal, or artificial body of inland water of any size. Two nonindigenous fish, the European carp and the tilapia (originally brought from Thailand), have been introduced and have bred well in impounded waters.

Forestry has been particularly important as a source of foreign exchange. Myanmar is estimated to have the bulk of the world's exploitable teak supplies. Teak is found in the tropical-deciduous forests of the hills. The forests are owned and regulated by the state, but concern has been raised about illegal logging.

Mining and power. The modern development of Myanmar's rich mineral deposits began in the mid-1970s. Deposits of silver, lead, and zinc are worked in the northern Shan Plateau, tin and tungsten in Tenasserim, and barite from the Maymyo area. Copper mining at Monywa began in the early 1980s. Rubies and sapphires have been mined in the northern Shan Plateau since precolonial times. Jade is mined in the northern mountains. Oil and natural gas are produced for domestic consumption. Coal is found in the upper Chindwin valley.

The demand for electricity chronically has outstripped capacity. The government has built several hydroelectric power plants, including those on the Balu River (a tributary of the Salween), at Taikkyi near Pegu (Bago), in northern Arakan state, and near Mandalay. Hydroelectricity now accounts for nearly half of Myanmar's total generating capacity.

Hydroelectricity

Industry. There was little industrialization until after independence, when a limited program began. Yangôn, Myingyan (in the dry zone), and Arakan state were selected to become the new industrial centres. There are textile factories at Yangôn and Myingyan and one near Paleik in the central region. Oil refineries are located at Chauk, Syriam, and Mann. Yangôn also has steel-processing and pharmaceutical plants, and there is a paper mill in Arakan. Existing food-processing plants (mainly rice mills) and lumber mills have been improved and expanded. Cottage industries are encouraged by subsidies.

Trade. The decision in the early 1960s to limit foreign trade reversed the export orientation of the British colonial period. Subsequent relaxation of trade restrictions, especially in the late 1980s, has again allowed trade to become a significant component of the national economy. Myanmar's economy remains dependent on the export of commodities, mainly rice, teak, and minerals and gems. It imports machinery and equipment, industrial raw materials, and consumer goods. Myanmar's chief trading partners are Japan, the European Community, other Southeast Asian nations (especially Singapore), India, and China.

Transportation. The Irrawaddy River is the backbone of Myanmar's transportation system. Trade in rice is dependent on water transport. The Irrawaddy is navigable year-round up to Bhamo and to Myitkyina during the dry season when there are no rapids. The Chindwin is navigable for some 500 miles from its confluence with the Irrawaddy below Mandalay. The many streams of the Irrawaddy delta are navigable, and there is a system of connecting canals. The Sittang, in spite of its silt, is usable by smaller boats; but the Salween, because of its rapids, is navigable for less than 100 miles from the sea. Small steamers and country boats also serve the coasts of Arakan and Tenasserim.

The first railway line, running from Rangoon (Yangôn) to Pye (Prome) and built in 1877, followed the Irrawaddy valley. The line was not extended to Mandalay; instead, after 1886 a new railway from Rangoon up the Sittang valley was constructed, meeting the Irrawaddy at Mandalay. From Mandalay it crosses the river and, avoiding the Irrawaddy valley, goes up the Mu River valley to connect with the Irrawaddy again at Myitkyina. A short branch line connects Naba to Katha on the Irrawaddy below Bhamo.

The Yangôn-Mandalay-Myitkyina railway is the main artery, and from it there are branch lines connecting the

Railways

northern and central Shan Plateau with the Irrawaddy. Other branches run from Pyinmana across the Pegu Mountains to Kyaukpadaung and from Pegu to Moulmein to Ye. The Pye-Yangôn railway has a branch line crossing the apex of the delta to Henzada and Bassein (Pathein).

The road system, until independence, was confined to the Irrawaddy and Sittang valleys, duplicating the railway route. A road goes from Pye along the Irrawaddy to the oil fields. Government policy is to improve and extend existing highways and to construct new ones. There were originally three international roads in use during World War II—the Burma Road from Lashio to K'unming in China; the Stillwell, or Ledo, Road between Myitkyina and Ledo in India; and the road between Kêng Tung in the southeastern Shan Plateau and northern Thailand. These roads subsequently became neglected but more recently were rebuilt and extended.

The state-run airline runs frequent domestic flights between Yangôn and other cities, and Yangôn has an international airport. Yangôn, as the terminus of road, rail, and river transport systems, is the country's major port, with up-to-date equipment and facilities. Bassein, Moulmein, and Sittwe are also important ports.

Administration and social conditions. *Government.* Myanmar's constitution came into force on Jan. 4, 1974, the 26th anniversary of the country's independence. According to the constitution, supreme power rested with a unicameral People's Assembly (Pyithu Hluttaw), which exercised legislative, executive, and judicial authority. By the late 1980s the assembly consisted of 489 members, who were elected to four-year terms.

The organs of the People's Assembly were the Council of State, the Council of Ministers (Cabinet), the Council of People's Justices, the Council of People's Attorneys, and the Council of People's Inspectors. The Council of State consisted of 29 members: one representative elected from each of the country's 14 states and divisions, an equal number elected by the People's Assembly as a whole, and the prime minister as an ex officio member. The Council of State elected its own chairman, who was ex officio president of the country, and its own secretary. The president and the secretary were also, respectively, the chairman and the secretary general of the Burma Socialist Programme Party (BSPP). The Council of State appointed senior civil servants and deputy ministers and submitted lists of names for election by the assembly of the prime minister and the councils of ministers, justices, attorneys, and inspectors. The Council of People's Justices was the equivalent of a supreme court in a parliamentary democracy; the Council of People's Attorneys was comparable to an attorney general and the Council of People's Inspectors to an auditor general.

From 1962 to 1988 the official political party was the BSPP. Membership at first was restricted to cadres, but, after the party held its first national assembly in 1971, its membership was widened so that it became a national party. Civil servants and members of the armed forces, as well as workers and peasants, were members, and senior military officials and civil servants were included in the party's hierarchy.

In September 1988 the armed forces took control of the government, creating a new ruling body, the State Law and Order Restoration Council (SLORC). All state organs, including the People's Assembly, the Council of State, and the Council of Ministers, were abolished, and their duties were assumed by the SLORC. A Supreme Court was established as the supreme judicial authority, its members appointed by the SLORC.

The SLORC

The law maintaining the BSPP as the sole political party was abrogated, and new parties were encouraged to register for general elections to a new Constituent Assembly, which would revise the 1974 constitution. More than 90 parties participated in the elections, which were held in May 1990; of these the most important were the ruling BSPP, which had changed its name to the National Unity Party (NUP), and the main opposition party, the National League for Democracy (NLD). The NLD won an overwhelming majority of seats to the new assembly, but the SLORC did not permit the assembly to convene until January 1993.

Myanmar is divided administratively into seven states based largely on ethnicity—Arakan (Rakhine), Chin, Kachin, Karen (Kayin), Kayah, Mon, and Shan—and seven more truly administrative divisions of Myanmar proper—Irrawaddy (Ayeyarwady), Magwe (Magway), Mandalay, Pegu (Bago), Yangôn, Sagaing, and Tenasserim (Taninthary). Until 1988 there were several levels of local People's Councils—division or state, township, and ward or village—that followed the pattern of the People's Assembly; local and national elections were held simultaneously. Every council had an Executive Committee and a Judges' Committee, and all but the village or ward councils also had a Committee of Inspectors. The Judges' Committee sat as the local court, exercising criminal and civil jurisdiction. In 1988 the SLORC dissolved these bodies and assumed control of local administration.

Armed forces. Myanmar's armed forces consist of an army, a navy, and an air force. The army is by far the largest and best-equipped of the three branches, and for a number of years it has borne the chief responsibility for combating armed insurgency within the country. Members of the armed forces are recruited from throughout the country, and military service is a prime means of improving socioeconomic status. The police force, although armed and equipped and often used as a branch of the army in emergencies, remains essentially civilian in character and regional in organization.

Health and welfare. The BSPP government gave special attention to workers and peasants and to the hill peoples. In spite of a shortage of imported building materials, the

Frank Folwell/Tony Stone Images

Ruins of ancient Buddhist temples, Pagan, Myanmar.

housing problem was stabilized somewhat. A high mortality rate has been lowered substantially, although infant mortality rates have remained higher than in all other Southeast Asian states except Cambodia and Laos. Every village has a health unit and access to a hospital, but the lack of adequate sanitation and a shortage of medicines have contributed to relatively high rates of gastrointestinal diseases, tuberculosis, and malaria.

Literacy

Education. Myanmar has a long tradition of educational achievement. The literacy rate always has been high and has continued to improve. Education is compulsory between ages five and nine (primary school) and is free at primary, lower secondary (middle), and vocational schools; upper secondary (high) schools and universities charge nominal fees. The University of Yangôn (Rangoon) and the University of Mandalay (until 1958 a branch of the University of Yangôn) are the oldest and best-known institutions of higher education.

Cultural life. Myanmar's traditional culture is an amalgam of folk and royal culture. Buddhism has been a part of Myanmar's culture since the 1st century AD and has blended with non-Buddhist beliefs. The most conspicuous manifestation of Buddhist culture is the magnificent architecture and sculpture of Myanmar's many temples and monasteries, notably those at Pagan, Mandalay, and Yangôn.

In 1886 the traditional drama appeared to be dying with the elimination of the monarchy, but it had permeated the masses and survived as part of the folk tradition. With the growth of nationalism and regaining of independence, it gathered new strength. The most popular dramatic form is the pwe, which is performed outdoors. There are a variety of pwe genres, but most often the subject matter is taken from the Jātakas, the stories of the former lives of the Buddha. Traditional musical forms, influenced by those from neighbouring lands, are highly percussive. Dance forms are derived largely from southern India.

Wood carving, lacquerwork, goldwork, silverwork, and the sculpting of Buddhist images and mythological figures also survived during colonial rule; there has been a revival of these indigenous art traditions under government patronage. Both the arts of bronze casting among the Burmans and of making bronze drums among the Karen, however, disappeared. The traditional marionette show also declined, although occasionally there have been attempts to revive it. The cinema and rock music are two Western art forms that have been accepted in the cultural life of Myanmar.

Burmese literature is an intimate blend of religious and secular genres. It remained alive throughout the colonial period and, both in verse and prose, has continued to thrive. A later (though not entirely new) development was biography, which has become more popular than fiction. Government-sponsored awards are given annually for the best translation, the best novel, and the best biography.

There are state schools of dance, music, drama, and fine arts at Yangôn and Mandalay. The National Museum is at Yangôn, and there are regional museums at Pagan, Mandalay, and other regional centres.

(M.H.Au./M.A.A.-T.)

For statistical data on the land and people of Myanmar, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

In prehistoric times Myanmar was inhabited along its coasts and its river valleys. During most of the 1st millennium AD the overland trade route between China and India passed through Myanmar's borders, and merchant ships from India, Sri Lanka, and even farther west converged on its ports, some of which also were the termini of the portage routes from the Gulf of Thailand across the narrow Isthmus of Kra on the Malay Peninsula. Thus, Myanmar often was the western gateway of mainland Southeast Asia.

Indian influences

The Indian merchants brought with them not only precious cargoes but their religious, political, and legal ideas; and within a few decades Indian cultural traditions had remolded indigenous society, thought, and arts and crafts. Yet important components of Myanmar's own native culture were retained, creating a lasting synthesis with Indian culture. Surrounded on three sides by mountains and on the fourth by the sea, Myanmar always has been somewhat isolated; as a consequence, its culture has remained distinct in spite of the many Indian influences and in spite of its close affinity with the cultures of the other countries of Southeast Asia.

Myanmar was one of the first areas in Southeast Asia to receive Buddhism, and by the 11th century it had become the centre of the Theravāda branch of Buddhism. The faith was patronized by the country's leadership, and it became the ideological foundation of the Myanmar state that blossomed at Pagan on the dry central plains.

The origins of civilization in Myanmar. The Irrawaddy River, flowing southward through the entire north-south length of modern-day Myanmar, divides the country in two, and its valley forms the central plain. In addition, the region has long been divided culturally into northern Myanmar (or Upper Burma), the areas north of the Irrawaddy delta, and southern Myanmar (or Lower Burma), the delta and peninsular areas.

The first human settlements in Myanmar appeared some 11,000 years ago in this valley. The stone and fossilized-wood tools used by these people have been named Anyathian, from Anyatha (another term for Upper Burma); little else, however, is known of these people. A discovery in 1969 by workers from the government's Department of Archaeology of some cave paintings and stone tools in the eastern part of present-day Shan state shows that that area, too, had Paleolithic and Proto-Neolithic settlements, the culture of which was similar to the Hoabinhian culture that was widespread in the rest of Southeast Asia. Crude shards and ring stones found at the site appear to have been attached to stonecutting tools to make them more suitable for digging. The woodcutting tools in the find probably were used to clear patches of forest for cultivation, which would indicate that the shift from gathering to agriculture had already begun.

The Pyu state. Between the 1st century BC and the 9th century AD, speakers of Tibeto-Burman languages known as the Pyu were establishing city-kingdoms in Myanmar at Binnaka, Mongamo, Śrī Kṣetra, and Halingyi. There long had been a trade route between China and India that passed through northern Myanmar and then across the Chindwin River valley. In AD 97 and 121 Roman embassies to China chose the overland route through Myanmar for their journey. The Pyu, however, provided an alternative route down the Irrawaddy to Śrī Kṣetra and then by sea westward to India and eastward to insular Southeast Asia, from where the China trade connected with the portage routes and the islands. Chinese historical records noted that the Pyu claimed sovereignty over 18 kingdoms, many of them in the southern portions of Myanmar.

Pyu life

The same Chinese records emphasized the humane nature of Pyu government and the elegance and grace of Pyu life. Fetters, chains, and prisons were unknown, and punishment for criminals was a few strokes with the whip. The men, gaily dressed in blue, wore gold ornaments on their hats, and the women wore jewels in their hair. The Pyu lived in houses built of timber and roofed with tiles of lead and tin; they used golden knives and utensils and were surrounded by art objects of gold, green glass, jade, and crystal. Parts of the city walls, the palace, and the monasteries were built of glazed brick. The Pyu also appeared to have been Buddhists of the Sarvāstivāda school. Their architects may have developed the vaulted temple, which later found its greatest expression at Pagan during its golden age. Pyu sons and daughters were disciplined and educated in monasteries or convents as novices. In the 7th century the Pyu shifted their capital northward to the dry zone, leaving Śrī Ksetra as a "secondary" centre to oversee trade.

The Mon. To the south of the Pyu lived the Mon, who were speakers of an Austro-Asiatic language. The Mon were closely related to the Khmer, who lived to the east of the Mon in what is now Cambodia. The capital of the Mon probably was the port of Thaton, which was

located northwest of the mouth of the Salween River and not far from the portage routes of the Malay Peninsula; through this window to the sea the Mon saw India, in its full glory, under the Gupta empire. Earlier, in the 3rd century BC, the great Mauryan emperor Aśoka apparently had sent a mission of Buddhist monks to a place called Suvarnabhūmi (the Golden Land), which is now thought to have been in the Mon region of the Isthmus of Kra. The ancient monastic settlement of Kelasa, situated near Thaton in southern Myanmar and claimed by Burmese and Mon chronicles to have been founded by Aśoka's missionaries, was mentioned in early Sinhalese records as being represented at a great religious ceremony held in Sri Lanka in the 2nd century BC.

With the expansion of Indian commerce in Southeast Asia between the 1st and 4th centuries AD, Thaton's prosperity and importance increased. Indian merchants and seamen came to Thaton as traders rather than as conquerors or colonists. The number of Indians was never great, and their settlements were of a commercial, not military, nature. As a result, Indian culture was readily accepted by the Mon.

Mon culture

The Mon culture was not abandoned or displaced, and the Mon blended the old with the new. They integrated many of their own beliefs into those of Theravāda Buddhism, which arrived in Southeast Asia already replete with folk beliefs. The power and prestige of the Mon kingship were enhanced by the notions of kingship found in India. The Mon developed a new art of sculpture by blending native traditions with Gupta conventions of iconography. They built stupas (Buddhist ceremonial mounds) according to Indian models, which were adapted, however, to indigenous aesthetic tastes. The Mon subsequently became one of the most culturally advanced peoples in Southeast Asia. They assumed the role of teachers to their neighbours, spreading Theravāda Buddhism and their new culture over the entire region.

The Mon centre eventually shifted to Pegu, located on the Pegu River, about 50 miles northeast of present-day Yangôn (Rangoon). From there the Mon were able to control the trade of southern Myanmar.

The Pagan kingdom (849–1287). *The advent of the Pagan Burmans.* Another group of Tibeto-Burman speakers, the Burmans, also had become established in the northern dry zone. They were centred on the small settlement of Pagan on the Irrawaddy River. By the mid-9th century, Pagan had emerged as the capital of a powerful kingdom that would unify Myanmar and would inaugurate the Burman domination of the country that has continued to the present day.

During the 8th and 9th centuries the kingdom of Nanchao became the dominant power in southwestern China; it was populated by speakers of Lolo (or Yi), a Tibeto-Burman language. Nanchao mounted a series of raids on the cities of mainland Southeast Asia in the early decades of the 9th century and even captured Hanoi in 861. The Mon and Khmer cities held firm, but the Pyu capital of Halingyi fell. The Burmans moved into this political vacuum, establishing Pagan as their capital city in 849.

By that time the Mon apparently had become supreme in southern Myanmar. They may have occupied the whole of the region and controlled the port of Bassein (now Pathein) in the west and the city of Pegu in the centre. They could have stepped into the vacuum caused by the destruction of the Pyu kingdom, but their power was linked to the trade of southern Myanmar and not with the agrarian-based economy of northern Myanmar.

The unification of Myanmar. Nanchao acted as a buffer against Chinese power to the north and allowed the infant Burman kingdom to grow. The Burmans learned much from the Pyu, but they were still cut off from the trade revenues of southern Myanmar. Theravāda Buddhism had disappeared from India, and in its place were Mahāyāna Buddhism and a resurgent Hinduism.

Reign of Anawrahta

In 1044 Anawrahta came to the throne at Pagan and began the unification process in Myanmar that would recur in cyclic fashion until the British conquered the country in 1886. Anawrahta first strengthened his defenses on the north—the "front door" of Myanmar—and created alliances through marriage with the neighbouring Shan to the east. He then harnessed the economic resources of northern Myanmar by repairing old irrigation works and building new ones. Finally, he declared himself the champion of Theravāda Buddhism and used that ideology to justify his conquest of southern Myanmar, which was accomplished with the defeat of the Mon city of Thaton in 1057.

Thus, by the mid-11th century the core of modern-day Myanmar had been united into a single kingdom centred at Pagan, and Myanmar's longest-surviving dynasty had been established. Anawrahta's work was continued by his great commander Kyanzittha (ruled 1084–*c.* 1112) and by another great ruler, Alaungsithu (ruled *c.* 1112–*c.* 1167). Pagan's consolidation of the Irrawaddy valley southward to the ports of southern Myanmar divided most of mainland Southeast Asia into two great empires, Khmer and Burman. Anawrahta's dynasty of kings lasted until the 13th century. By that time, their great temples had been built, and their message of Theravāda Buddhism had been carried not only to the Shan but also to the Khmer.

Centuries of temple building and of donations of land and manpower to the tax-exempt sangha (monkhood), however, had diverted much of the state's most valuable resources. Yet, the legitimacy of state and society depended on continued patronage of the sangha. As a result, Pagan had been weakened by the end of the 13th century, precisely when the Mongols threatened. Pagan had lost its northern buffer in the early 1250s when Nanchao was destroyed and subjugated by the Mongols under Kublai Khan. The Mongols demanded submission by and tribute from Pagan, which refused to comply. It is not clear if the Mongol armies actually reached Pagan, but by 1300 Pagan no longer was the centre of power in Myanmar.

Pagan state and society. Pagan was a fabulous kingdom even to its contemporaries; although he did not visit it, the Venetian traveler Marco Polo was impressed by the tales of its splendour that were recounted to him. By the time of its conquest, Pagan had an estimated 3,000 to 4,000 temples and monasteries. Hundreds of these still stand today and testify to the prosperity of its people and the richness of its culture. The conquest of the Mon kingdom of Thaton was the foundation of both Pagan's economy and its culture, for it delivered into Burman hands all the ports of the country and the core of artisans who built Pagan's magnificent temples. These artisans were paid in wages of gold and silver, as well as in kind (food and horses and elephants). Their clothing, shelter, health, comfort, and safety were the responsibility of their employers (as evidenced by contemporary inscriptions that provide the details connected with these topics).

Cultural achievements

The Mon craftsmen, artisans, artists, architects, goldsmiths, and wood-carvers who were captured at Thaton and taken to Pagan taught their skills and arts to the Burmans. Mon monks and scholars taught the Burmans the Pāli language and the Buddhist scriptures, and the Burmans soon became scholars themselves, making Pagan the centre of Theravāda learning. Some of their religious commentaries came to be accepted as part of the Pāli canon by other Theravāda countries. The women of Pagan took part in all these activities, particularly in the building and endowment of temples and monasteries.

The people of Pagan largely were devout and orthodox, and they made Buddhism their way of life while still retaining animistic and other unorthodox beliefs. They established the principles underlying religion, government, and society that later generations accepted almost without change. Thus, it is to Pagan that the designation the "classical age" of Myanmar is given.

Myanmar from the end of Pagan to 1885. *The first Ava dynasty.* After the decline of Pagan as a political centre, three small centres of power emerged by the first decade of the 14th century from polities that once had been under Pagan suzerainty. The political situation remained fragmented until 1364, when Ava became the seat of authority. It was located in the northern Irrawaddy valley at the entrance to the rice-producing region of Kyaukse, near present-day Mandalay. The kings of Ava resurrected the traditions of Pagan, encouraging scholarship and learning

and making the period a great age of Burmese literature. Without a northern buffer, however, they could not control the coasts for any length of time and were thus deprived of shipping revenues.

After the decline of Pagan's political authority, the Mon reestablished themselves at Pegu, and by the 15th century they were experiencing their own golden age under rulers like Dhammazedi (reigned 1472–92). Pegu became a major centre of Theravāda scholarship and of commerce in Southeast Asia, attributes that protected it from conquest. In 1527 Ava was sacked by the Shan, who had been moving southward down the Irrawaddy and Chao Phraya valleys since Nanchao had been destroyed. The Ava refugee population fled south to Toungoo, a city on the Sittang River that had been a seat of Pagan and Ava authority.

The Toungoo dynasty. In 1531 a dynasty was established at Toungoo by Tabinshwehti, and by then the new kingdom had become powerful enough to conquer northern Myanmar from the Shan and southern Myanmar from the Mon. In 1511 the great trading entrepôt of Malacca (Melaka) on the Malay Peninsula had been conquered by the Portuguese, which led to a renewal of interest in trade in Myanmar's coastal waters. Tabinshwehti transferred his capital to Pegu in order to tap this commercial potential, and he attempted to unite Burmans, Mon, and Shan into a single nation. He died in 1550, however, and was succeeded by his brother-in-law, Bayinnaung.

Meanwhile, the Shan in the Chao Phraya valley had consolidated their power under the Tai kingdom of Ayutthaya (Ayudhia, or Siam), and they also recognized the potential value of controlling this renewed commercial activity. In addition, the Ming Chinese were active in Southeast Asian waters during the 14th and 15th centuries, further contributing to the growth of economic activity there. Thus, Pegu and Ayutthaya became rivals.

The rule of Bayinnaung

Bayinnaung twice marched on Ayutthaya and conquered the entire Chao Phraya valley by 1569, using Portuguese mercenaries and Portuguese cannon to accomplish his goals. Bayinnaung's wars exhausted Myanmar's resources, however, and after his death the kingdom began to break up. Manipur, a Hindu princely state to the northwest of Myanmar that had been subjugated in 1560, declared itself independent, and Ayutthaya also regained its independence. Toungoo, joined by Arakan (Rakhine), proceeded to ravage Pegu. The Portuguese founded a small centre of power at Syriam, which was located on the Pegu River across from the site of present-day Yangôn. At this point, the rulers of Toungoo decided to return to the predictability, security, and comfort of the agrarian dry zone of northern Myanmar.

By the end of the 16th century, Ava had been resurrected and the second Ava dynasty established. Bayinnaung's grandson, Anaukpetlun, reunited Myanmar once more by 1613. His successor, Thalun, reestablished the principles of the classical Myanmar state created half a millennium earlier at Pagan. Heavy religious expenditures, however, weakened Ava politically, much as they had done in Pagan. In the meantime, southern Myanmar had been rejuvenated by the new commercial activity spurred by the British and Dutch. Pegu had grown stronger while Ava had been preoccupied with resurrecting the "heartland." Finally, Pegu rose in rebellion, encouraged by the French in India. Assailed internally as well as externally, Ava fell in 1752.

The Konbaung dynasty. It was soon apparent, however, that only the centre of power had been destroyed, not the system nor the wherewithal for power; before the year had ended, a popular Burman leader, Alaungpaya, drove Pegu's forces out of northern Myanmar and regained the Shan states. By 1759 he had regained Manipur and defeated Pegu. The Siamese became alarmed and attempted to rouse the Shan chiefs to rebel. Alaungpaya retook Tenasserim, the site of the old portage kingdoms, and invaded Siamese territory. Although Alaungpaya's invasion failed and he himself died during the retreat in 1760, the Myanmar now felt that, unless the Siamese were conquered, the coastal cities of southern Myanmar could not be retained. Alaungpaya's son, Hsinbyushin, sent his armies into Siam in 1766, and they captured Ayutthaya in 1767. China, alarmed over the growing power of Myanmar, invaded the country four times during the period 1766–69, without success.

Myanmar then conquered Arakan and occupied the princely state of Assam to the northwest of Manipur, thus coming face to face with British power in India. The result was the First Anglo-Burmese War (1824–26), in which the Siamese fought on the British side. Myanmar eventually had to sue for peace and lost Assam, Manipur, Arakan, and Tenasserim.

The Second Anglo-Burmese War (1852) was provoked by the British, who wanted access to the teak forests in and around Pegu and also wanted to secure the gap in their coastline stretching from Calcutta to Singapore; it resulted in the British annexation of Pegu province, which they renamed Lower Burma. As the British became increasingly interested in the legendary trade with China through its back door—as well as in the teak, oil, and rubies of northern Myanmar—they waited for a suitable pretext to attack. In 1885 Britain declared war on Myanmar for the third and final time. To meet the criticism of their action that arose in Parliament, the British government gave the excuses that the last independent king of Myanmar, Thibaw (ruled 1878–85), was a tyrant and that he was conspiring to give France greater influence over the country. Neither of these charges seems to have had much foundation.

The Third Anglo-Burmese War

The administration of traditional Myanmar. The king was the chief executive and the final court of appeal, but there were checks on his power. He could not make laws, only issue administrative edicts that might or might not be upheld after his death. Custom was a strong and recognized source for proper behaviour, along with codified bodies of civil and criminal law called, respectively, the Dammathat and Rajathat.

The king, as the patron of Buddhism and the head of state, was expected to be both a conqueror and one who renounced the world. Buddhist monks were formally organized into a church that was headed by a primate who, although appointed by the king, sometimes proved to be the king's sternest critic. Although monks technically were supposed to remain outside the sphere of politics, they gave sanctuary to political exiles. Monasteries also served as schools for all children, and monks educated the people and molded public opinion regarding the state and the king. Because the state and church owned virtually all the productive land in Myanmar, there were no landed, hereditary nobles who could weaken the power of the state. The king's officials were appointed, and their appointments could lapse with the king's death.

The Hluttaw, or Hlutdaw ("Place of Release"), was the centre of government. It had several integrated functions—including fiscal, executive, and judicial responsibilities—and it was the final court of appeal; in theory and often in practice the king presided over its deliberations. All proclamations and appointments that were made by the king became valid only when orders giving effect to them were issued by the Hluttaw.

Every province had a governor, to whom were delegated certain powers by the Hluttaw. There always was a right of appeal against all decisions of the governer to the Hluttaw. Local government was in the hands of hereditary "headmen," who were advised by village elders. The position of the headman was officially confirmed by the king.

The British in Burma (1885–1948). The Third Anglo-Burmese War lasted less than two weeks during November 1885. The Myanmar people never expected the speed with which the capital would be taken. The hopelessly outmatched royal troops surrendered quickly, although armed resistance continued for several years. The Myanmar also believed that the British aim was merely to replace King Thibaw with a prince who had been sheltered and groomed in India for the throne. This belief seemed to be confirmed when the British commander called upon the High Court of Justice to continue to function. The British finally decided, however, not only to annex all of northern Myanmar (which they called Upper Burma) as a colony but also to make the whole country a province of

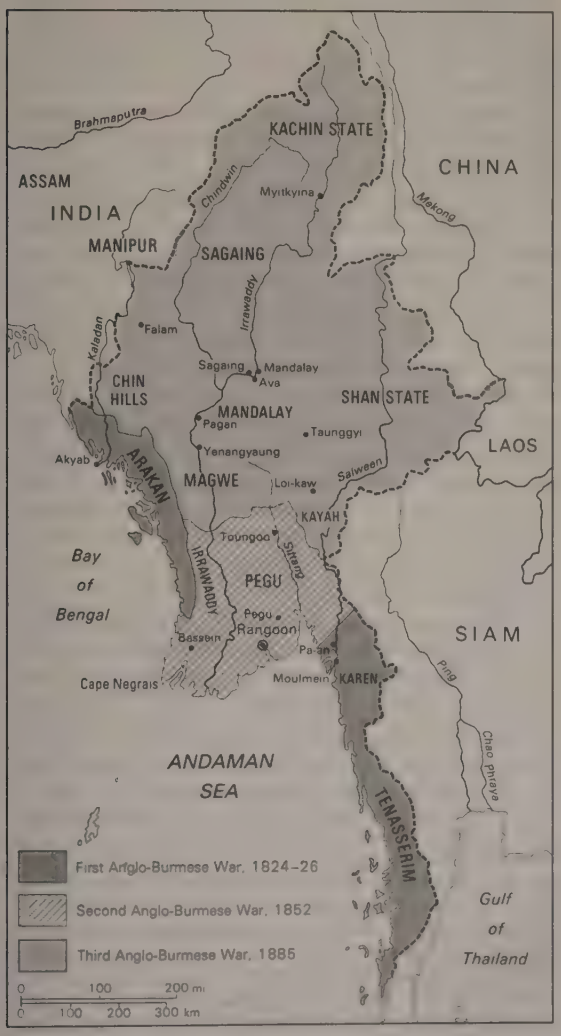
Burma as a province

India (effective Jan. 1, 1886). Rangoon became the capital of the province, after having been the capital of British Lower Burma.

The initial impact of colonialism. This chain of events was a bitter blow to Myanmar society. The loss of independence was painful enough; worse still were the British decisions to eliminate the monarchy—in the process sending Thibaw into exile—and to stay out of religious affairs, thus depriving the church of its traditional status and official patronage. The demise of these twin pillars of Myanmar society was perhaps the most devastating aspect of the colonial period.

Many refused to accept the British victory as final and resorted to guerrilla warfare against the British army of occupation. The guerrillas were led mainly by former officers of the disbanded royal army, former officials (including village headmen), and royal princes, and they considered themselves to be royal soldiers still fighting the Third Anglo-Burmese War. To the British, however, the war had ended legally with the annexation of the kingdom; those opposing them, therefore, were considered rebels and bandits. For the next five years the British military officers acted as both judge and jury in dealing with captured guerrillas. Villagers who aided the rebels also were sternly punished. British troops carried out mass executions and committed other atrocities.

As the guerrillas fought on, the British adopted a "strategic-hamlet" strategy: villages were burned, and families who had supplied villages with their headmen were uprooted from their homes and sent away to Lower Burma (which had been under British control since the Second Anglo-Burmese War). Strangers loyal to the British were appointed as headmen for the new villages established by the British. The guerrillas resorted to desperate measures against the new village officials. By 1890, with more than 30,000 British troops engaged in the campaign, the military part of the struggle was over.



British territorial acquisitions in Burma.

The religious dilemma. The colonial period was one of relative civil order, but it also was one of great social disintegration. Chief among the reasons for this was the British-imposed separation of church and state. The British did not wish to touch the issue of religion—given their experience in India that had led to the revolt of 1857–59—and thus were unwilling to patronize Burmese Buddhism as the monarchy had done.

Under the monarchy, church and state had shared a symbiotic relationship. Royal patronage of Burmese Buddhism had included both financial and moral support, and this had extended legitimacy and authority to the church. The king had had the right to appoint the primate, who exercised supervision and discipline among the ranks of the clergy. In addition, the king had been given the right to attach two royal officials to the primate: a commissioner of ecclesiastical lands and an ecclesiastical censor. The duty of the commissioner had been to see that ecclesiastical lands were exempted from payment of taxes, at the same time ensuring that bogus and illegal endowments did not escape taxation. The duty of the censor had been to maintain a register of monks, which had given the king indirect control over the clergy. The power to defrock a wayward monk had rested largely with the primate, but the same result could be achieved if the king declared the monk to be "impure," which was one of the king's prerogatives. This arrangement was designed to prevent the abuse of the exemptions granted to the clergy.

The British refusal to heed a plea by the clergy and church elders to continue the traditional church-state relationship resulted in the decline of the sangha and its ability to instill discipline in the clergy. This, in turn, lowered the prestige of the clergy and contributed to the rise of secular education and of a new class of teachers, depriving the sangha of one of its primary roles. Added to this, the colonial government of India founded secular schools teaching in both English and Burmese and encouraged foreign Christian missions to found schools by offering them financial assistance. Many mission schools were founded; parents were compelled to send their children to these schools, as there were no realistic alternatives. The teachers were missionaries, and the lessons they gave were marked by repeated criticism of Buddhism and its culture. In the government schools the first teachers, British and Indian, were mere civil servants, unable and unwilling to continue the older traditions.

Education under the British

The colonial economy. The traditional Myanmar economy had been one of redistribution—an early form of the modern command economy—a concept that was embedded in society, religion, and politics. Prices of the most important commodities were set by the state, and in general the mechanism of supply and demand was relatively unimportant. Agrarian self-sufficiency was vital, while trade was only of secondary importance. The British impact on this system proved disastrous, as Burma's economy became part of a vast colonial export economy tied to global market forces. The cause of this was not so much the usual economic exploitation of a country by a foreign ruler as it was the effects of an economy designed to benefit the colonial power.

The British dream of a golden road to China through Burma could not be realized, but the opening of the Suez Canal in 1869 created a much higher international demand for Burma's rice than had previously existed. The Irrawaddy delta was swiftly cleared of its mangrove forests and in a matter of decades became covered with rice fields. Even in 1857 the price of rice had increased 25 percent; by 1890 the price had more than doubled from 1857 rates, and it continued to increase until the worldwide economic depression of the 1930s. The area of productive rice fields in Lower Burma rose from approximately 60,000 acres (24,000 hectares) in the 1850s to nearly 10,000,000 acres in 1939. This tremendous increase in production created a significant shift in population from the northern heartland to the delta, shifting as well the basis of wealth and power.

In order to prepare the land for cultivation, however, the farmers had to borrow capital from Indian moneylenders from Madras at exorbitant interest rates. The British banks would not grant mortgage loans on rice land, and the British government had no policy for establishing land-mortgage banks or for making agricultural loans. Prevailing prices were high in the international market, but the local price was kept down by a handful of British firms that controlled wholesale trade and by Indian and Chinese merchants who controlled retail trade. With land values and rice prices soaring, the Indian moneylenders foreclosed mortgages at the earliest opportunity.

Plight of the farmers

The dispossessed farmers could not find employment even on their lost lands because, with a higher standard of living, they could not compete with the thousands of Indian labourers who came to Burma. Burmese villagers, unemployed and lost in a disintegrating society, took to petty theft and robbery and soon acquired the reputation of being lazy and undisciplined. The level of dysfunction in Burmese society was revealed by the dramatic rise in homicides: during the early decades of the 20th century, Burma's annual homicide rate was second only to that of the United States.

Thus, although the Burmese economy and transportation infrastructure developed rapidly from 1890 to 1900, the majority of Burmese people did not benefit from it. A railway had been built through the entire valley of the Irrawaddy, and hundreds of steamboats plied the length of the river; but the railway and the boats belonged to British companies. Roads had been built by the government, but they were meant for the swift transport of troops. A British company worked the ruby mines until they became nearly exhausted. The extraction of oil and timber was monopolized by two British firms. The balance of trade was always in favour of Burma, but that meant little to Burmese people or society.

The emergence of nationalism. Those Burmese who attended the new schools managed to gain admission to the clerical grades of government service, but even in those lower grades they encountered competition from Indians. Because science courses were not available, the professions of engineering and medicine were closed to the Burmese. Those who advanced to the government liberal arts college at Rangoon entered the middle grades of the civil service, while a few went on to London to study law. When these young barristers returned to Burma, they were looked upon by the people as their new leaders. Their sojourn in the liberal atmosphere of London had convinced these new leaders that some measure of political independence could be regained by negotiation.

The new leaders first gave their attention to the national religion, culture, and education. In 1906 they founded the Young Men's Buddhist Association (YMBA) and through it began establishing a number of schools supported by private donations and government grants-in-aid (the YMBA was not antigovernment). Three years later the British, attempting to pacify the Indian National Congress, introduced some constitutional reforms in India. Only a few minor changes were made in the Burmese constitution, but these confirmed the young leaders' faith in British liberalism. In 1920, however, when it was found that Burma would be excluded from new reforms introduced in India, the barristers led the people in a nationwide protest, which involved a boycott of British goods.

Also in 1920 Rangoon College was raised to the status of a full university; yet, because its control was vested in a body of government nominees, its students went on strike. Younger schoolboys and schoolgirls followed suit. The strikers camped in the courtyards of monasteries, reviving memories of days when education was the concern of the monks. The general public and the Buddhist clergy gave full support to the strike. The University Act was amended and the strike settled, but many strikers refused to go back to mission and government schools. The YMBA schools, now calling themselves "national" schools, opened their doors to the strikers.

Constitutional reforms were finally granted in 1923, but the delay had split the leaders, some of whom, like the masses, were beginning to doubt whether political freedom could be attained by peaceful protest. In the University of Rangoon itself, students began to resent their British professors. A radical student group began organizing protests, which came to be known as the Thakin movement. The name for this movement was purposely ironic: the Burmese word *thakin* ("master") was the term that the Burmese were required to use when addressing the British. (M.H.Au./M.A.A.-T.)

The Thakin movement

In late 1930 Burmese peasants, under the leadership of Saya San, rose in rebellion. Armed only with swords and sticks, they resisted British and Indian troops for two years. The young Thakins, though not involved in the rebellion, won the trust of the villagers and emerged as leaders in place of the British-educated Burmese elite. In 1936 university students again went on strike, and two of their leaders, Thakin Nu (later called U Nu) and Aung San, joined the Thakin movement. In 1937 the British government separated Burma from India and granted it a constitution, but the masses interpreted this as proof that the British planned to exclude Burma from the next phase of Indian reform.

World War II and after. When World War II broke out in Europe in 1939, the Burmese leaders wanted to bargain with the government before giving their support to the British. A warrant was issued for the arrest of Aung San, but he escaped to China, where he attempted to contact radical groups for support. Japanese assistance was offered instead. Aung San returned to Burma in secret, recruited 29 young men, and took them to Japan, where the "Thirty Comrades" received military training. The Japanese promised independence for Burma; hence, when Japanese troops reached Bangkok (Thailand) in December 1941, Aung San announced the formation of the Burma Independence Army (BIA). The Japanese advanced into Burma and by the end of 1942 had occupied the country. They subsequently disbanded the BIA and formed a smaller Burma Defense Army, with Aung San still as commander.

Ba Maw, the first prime minister under the 1937 constitution and later the leader of the opposition, was appointed head of state by the Japanese, with a cabinet including Aung San and Thakin Nu. In 1943, when the tide of battle started to turn against them, the Japanese declared Burma a fully sovereign state. The Burmese government, however, was still a mere facade, with the Japanese army ruling. Meanwhile, Aung San had contacted Lord Mountbatten, the Allied commander in Southeast Asia, as early as October 1943 to offer his cooperation, and in March 1945 Aung San and his army—renamed the Burma National Army (BNA)—joined the British side.

During the war Aung San and the Thakins formed a coalition of political parties called the Anti-Fascist Organization—after the war renamed the Anti-Fascist People's Freedom League (AFPFL)—which had wide popular support. After the defeat of the Japanese in Burma in May 1945, the British military administration and members of the prewar government who had returned from exile demanded that Aung San be tried as a traitor. Mountbatten, however, recognized the extent of Aung San's hold on the BNA and on the general populace, and he hastily sent the more conciliatory Sir Hubert Rance to head the administration. Rance regained for the British the trust of Aung San and the general public. When the war ended, the military administration was withdrawn, and Rance was replaced by the former civilian governor, who formed a cabinet consisting of older and more conservative politicians. The new administration arrested Aung San and charged him with treason. Surprised and angered, the Burmese people prepared for rebellion, but the British government in London wisely replaced the governor with Rance. Rance formed a new cabinet, including Aung San, and discussions for a peaceful transfer of power began. These were concluded in London in January 1947, when the British agreed to Burma's independence; by June the decision also had been made to leave the Commonwealth.

The AFPFL

The communist and conservative wings of the AFPFL were dissatisfied with the agreement. The communists broke away and went underground, and the conservatives went into opposition. In July Aung San and most mem-

bers of his cabinet were assassinated by gunmen sent by U Saw, a former prime minister and now a conservative. Rance asked Thakin Nu to form a new cabinet. A new constitution was written, and on Jan. 4, 1948, Burma became a sovereign, independent republic.

The country since independence. *Parliamentary government.* With its economy shattered and its towns and villages destroyed during the war, Burma needed peace. A foreign policy of neutrality was decided upon, but, because of internal strife, no peace resulted. The communists were the first insurgents, followed by some of Aung San's veterans and then the Karen, the only ethnic minority on the plains; but the other minorities—Chin, Kachin, and Shan—who had been ruled separately by the British but who had enthusiastically joined the union, stood firm.

A division of Chinese Nationalist troops occupied parts of the Shan Plateau after their defeat by the Chinese Communists in 1949; and, because of the general support given to Nationalist China (Taiwan) by the United States, Myanmar stopped accepting U.S. aid and rejected all foreign aid. At the United Nations Myanmar endeavoured to show impartiality. It was one of the first countries to recognize Israel and also the People's Republic of China.

By 1958 Burma was well on the road to internal peace and economic recovery, but the ruling AFPFL had become divided by personal quarrels between U Nu and his closest associates. Amid rumours of a military takeover, U Nu invited the army chief of staff, Ne Win—who had been a Thakin, one of the Thirty Comrades, and Aung San's second in command—to take the premiership. Ne Win established internal security, stabilized the military situation, and prepared the country for general elections, which took place in February 1960. U Nu was returned to office with an absolute majority.

The socialist takeover. In March 1962 Ne Win led a coup d'état and arrested U Nu, the chief justice, and several cabinet ministers. His justification for this was that it was a means of keeping the union from disintegrating. He suspended the 1947 constitution and ruled the country with a Revolutionary Council consisting of senior military officers. Ne Win's stated purpose was to make Burma a truly socialist state. A one-party (Burma Socialist Programme Party [BSPP]) system was established, and measures were introduced to decentralize the administration. In April 1972 Ne Win and other members of the Revolutionary Council retired from the army, but they retained their positions of power in the BSPP. Land had been nationalized in U Nu's administration, and now much of the country's commerce and industry were nationalized as well. These measures did not improve the economy, however, particularly as investment in agriculture generally was sacrificed in favour of industrial growth.

The constitution of 1974

U Ne Win (as he was called after leaving the army) had promised a new constitution, and in September 1971 representatives of the party's central committee, of the country's various ethnic groups, and of other interest groups were appointed to draft a document. A referendum to ratify the new constitution was held in December 1973, with more than 90 percent of eligible voters signifying approval, and the constitution was promulgated in January 1974. Elections to the People's Assembly (Pyithu Hluttaw)—the supreme legislative, executive, and judicial authority—and to local People's Councils were held early in 1974; the new government took office in March with U Ne Win as president.

After the establishment of the new political organization, Burma's economy grew steadily at a moderate pace. A notable policy change was a partial relaxation of the ban on foreign financial aid, and considerable funding was received from the Asian Development Bank and the International Bank for Reconstruction and Development. By the early 1980s, however, growth increasingly was being hindered by mounting trade deficits caused largely by falling commodity prices and rising external debt payments. A series of economic reforms were proposed in 1987–88 that would reverse the socialist policies enacted in the early 1960s. Chief among these were the further encouragement of foreign investment and a considerable liberalization of foreign trade.

Communist and ethnic insurgency continued in the eastern and northern parts of the country throughout the BSPP period. In May 1980 U Ne Win offered full amnesty to all political insurgents inside or outside Burma who reported to authorities within a 90-day period. Most notable among those accepting was U Nu, who, after having gone into exile in India in 1969, returned to enter a Buddhist monastary. Most insurgents, however, chose to continue opposing the government, and repeated attempts by government troops to suppress them met with only limited success. After four decades, insurgency had become a way of life.

The military regime. U Ne Win retired as president and chairman of the Council of State in November 1981 but remained in power until July 1988, when he resigned as chairman of the BSPP amid violent protests. Student and worker unrest had erupted periodically throughout the 1980s, but the intensity of the protests in the summer of 1988 made it seem as if the country was on the verge of revolution. In September the armed forces, led by General Saw Maung, seized control of the government. The military moved to suppress the demonstrations, and thousands of unarmed protesters were killed. Martial law was imposed over most of the country, and constitutional government was replaced by a new body called the State Law and Order Restoration Council (SLORC). Saw Maung became chairman of the SLORC and prime minister.

The SLORC implemented the economic reforms drafted by the previous government and called for elections for a new Constituent Assembly to revise the 1974 constitution.

Election of 1990

In May 1990 Myanmar held its first multiparty elections in 30 years. Of the dozens of parties that participated, the two most important were the government's National Unity Party (NUP), which was the successor of the BSPP, and an opposition coalition called the National League for Democracy (NLD). The result was a landslide victory for the opposition NLD.

The SLORC, however, would not permit the Constituent Assembly to convene immediately. In addition, the NLD's leaders, U Tin U, a former colleague of U Ne Win, and Daw Aung San Suu Kyi, the daughter of the nationalist leader Aung San, had been under house arrest since July 1989, while another leader, U Sein Win, remained in exile in the West. International condemnation of the military regime was strong and widespread, both for its bloody repression of the demonstrations in 1988 and for its actions in connection with the 1990 elections. Worldwide attention remained focused on Myanmar after Aung San Suu Kyi was awarded the Nobel Peace Prize in 1991. In April 1992 Saw Maung was replaced as chairman of the SLORC and prime minister by General Than Shwe. The SLORC permitted the new assembly to convene for the first time in January 1993. (M.A.A.-T.)

For later developments in the history of Myanmar, see the BRITANNICA BOOK OF THE YEAR.

Singapore

The Republic of Singapore (Chinese [Wade-Giles transliteration]: Hsin-chia-p'o Kung-ho-kuo; Malay: Republik Singapura; Tamil: Singapore Kudiyarasu) is a city-state situated at the southern tip of the Malay Peninsula, about 85 miles (137 kilometres) north of the Equator. It consists of the diamond-shaped Singapore Island and some 60 small islets, for a combined area of about 240 square miles (622 square kilometres); the main island occupies all but about 18 square miles of this territory. The main island is separated from Peninsular Malaysia to the north by Johor Strait, a narrow channel crossed by a road and rail causeway that is more than half a mile long. The southern limits of the state run through Singapore Strait, where outliers of the Riau-Lingga Archipelago—which forms a part of Indonesia—extend to within 10 miles of the main island.

Singapore is the largest port in Southeast Asia and one of the busiest in the world. It owes its growth and prosperity to its focal position at the southern extremity of the Malay Peninsula, where it dominates the Strait of Malacca, which connects the Indian Ocean to the South China Sea. Once a British colony and now a member of

the Commonwealth, Singapore first joined the Federation of Malaysia on its formation in 1963 and subsequently seceded to become an independent state on Aug. 9, 1965.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Nearly two-thirds of the main island is less than 50 feet (15 metres) above sea level. Timah Hill, the highest summit, has an elevation of only 531 feet (162 metres); with other peaks, such as Panjang and Mandai hills, it forms a block of rugged terrain in the centre of the island. To the west and south are lower scarps with marked northwest-southeast trends, such as Mount Faber. The eastern part of the island is a low plateau cut by erosion into an intricate pattern of hills and valleys.

Geology

These physical units reflect their geologic foundations: the central hills are formed from granite rocks, the scarp lands from highly folded and faulted sedimentary rocks, and the eastern plateau from uncompacted sands and gravels.

Drainage and soils. A dense network of short streams drains the island, but floods are locally severe because the streams have low gradients and because of excessive water runoff from cleared land. Many streams, especially those draining northward, have broad mangrove-fringed estuaries that extend far inland. None of the soils is even reasonably fertile, but those derived from the granites tend to be better than most. Soils developed from the sedimentary rocks are variable, but many contain hardpans (compacted layers) that restrict plant roots and impede soil drainage. The soils of eastern Singapore are extremely infertile. All have suffered extensive degradation through erosion as a result of generations of careless human exploitation.

Climate. Singapore is in the equatorial monsoon region of Southeast Asia, and its climate is characterized by uniformly high temperatures and nearly constant precipitation throughout the year. The average monthly temperature varies from about 81° F (27° C) in June to 77° F (25° C) in January. The daily range is somewhat greater, averaging about 13° F (7° C). Singapore's maritime location and constant humidity, however, keep maximum temperatures relatively moderate: the highest temperature ever recorded was only 97° F (36° C).

The seasons are defined by the relative incidence of rainfall, which, in turn, is determined by the movements of the monsoon air masses. The wettest and windiest period is during the northeast monsoon (November–March), with rainfall reaching an average monthly high of more than 10 inches (250 millimetres) in December. Conversely, the period of the least amount of rainfall and the lightest winds is during the southwest monsoon (May–September), with rainfall dropping to a monthly low of less than 7 inches in July. April and October are intermonsoonal periods characterized by sluggish air movements and intense afternoon showers and thunderstorms. Altogether, Singapore's precipitation averages about 95 inches annually, and rain falls somewhere on the island every day of the year.

Plant and animal life. Little remains of the original vegetation or animal life, except for a few thousand acres of evergreen rain forest preserved around catchment areas. Some mangrove vegetation survives in the Kranji area on the northwest side of the island, but elsewhere tracts of scrub or cogon grass (called *lalang* locally) are common. Many exotic plants have been introduced for ornamental use. The largest native animals are the long-tailed macaque (an Asian species of monkey), the slow loris (a large-eyed tailless nocturnal lemur), and the scaly anteater. Birds are numerous, especially those like the Indian mynah bird, the brahminy kite (a kite with reddish brown plumage and a white head and breast), and the house swallow that have adapted to a symbiotic relationship with humans. Reptiles, such as cobras and lizards, also are common. Fringing coral reefs with their associated fish and wildlife occur around many parts of the coast.

Birds

Settlement patterns. The city of Singapore is situated in the southern portion of the main island. Over time, urbanization has blurred the differences between city and country. Built-up areas now cover a large part of the city-state. The older parts of the city have been substantially refurbished, especially along the Singapore River but elsewhere as well. The once-common Chinese shop-house, consisting of living quarters above a commercial establishment, gradually has been disappearing from the city. Instead, the government's Housing and Development Board (HDB) has relocated commerce into separate districts and has created integrated residential communities inhabited by people with a mixture of incomes. About four-fifths of Singapore's population now resides in high-rise HDB flats located in housing estates and new towns. The new towns—such as Woodlands, Tampines, and Yishun—are scattered across the island and are characterized by easy access to places of employment and shopping districts. The traditional Malay kampong settlements—consisting of stilt houses built along the shoreline—are declining in number and are now found only in select rural areas.

The people. *Ethnolinguistic composition.* The population of Singapore is diverse, the result of considerable past immigration. Chinese predominate, making up more than three-fourths of the total. Malays are the next largest ethnic group, and Indians the third. None of these three major communities is homogeneous. Among the Chinese, more than two-fifths originate from Fukien province and speak the Amoy dialect, about one-fourth are Teochew from the city of Swatow in Kwangtung province, and a smaller number are from other parts of Kwangtung. The Chinese community as a whole, therefore, speaks mutually incomprehensible dialects. Linguistic differences are less pronounced among the Malays, but the group includes Indonesians speaking Javanese, Boyanese, and other dialects. The Indian group is most diverse, consisting of Tamils (more than half), Malayalis, and Sikhs; it also includes Pakistani and Sinhalese communities.

Official languages

Because of this ethnic diversity, no fewer than four official languages are recognized—English, Mandarin Chinese, Malay, and Tamil. English remains the main medium for administration, commerce, and industry, and it is the primary language of instruction in schools. Mandarin, the official language of China, transcends dialect barriers, and its use is strongly promoted; one-third of the school population is taught in that language. Malay, like English, is widely used for communication among ethnic groups and plays a particularly useful role in view of the close ties between Singapore and Malaysia.

Religions. Religious affiliations reflect ethnic patterns. About two-thirds of all Chinese profess some degree of attachment to Confucianism, Buddhism, or Taoism or to some combination thereof. Virtually all Malays, and some Indians, adhere to Islām, which is the formal religion of about one-sixth of the population. The Christian community has grown rapidly and now constitutes more than 10 percent of the population; nearly all Christians are Chinese. Almost all of the remaining population is Hindu.

Demographic trends. Heavily urbanized, Singapore has a high population density, but it also has been a regional leader in population control. Its birth and population growth rates are the lowest in Southeast Asia. Singapore's high average life expectancy and its low infant-mortality rate reflect high standards of hygiene and access to a superb health care system. The low birth rate and greater longevity of the population have raised the median age, a trend also occurring in other developed nations.

The economy. Singapore, one of the great trading entrepôts of the British empire, has experienced remarkable economic growth and diversification since 1960. In addition to enhancing its position as a world trade centre, it has developed powerful financial and industrial sectors. Singapore has the most advanced economy in Southeast Asia and is often mentioned along with the other rapidly industrializing countries of Asia: Hong Kong, South Korea, and Taiwan. Singapore's economy always has differed from those of the other Southeast Asian countries in that it never has been primarily dependent on the production and export of commodities.

Economic development has been closely supervised by the Singaporean government, and it has been highly dependent on investment capital from foreign multinational corporations. The government holds about three-fourths of all land and is the chief supplier of surplus capital, which is derived largely from contributions to the Central Provident Fund (CPF) social-security savings program. In

addition, the government has attempted to enhance the value and productivity of labour in order to attract investment and boost export competitiveness. This has been accompanied by a strong commitment to education and health. Labour shortages and rising wages have heightened the push for restructuring the economy even more toward higher value-added production.

The rationale for extensive government intervention in economic development has weakened. Official policy relies on market forces, privatization of government enterprise, and more support for domestic private businesses. Union membership has declined as centralized union structures have been replaced by smaller industry- and enterprise-based unions. Greater reliance has been placed on local labour-management negotiations.

Unions

Resources, agriculture, and fisheries. Singapore has few natural resources. There are no natural forests remaining on the island. Only a tiny fraction of the land area is classified as agricultural, and production contributes a negligible amount to the overall economy. Cultivation is intensive, with vegetables and fruits grown and poultry raised for local consumption. The local fishing industry supplies only a portion of the total fresh fish requirement; most of the catch comes from offshore fishing vessels. There also is a small aquaculture industry that raises groupers, sea bass, and prawns. Singapore is a major exporter of both orchids and aquarium fish.

Industry. Since the late 1960s Singapore has pursued a general policy of export-oriented industrialization. In order to attract foreign investment, the economy was liberalized, and a series of incentives were provided to multinational corporations; chief among these was the establishment of free trade zones. Gradually, production has been diversifying from such labour-intensive industries as textiles to high-technology activities like the manufacture of electronics and precision equipment and oil refining, which yield a much higher added value to production.

Services and tourism. Singapore has been able to emphasize its comparative advantage in knowledge-intensive activities—especially communications and information and financial services—which are less dependent on foreign investment. Higher productivity and research and development are encouraged through schemes that provide investment credits and allowances. An effective economic strategy has been to invest local funds abroad and simultaneously to export management skills. Singapore has sought to recruit skilled people, particularly Chinese from Hong Kong, the United States, and China.

Tourism is important to Singapore's economy. The city's central location in Southeast Asia and its excellent air-transport facilities have been augmented by massive investments in hotels and shopping centres. Duty-free shopping and a variety of recreational attractions, along with a refurbished beachfront, are among the primary attractions.

Finance. Singapore's financial services are highly sophisticated and are available through a wide variety of institutions. There is a growing venture-capital market that offers seed funding to firms that develop or introduce new technology. The government's Monetary Authority of Singapore performs all the functions of a central bank except issuing currency. A focal point of Singapore's growth as an international financial centre has been the Asian Dollar Market, which is essentially an international money and capital market where currencies other than the Singapore dollar are traded. The Development Bank of Singapore is the largest local bank in terms of assets. The Stock Exchange of Singapore is an important component of the financial activity in the region. The economic crisis that swept Asia in the late 1990s reduced the country's rapid economic growth, though Singapore weathered the crisis better than most of its neighbours.

Trade. Singapore continues to perform its traditional function as a financial intermediary, shipping raw materials such as rubber, timber, and spices from the Southeast Asian region in exchange for finished goods from both within and, especially, outside the region. Major imports are machinery and transport equipment and crude petroleum, while machinery, telecommunications products, and refined petroleum products are the major exports. The United States, Malaysia, and Japan are Singapore's principal trading partners. Entrepôt activities, where goods are transhipped and sometimes processed or manufactured in the immediate area, account for about one-third of Singapore's export trade. Notable in this capacity has been the oil-refining industry. In an attempt to foster additional trade, Singapore has become a joint-venture partner in numerous projects with Malaysia and Indonesia.

Entrepôt activities

Transportation. Singapore has one of the world's busiest ports in terms of shipping tonnage. The Port of Singapore Authority oversees all shipping activity and operates a number of terminals on the island. Containerized cargo accounts for more than half of the general-cargo tonnage. The island has a well-developed network of roads and highways, but traffic congestion frequently is a serious problem. In the late 1980s and early 1990s the government opened a light-rail mass-transit system that links the major population centres in the housing estates with employment centres and the central business district. Singapore is linked by rail to Peninsular Malaysia via the connecting causeway at Johor. Singapore's international airport, Changi, at the eastern end of the main island, is a major regional and overseas air hub.

Administration and social conditions. *Government.* Singapore is a parliamentary democracy based on the Westminster model. The government consists of a president who is head of state and a unicameral Parliament of 81 members who are elected to terms of up to five years. The parliamentary majority selects the prime minister and cabinet from its own ranks, and they in turn form the government. Until 1991 the largely ceremonial post of president was filled by parliamentary election; in that year the constitution was amended to allow for the direct popular election of the president and for presidential powers to be expanded. In each constituency there is a Citizens' Consultative Committee, designed to link local communities to the ruling party.

Close liaison is maintained between the political and administrative arms of government. The administrative structure consists of the various ministries and statutory boards. These are staffed by civil servants who are monitored by an independent Public Service Commission.

The political process. Singapore's electorate includes every adult citizen who is a registered voter, and voting is compulsory. A number of parties contest elections, but since 1959 Singaporean politics have been dominated by the People's Action Party (PAP). The PAP's ability to maintain its control largely has been attributable to Singapore's rapid economic growth and improved social welfare. In addition, the PAP often has suppressed and co-opted domestic opposition—notably through internal-security laws that allow political dissidents to be held in-

The PAP

definitely without trial—and it has promoted a national paternalistic ideology through a variety of laws and corporate institutions. The emphasis of this ideology has been a rigid public morality focused on personal appearance and cleanliness, political loyalty, and family planning.

Justice. Justice is administered by the Supreme Court and by courts of lesser jurisdiction, such as district and magistrates' courts. Appeals can be made from the lower to the higher courts, with final appeal to the judicial committee of the Privy Council in London. A Sharī'ah court has jurisdiction in matters of Islāmic law.

Armed forces and security. The armed forces of Singapore are divided into army, air force, and navy branches. The army is by far the largest of the services and consists primarily of infantry battalions with supporting artillery, armour, engineer, and logistics units. The main duties of the air force are air defense, support of ground forces, and long-range surveillance and tracking. The navy patrols the country's coastal waters and protects shipping lanes. Compulsory military conscription for 18-year-old males was introduced in 1967. There are two paramilitary forces: the Peoples' Defence Force, composed mainly of reservists, and the National Cadet Corps, consisting of high-school and college students.

The police force is responsible for internal security, traffic management, and crime prevention. It is assisted by a Civil Defence Force consisting of reservists and volunteers.

Education. Education is highly valued in Singapore, and its education system is elaborately structured. Primary education is free and lasts from six to eight years; the language of instruction is English, and students are required to learn any one of the other three official languages as a second language. Students at the secondary level are placed into academic or vocational and commercial tracks. Those on academic tracks are further channeled into four- or five-year courses of instruction. Opportunities for higher education are determined by academic performance and usually involve two or three years of preuniversity instruction followed by enrollment at a university or technical college. The National University of Singapore, founded in 1980 by a merger of the University of Singapore and Nanyang University, is the largest and best-known institute of higher education.

Health and welfare. Health conditions in Singapore compare favourably with those in other economically developed nations. The range and quality of medical services is notably high, with a large number of doctors and dentists. There are both government and private hospitals, while nonhospital care is dispensed from numerous outpatient clinics and mobile centres. The government and voluntary associations, the latter coordinated by the Council of Social Service, provide welfare services for the aged, sick, and unemployed.

Cultural life. Cultural activities in Singapore are largely derivative, springing from one or another of the major civilizations of China, India, Indonesia, or the West. Traditional Chinese and Indian music, painting, and drama are practiced by numerous cultural societies and professional groups. Popular culture, based on modern mass media, is far more widespread. Malay music, which has adopted the rhythms of Western orchestras, has general appeal. Musical films that popularize Hindi and Tamil songs have a considerable following, as do films from Hong Kong, Taiwan, and the United States.

The press

Several Chinese, English, Indian, and Malay newspapers serve a largely literate population. Magazines published in the West, Hong Kong, and Japan also have wide appeal. The government monitors the press to a certain extent and on occasion places circulation restrictions on periodicals and newspapers that are critical of its policies. The government-owned Singapore Broadcasting Corporation controls all local radio and television broadcasting.

For statistical data on the land and people of Singapore, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

Singapore Island originally was inhabited by fishermen and pirates, and it served as an outpost for the Sumatran empire of Śrīvijaya. In Javanese inscriptions and Chinese records dating to the end of the 14th century, the more common name of the island is Tumasik, or Temasek, from the Javanese word *tasek* ("sea"). Rājendra, ruler of the southern Indian Coḷa kingdom, attacked the island in 1025, and there was another Coḷa raid in 1068. In 1275 the Javanese king Kertanagara probably attacked Temasek when he raided Pahang on the east coast of the peninsula. According to a Chinese traveler, Wang Ta-yuan, just before 1349 about 70 Tai war boats besieged Temasek for a month but had to withdraw. The Javanese epic poem *Nāgarakeṛtāgama* (written 1365) includes Temasek among the conquests of the Javanese empire of Majapahit. At the end of the 14th century, Temasek fell into decay and was supplanted by Malacca (now Melaka). Yet in 1552 it was still a port of call from which St. Francis Xavier dispatched letters to Goa, and João de Barros described its busy shipping activity in his history *Décadas da Ásia* (1552–1615).

Rājendra may have named the city Singapura ("Lion City"), later corrupted to Singapore, or the name may have been bestowed in the 14th century by Buddhist monks, to whom the lion was a symbolic character. According to the *Sejarah Melayu,* a Malay chronicle, the city was founded by the Śrīvijayan prince Sri Tri Buana; he is said to have glimpsed a tiger, mistaken it for a lion, and thus called the settlement Singapura. (Rt.H./T.R.L.)

East India Company. In January 1819 Sir Thomas Stamford Raffles of the English East India Company, searching for a trading site, forestalled by the Dutch at Riau, and finding the Carimon (Karimun) Islands unsuitable, landed at Singapore. He found only a few Chinese planters, some aborigines, and a few Malays and was told by the hereditary chief, the *temenggong* (direct ancestor of the sultans of modern Johor), that the company could purchase land. The *temenggong,* however, was a subordinate of his cousin Abdul Rahman, sultan of Riau-Johor, who was under Dutch surveillance. Furthermore, Abdul Rahman was a younger son and not a sultan de jure. Raffles, disobeying instructions not to offend the Dutch, withdrew his own recognition of Abdul Rahman's suzerainty over Singapore and installed Abdul Rahman's elder brother, Hussein (Husain), to validate the purchase of land there on behalf of the company. The Dutch protested. In London the court of directors, though it decided Raffles had contravened instructions, took no action.

British rule

In 1824 an Anglo-Dutch treaty left Malaya and Singapore in the British sphere, and in August the whole of Singapore Island was ceded to the British for a monetary payment. Two years later Singapore, Penang, and Malacca (Melaka) were combined as the Straits Settlements to form an outlying residency of India. In 1830 they were reduced to a residency under Bengal, and two years later Singapore became their capital. When the East India Company lost its monopoly of the China trade (1833), it also lost its interest in Malaya. The settlements were transferred to the direct control of the governor-general of India in 1851. In 1867 they were made a crown colony under the Colonial Office in London.

Development of the port. Meanwhile, Singapore's trade had suffered after 1842 from British development of a rival port, Hong Kong, as later it was to suffer from the French occupation of the Indochinese Peninsula and their development of Saigon and Haiphong in Vietnam and from the establishment of Dutch ports and shipping lines in the Dutch East Indies. With the opening of the Suez Canal in 1869 and the advent of steamships, however, an era of prosperity began that led eventually to the construction of three miles of wharves at Tanjong Pagar and finally, in 1921, a naval base. The economic growth of the Malay states after they became British protectorates enlarged transit trade. (R.O.Wt.)

The demand of the industrial West for tin and rubber was what made Singapore one of the greatest ports in the world. After World War I, steps were taken to modernize Malayan defenses and, with the lapsing of the Anglo-Japanese alliance, to build a large naval base in Singapore.

World War II and the end of colonialism. In early December 1941 the Japanese landed in northern Malaya and

southern Thailand on the Malay Peninsula. They quickly gained air and naval superiority in the region, and by the end of January 1942 they had overrun the peninsula and were opposite Singapore Island. The Japanese crossed the Johor Strait on Feb. 8, 1942, and the British command surrendered the island and city one week later. Singapore remained in Japanese hands until September 1945.

Postwar British political plans for Malaya excluded Singapore from a proposed Malayan Union and later from the Federation of Malaya, mainly because it was thought that Singapore's predominantly Chinese population would be an ethnic obstacle to common citizenship. As a separate crown colony (from 1946), Singapore made constitutional progress despite the communist insurrection in Malaya. Elected ministers and a Legislative Assembly with an elected majority assumed government responsibility in 1955, except for matters of defense and foreign policy. In 1959 the official and nominated elements were eliminated, and Singapore became self-governing, although Britain still retained control of defense and foreign policy.

Singapore since 1963. Singapore joined the Federation of Malaysia on its formation in September 1963. The ruling People's Action Party (PAP), led by Lee Kuan Yew, had refused in 1959 to form a government until extreme left-wing leaders of the party who had been detained by the colonial authorities were released. These leaders opposed the concept of Malaysia and broke away from the PAP to form the Socialist Front (Barisan Sosialis), which was accused of being a communist front organization. The PAP faced fresh dangers of subversion when Indonesian opposition to Malaysia took the form of military and economic confrontation (1964).

Secession from Malaysia

Confrontation ended in 1966, but Singapore had seceded from Malaysia in 1965 (at the invitation of the Malaysian government) because of political friction between the state and central governments. This conflict had ethnic overtones and continued to affect relations between Singapore and Malaysia until the mid-1970s, when relations became more cordial.

In January 1968 the British government had announced that all British defense forces would be withdrawn from East and Southeast Asia (except Hong Kong) by the end of 1971. In April Singapore's unprepared major opposition parties boycotted an election called seven months before it was due. The ruling PAP termed its sweep of all parliamentary seats a mandate for its plans for reducing the economic effects of the British military withdrawal.

At the end of October 1971, British military presence in Singapore came to an end. The Anglo-Malayan treaty concluded in 1957, which had committed Britain to the defense of the region, was terminated, and in its place a five-power defense arrangement—involving Britain, Australia, New Zealand, Malaysia, and Singapore as equal partners—came into force.

Since the 1970s Singapore has pursued an aggressive policy of economic growth based primarily on export manufacturing and trade. Gradually, it also has taken a more active role in regional diplomacy. Singapore was a founding member of the Association of Southeast Asian Nations (ASEAN) in 1967, and by 1980 it had emerged as one of ASEAN's leaders. The PAP has continued to dominate Singaporean politics, although Lee stepped down as prime minister in 1990, and between 1981 and 1991 opposition parties gradually increased their number of seats in Parliament from one to four. Yet, despite the country's phenomenal economic success, resultant high standards of living, and subsequent goal of internationalization, the government's policies of developmental paternalism have bred some discontent among those who have come to expect greater openness to new ideas and a freer flow of information. (A.Ke./T.R.L.)

For later developments in the history of Singapore, see the BRITANNICA BOOK OF THE YEAR.

Thailand

Located in the centre of mainland Southeast Asia, the Kingdom of Thailand (Thai: Muang Thai, or Prathet Thai) has emerged as a pivotal nation in the region's political and economic life. The country was officially called Siam until 1939 and again briefly in 1945–48. The several ethnic and religious groups represented among Thailand's people are characteristic of the cultural diversity that for centuries has spread southward from China and eastward from India. Indeed, the name "Thai" to describe the country's people came into use only in the 20th century.

Thailand's area of 198,115 square miles (513,115 square kilometres) consists of two broad geographic areas: a larger main section in the north and a smaller peninsular section in the south. The main body of the country is surrounded by Myanmar (Burma) to the west, Laos to the north and east, Cambodia to the southeast, and the Gulf of Thailand (Gulf of Siam) to the south. Peninsular Thailand stretches southward from the southwestern corner of the main part down the Malay Peninsula; Myanmar extends along the western portion of the peninsula as far as the Isthmus of Kra, after which Thailand occupies the entire peninsula until reaching its southern border with Malaysia at roughly latitude 6° N. Bangkok, Thailand's capital and chief port, is in the main portion at the head of the Gulf of Thailand.

PHYSICAL AND HUMAN GEOGRAPHY

The land. Thailand's landscapes vary from high mountains to fertile alluvial plains dotted with rice paddies to sandy beaches set amid the equatorial latitudes of the Asian monsoons. Three physiographic regions cover most of the country: the folded mountains in the north and west, the Khorat Plateau in the east, and the west-central Chao Phraya River basin. The maritime southeastern corner of the main portion and the long, slender peninsular portion in the southwest constitute separate physical regions.

Relief. The northern mountains, the southeastern continuation of the uplift process that formed the Himalayas, extend southward along the Thai-Myanmar border and reach as far south as northern Malaysia. Long granitic ridges were formed when great masses of molten rock forced their way upward through the older sedimentary strata. Peaks average about 5,200 feet (1,585 metres) above sea level. Mount Inthanon, at 8,481 feet (2,585 metres) the highest in the country, is in northwestern Thailand, near the ancient city of Chiang Mai (Chiengmai); the city is overshadowed by Mount Suthep, a tourist attraction and site of the royal summer palace. Some of the rugged limestone hills contain caves from which remains of prehistoric humans have been excavated.

The Khorat Plateau

The Khorat Plateau is a vast tableland bounded by the Mekong River on the north and east. It was formed by uplifting along two perpendicularly arranged crustal faults—one trending north-south in the west and the other east-west in the south. As a result, the underlying sedimentary rocks were tilted rather than uniformly uplifted. This tilting created ranges of low hills and mountains along the western and southern edges of the plateau: the Phetchabun and Dangrek (Thai: Dong Rak) mountains, respectively. The escarpments of these uplands overlook the plain of the Chao Phraya basin to the west and the Cambodian plain to the south. Surface elevations on the Khorat Plateau range from about 650 feet in the northwest to about 300 feet in the southeast: the terrain is rolling, and the hilltops generally slope to the southeast in conformity with the tilt of the land.

Situated between the northern and western mountain ranges and the Khorat Plateau is the extensive Chao Phraya River basin, which is the cultural and economic heartland of Thailand. The region, sometimes called the Central Plain, consists of two portions: heavily dissected, rolling plains in the north and the flat, low-lying floodplain and delta of the Chao Phraya in the south. It was formed by the outwash of immense quantities of sediment brought down from the mountains by the Chao Phraya's tributaries, which produced vast fan-shaped alluvial deposits.

The generally rolling countryside of the southeast has high hills in the centre and along the eastern boundary with Cambodia. Notable peaks are Mount Khieo (2,614 feet), visible from the top of Mount Phu Thong (the Golden Mount) in Bangkok, and Mount Soi Dao, which attains a height of 5,471 feet. The hills, reaching nearly to the sea, create a markedly indented coastline fringed with many

islands. With their long stretches of sandy beach, such coastal towns as Chon Buri and Rayong and some of the islands have become popular year-round tourist resorts.

The topography of the peninsula is rolling to mountainous, with little flat land. A gently sloping sandy coastline, including such resort communities as Hua Hin, borders the Gulf of Thailand on the east. Higher mountains reaching about 4,900 feet line the peninsula on the west and contain narrow passes linking Thailand and Myanmar. These ranges separate the Andaman and South China seas as the peninsula narrows near the Malaysian border. Off the rugged and much indented west coast lie numerous large islands, including tin-rich Phuket Island.

Drainage and soils. Thailand is drained largely by two river systems: the Chao Phraya in the west and the Mekong in the east. Three major rivers in the northern mountains—from west to east, the Ping and its tributary the Wang, the Yom, and the Nan—flow generally south through narrow valleys and onto the plains and then merge to form the Chao Phraya, Thailand's major river.

The Chao Phraya delta

The delta floodplain of the Chao Phraya is braided into numerous small channels and is joined by other rivers—notably the Pa Sak—as the river flows toward its mouth in the Gulf of Thailand. The flooding of the flat delta in the wet season is an asset to rice cultivation, although higher ground on the extreme eastern and western edges of the plain requires irrigation. The entire delta was once part of the Gulf of Thailand, but over time the sediments carried down from the north have filled it in. Such silting is a continuing obstruction to river navigation, but it also extends the river's mouth into the gulf by several feet each year.

The rivers of the Khorat Plateau flow generally southeastward and empty into the Mekong. Monsoon rains over the degraded forest cover of the region produce rapid runoff; flooding occurs almost yearly at Ubon Ratchathani at the junction of the plateau's two major rivers, the Mun and the Chi. Swampy land and lakes are common close to the Mekong, in contrast to the aridity of much of the rest of the region. A high groundwater table there contains mostly brackish, unpotable water. The Mekong itself is either studded with islands or broken up by impassable rapids.

The southeast and the peninsula are drained by short streams and rivers. In the southeast the rivers in the north flow into the Chao Phraya delta, while those in the west and south run directly into the sea, where they have built up small alluvial basins and deltas along the coast; the mouths of the rivers along the southern coast consist of tidal flats and mangrove swamps. Nearly all the rivers on the peninsula drain into the Gulf of Thailand. The Phet River is one of several that has been dammed for irrigation.

The great deposits of alluvial soils in the river valleys are the most fertile in Thailand. These are replenished annually with sediment washed down by rivers swollen with the annual monsoon rains. Chief among these areas is the delta floodplain of the Chao Phraya, but the relatively flat basins in the northern mountains, scattered lands along the Mun and Chi rivers on the Khorat Plateau, and much of the coast also have rich alluvial soils. Soils elsewhere tend to be relatively infertile, highly leached laterites. Near the Mekong, a high salt content in some soils limits crop production, although salt deposits there are mined commercially.

Climate. The major influences on Thailand's climate are its location in the tropical monsoon zone of mainland Southeast Asia and certain topographic features that affect the distribution of precipitation. Beginning in May, the warm, humid air masses of the southwest monsoon flow northeastward over the region from the Indian Ocean, depositing great quantities of precipitation; rainfall reaches a maximum in September. The wind pattern is reversed between November and February, when the northeast monsoon brings cool, relatively dry air masses in a southwesterly flow to create a seasonably cooler climate for much of the country. Stagnant air in March and April is associated with a distinct hot and dry intermonsoonal period.

Local relief acts to modify these general weather patterns. Topographic effects are most noticeable on the peninsula, where Ranong on the west coast receives approximately 160 inches (4,000 millimetres) of precipitation annually, while Hua Hin on the east coast receives less than 40 inches. Similar but less pronounced rain-shadow effects occur along the western margins of the Central Plain and on the Khorat Plateau. Songkhla, at the southern end of peninsular Thailand, has its rainy season during the cool season, the result of moisture picked up by the northeast monsoon winds while passing over the Gulf of Thailand; in this area a true tropical rain-forest climate prevails.

Temperatures

Nationwide, temperatures are relatively steady throughout the year, averaging between 77° and 84° F (25° and 29° C). The greatest fluctuations are in the north, where frost may occur in December at higher elevations; conversely, maritime influences moderate the climate in the south. The cooler, drier air of the northeast monsoon produces frequent morning fogs that generally dissipate by midday in the north and northeast regions.

Plant and animal life. Since 1970 the area of Thailand that is covered with forest has dwindled from about half to one-fourth. Forest clearing for agriculture, excessive logging, and poor management are among the main causes of this decline. Less than one-fifth of the country is covered by grass, shrubs, or swamps, and the remainder is under settlement or cultivation. Forests consist largely of such hardwoods as teak and timber- and resin-producing trees of the Dipterocarpaceae family. As elsewhere in Southeast Asia, bamboo, palms, rattan, and many kinds of ferns are common. Where forests have been logged and not replanted, a secondary growth of grasses and shrubs has sprung up that often limits land use for farming. Lotuses and water lilies dot most ponds and swamps throughout the country.

Elephants, buffalo, cattle, horses, and mules are among the domesticated animals important for agriculture and transportation. Only a few elephants are still found in the wild, and, although forestry is now largely mechanized, elephants remain helpful in difficult terrain. Mechanized agriculture is also rapidly replacing draft animals, and horses and mules increasingly are used only as pack animals along the mountain trails of the north. The forests abound in monkeys and species of birds. Large mammals such as the rhinoceros and tapir, however, are among the species endangered by deforestation and game hunting. The government has created a number of wildlife and conservation areas to protect these valuable resources and has acted to prevent the illegal sale of endangered species.

Lizards live in settled areas and prey on insects. Frogs and toads (some of them edible) are numerous, crocodiles are common in the south, and snakes are abundant, especially the king cobra and various species of dangerous water snakes. Several farms in Bangkok raise crocodiles and snakes for commercial and scientific purposes.

The once-abundant freshwater and marine fish have been rapidly depleted by overfishing and disruption of their natural habitats, as have such edible crustaceans as shrimp, prawns, and sea crabs. There are many species of wild silkworms, and some are raised for the silk industry. Mosquitoes still transmit malaria, although the incidence of this disease has been decreasing. White ants and moths are a scourge to clothing and books.

Traditional regions. Thailand can be divided into five historical regions: Lanna Thai (northern Thailand), Isan (northeastern Thailand), the Central Plain, Pak Tai (southern Thailand), and west and southwest Thailand.

The people of the mountainous Lanna Thai speak a dialect of the Thai language called Kham Mu'ang, or Yuan in its written form, and follow Buddhist traditions more akin to those practiced in Myanmar. They also share a preference with the Lao-speaking Thai of northeastern Thailand and the people of Laos for glutinous rice as their staple food. The mountains of the north also are the home of many upland minority groups that have migrated from Myanmar, Laos, and southern China over the centuries.

The Isan region shares various linguistic, artistic, and religious traditions with Lanna Thai and the Lao across the Mekong River. The regional dialect is referred to as Lao or Isan, but most people can easily communicate in standard Thai. This region also had a history of relative

autonomy until the late 18th century, which has helped to shape northeastern Thai identity.

The Central Plain

The Central Plain, occupying most of the Chao Phraya basin, is the core cultural region, and its people (often called the Siamese) speak the national language—standard Thai, or Siamese. Historically, the Siamese followed a Buddhist tradition that has been more closely linked to that of the Khmer of Cambodia. Because of the plain's central position, population and economic activity are heavily concentrated there, especially in Bangkok, and industrial and commercial enterprises have grown faster there than elsewhere. This rapidly growing economic heartland continues to be a strong magnet, attracting people from the northeast and other places who are seeking greater economic and social opportunities.

The southeast, lying close to the sea, is an undulating and hilly region extending eastward from Bangkok to the Cambodian border. Sino-Thai, or Thai of Chinese descent, are a prominent segment of the regional population, their ancestors having originally settled there in the late 19th century to work on sugarcane plantations, in lumber mills, and as small merchants. There is also a significant number of people living along the border with Cambodia who speak Khmer or Khmer-related languages and follow distinctive traditions.

The southern Pak Thai region has a distinctive identity linked to the historical role of such towns as Nakhon Si Thammarat, once called Ligor. Because this background is related to the later Siamese kingdoms, the language and customs of Pak Thai are similar to those of the Siamese of central Thailand. The extreme south is inhabited by Malay-speaking Thai, most of whom are Muslim.

The west and southwest, consisting mostly of hilly to mountainous terrain adjoining the Myanmar border, are sparsely populated. The Karen from Myanmar often migrate and live within Thailand, clearing and cultivating uplands in a manner similar to the upland minorities of northern Thailand.

Settlement patterns. Hill settlements depend much on shifting cultivation of upland crops. Such mountain peoples as the Karen, Hmong (Miao, or Meo), Yao, Lahu, Lisu, and the lowland Thai who have migrated to the uplands usually settle on the ridges and the slopes in groups ranging up to 100 or more houses, depending on the resources of the area. The Hmong are opium cultivators and prefer to live on high slopes where opium grows well in the cool climate. The Karen live along the stream valleys and grow rice on well-tended terraced fields. The lowland Thai who have migrated to these uplands earn a living from their tea and coffee plantations.

No true plains villages exist in Thailand. Villages in the northeast are scattered on the higher grounds above flood levels, while the lower grounds are used for rice farming. In the north, where the villages are found in the alluvial basins of major rivers, increased population and transportation have tended to disperse the villages away from the rivers and toward the main railroads and highways, reducing the amount of land available for growing rice.

The Chao Phraya delta is densely settled but only on the high ground that is free from flooding. A vast network of irrigation canals modifies the pattern of settlement. With increasing facility in transportation offered by small motorboats, the villages tend to become dispersed to the east and west away from the rivers. New highways also tend to modify settlement patterns, especially at their crossings of canals and rivers, where new towns grow up rapidly.

In the south and southeast, plantations, especially fruit and rubber plantations, are scattered along the fertile slopes, alternating with the low and narrow rice fields; the villages are therefore arranged accordingly. Most of them are joined by good roads and highways. Alluvial deposits containing tin, no matter how remote, are accessible by land and sea. Settlement is almost continuous along both sides of the peninsula. Most of the people live by fishing, except in areas where collecting bird's nests for cooking brings a good income. The coastal villages are connected by both land and sea.

Urbanization

Urban settlement in Thailand, as in many other developing countries, has grown dramatically since World War II,

A Lisu hill settlement near Pai, northwestern Thailand.
Jeffrey Alford/Asia Access

but that growth has been highly uneven. Bangkok remains the dominant and only major urban centre in the country, its population more than 20 times larger than that of Nonthaburi, the next largest city. The smaller urban centres typically are provincial capitals; among the oldest of these are Chiang Mai, Lampang, Phrae, and Nan in the north, which grew up along the major tributaries of the Chao Phraya River.

The people. The diversity of ethnic, linguistic, and religious groups in Thailand is characteristic of most nations of Southeast Asia, where shifting political boundaries have done little to impede the centuries-long migrations of people. Thailand's central position on the mainland has made it a crossroads for these population movements. As a result, speakers of all four major language families are represented in the country.

Ethnolinguistic composition. People speaking Tai languages constitute by far the dominant linguistic group in the country. The largest group of Tai speakers are the Thai, who constitute more than half the population. The Thai live in almost all areas of the country and speak related dialects that are differentiated by accents and a few words. The most common dialect is called standard Thai (Siamese), with the greatest concentration of speakers in the Chao Phraya delta. Since standard Thai is the national language, which is used in all schools and official publications and by the national press and broadcast media, most Tai speakers can communicate adequately among themselves.

Tai-speaking peoples are found not only in Thailand but also in Myanmar, Laos, Vietnam, and southern China. Little difference exists among the Tai speakers in Laos, Myanmar, China, and northern Thailand, but there is a noticeable difference between these peoples and the Thai living in the Central Plain and close to Cambodia. Speakers of Lao are the largest linguistic minority in Thailand; they live in the Khorat Plateau adjacent to Laos and constitute about one-fourth of Thailand's population.

Wars pitting Thailand against Myanmar and Cambodia in the past brought many refugees and prisoners of war into Thailand. The Mon, a people of Myanmar, settled in many parts of the north, centre, and west, although they are now concentrated in an area just west of Bangkok. The Khmer settled in the east along the Cambodian border. Both groups traditionally spoke languages of the Mon-Khmer group of the Austro-Asiatic family; most of these people, however, now use standard Thai, many speaking it as a first language.

Among speakers from the other two language families, Malays at the southern tip of peninsular Thailand are the most numerous. The Karen and other speakers of Sino-

Tibetan languages sparsely inhabit the western and northern mountains. Except for the Karen, who mixed rather easily with the northern Thai, the hill tribes prefer to keep themselves isolated. They occasionally come down to the markets to trade with the lowlanders. Two small hill tribes, the Lawa (or Wa) and Semang, are of special interest. The Lawa, who speak a Mon-Khmer language, are believed by some historians to be the original dwellers of the delta plain, who subsequently were driven into the hills of the northwest by the Tai speakers who conquered the area. The Semang of the southern mountains speak a dialect of Malay and live by hunting with blowpipes and spears.

The Lawa and Semang

The Chinese constitute a significant minority in Thailand. In the commercial centres of Bangkok and other cities, people of Chinese descent operate both large and small commercial enterprises. The Chinese also make a living as middlemen and storekeepers. Most of them speak Chinese, although many also speak standard Thai.

English is also widely used in Thailand, especially in the urban centres. English is a required subject in secondary schools and the universities, and frequent contact with English-speaking foreigners also encourages the use of English. The prevalence of various South Asian dialects reflects the large number of Indian merchants and their descendants in the commercial centres.

Religions. Buddhism is professed by the vast majority of Thailand's population and is considered the national religion; most Thai Buddhists are of the Theravāda school. Muslims constitute a sizable minority and live mostly in the south. Most of the country's small Christian community lives in the central region. Hindus also are concentrated in the central region, chiefly around Bangkok. Although several of the hill tribes have converted to Buddhism or Christianity, most remain animists.

An unusual aspect of Thai religious life is the considerable influence of the Hindu Brahmans, even though they total only a few thousand families. Most royal and official ceremonies are almost always directed or performed by the Brahmans, whose rites are blended harmoniously with those of the Buddhists. Brahmans are renowned for their astrological expertise, assume responsibility for preparing the national calendar, and officiate at such state ceremonies as the annual plowing ceremony, which is believed to bring a good rice harvest. There are no important new religious movements in Thailand, but Buddhist monks have become more vocal in advocating environmental and social issues

Demographic trends. Thailand's population has increased rapidly in the 20th century, especially between 1950 and 1970, when the government supported such growth. Since then, official policies and private family-planning programs have slowed this growth dramatically, making the country a model for other nations seeking to reduce their high growth rates. The more youthful age profile of the population that resulted from the earlier growth, however, has begun to place increasing demands on the country's education, housing, health, and employment systems.

Population movements

Internal migration in Thailand occurs primarily between rural areas and has had little effect on the regional distribution of population. Nonetheless, migration from the countryside has contributed significantly to the growth of Bangkok. Since 1960 Bangkok has received two-fifths of all interregional migrants in the country, many of whom have come from the central and northeast regions. As in most other areas of the world, these migrants are mainly young adults less than 30 years of age. After 1975, Thailand also received large numbers of Cambodian, Vietnamese, Laotian, and Hmong refugees who fled political conflicts in their own countries and settled in camps along the Thai border; most refugees, however, have been resettled in other countries or repatriated to their own countries.

The economy. Thailand's investment-oriented economy is among the most rapidly growing in Asia. Despite this success, economic development has been highly uneven, especially in agriculture. Although much of Thailand's export revenues and a majority of the labour force depend on agriculture, its contributions to economic growth have declined consistently since 1950. Aiming at diversification, the government has encouraged investment in small industry. To encourage exports, duties are low, except on rice, to which a premium is attached to prevent domestic shortages. Unions are prohibited and strikes not allowed unless management fails to agree with employees and government mediators.

Resources. Tin, mined mostly in the peninsula, long has been among Thailand's most valuable mineral resources, and the country has become one of the world's largest producers. The construction of a smelter made it possible to process most of the ore domestically. Fluctuations in the world tin market, however, have caused production to be reduced. Other important mining and quarrying operations produce coal (lignite), zinc, gypsum, fluorite, tungsten, limestone, and marble. Rubies and sapphires are mined along the east coast of the peninsula. Thailand is one of the world's largest exporters of gems and jewelry, and these are among the country's top sources of foreign exchange.

Agriculture, forestry, and fishing. Growing international market demand has contributed to a more diversified Thai agriculture. Rice is the main staple food crop, but foreign demand for other crops has significantly expanded the production of cassava, corn (maize), kenaf (a fibre used as a substitute for jute), and sugarcane; rice yields, however, are among the lowest in Asia. Despite the Thai farmers' interest in growing crops to meet this demand, the government has done little to help farmers withstand sharp fluctuations in the prices of major export crops.

The main agricultural region of Thailand, the Chao Phraya basin, is planted mostly in rice. Rice also is the principal crop of the cultivated regions of the Khorat Plateau. In the northern intermontane basins, rice, vegetables, tobacco, and fruit trees are raised. Large inland areas of the southeast and peninsula contain cassava, sugarcane, pineapple, and rubber plantations. Cattle breeding has been curtailed by disease among stocks, but pigs and poultry are widely raised, with the latter constituting a growing export commodity.

Hardwoods such as teak and yang (a source of gurjun balsam), once major forest products, are now exported only in small amounts, especially since a government ban on logging imposed in 1989. Rubber production—based on trees introduced into the country during the 19th century—is important in the south. Fish production includes both marine fishes and freshwater species caught in rivers and reservoirs or raised in ponds.

Rubber

Industry. The growth in manufacturing since 1970 has been especially dramatic, reflecting the large investments made by private firms. Clothing, canned goods, and electrical circuits are among the more important products exported. Many larger concerns have been financed by foreign and Thai capital. Japan, South Korea, Taiwan, and Singapore have been major sources of investment for new industries, especially those producing goods for local use. Most industry and manufacturing is concentrated in or near the Bangkok metropolitan area, while numerous cottage industries in the north produce textiles, teak carvings, lacquerware, and other craft products. In the southeast, oil refining and gem cutting, in addition to food processing, are carried on.

Thailand has several hydroelectric plants, but most electric power is produced by generating plants using natural gas and lignite. Only small amounts of petroleum are produced domestically; and most of the oil consumed in the country must be imported. Somewhat larger quantities of natural gas are recovered from the Gulf of Thailand and the northeast and contribute to national energy needs.

Finance and trade. The Bank of Thailand, established in 1942, issues currency, acts as central banker to the government and to the commercial banks, and serves as fiscal agent in dealing with international monetary organizations. More than half of the nation's retailing and other distribution businesses are located in the Bangkok metropolitan area. Middlemen handle most farm commodities. Retail stores are small, except in Bangkok, which has many large department stores and shopping malls. Prices in these stores are fixed, but bargaining occurs regularly in smaller shops and in markets throughout the country.

With agricultural and raw materials as the basic exports, manufactured goods, such as machinery and transportation equipment, account for the highest value among imports. Thailand's major trading partner is Japan; other important partners are the United States, Singapore, Germany, and Hong Kong.

Transportation. Bangkok is the centre of Thailand's water, land, and air transport systems. The rivers of the Chao Phraya delta have been used since antiquity, and modern irrigation canals have added to the inland-waterway network. Thailand has undertaken substantial highway development, but the seasonal rains make it difficult to keep some roads open year-round, especially in the peninsula. Mountain trails are often the only means of travel in remote areas. Where roads are inadequate, airplane and helicopter services often compensate. Rail lines radiate from Bangkok, with one linking up with the Cambodian rail system. The port of Bangkok, at Khlong Toei, is the largest and busiest in the country, handling nearly all imports and exports. Don Muang International Airport, north of Bangkok, is the hub of Thailand's air network; more than 20 smaller airports are located throughout the country.

Administration and social conditions. *Government.* Following a coup in 1932 that ended the absolute rule of the monarchy, a constitution was promulgated, in which the monarch, the National Assembly, the State Council, and the law courts were to exercise power on the behalf of the citizenry. Since then, several constitutions have been created because of changes of government, but the provisions have remained similar to the 1932 document. Under the present constitution, the king is head of state and of the armed forces. He is held to be sacred and inviolable, and in the name of the people he exercises legislative power, with the advice and consent of the National Assembly. He also appoints the prime minister. Executive powers are vested in the prime minister and cabinet, who operate in the name of the king. The royal family is very much at the core of modern Thai society, being regarded as the symbol of national unity and the protector of national welfare and traditions.

The 1932 constitution

In form, the Thai government resembles those of Western nations: various ministries are responsible for such matters as finance, agriculture, education, public health, communications, and justice. Despite this similarity, new administrations frequently have come to power through military-backed coups. These authoritarian governments dominated Thai politics until 1973, when a student-led movement forced a return to constitutional rule, popular elections, and registration of political parties. Since then, there has been a succession of military-installed or popularly elected governments in Thailand. Stronger democratic principles and opposition to military rule throughout the country make any future return to more authoritarian governments unlikely.

The provinces (*changwat*), of which there are 73, are the major units of local government. Below these are districts, subdistricts, communes, and villages. Municipalities in the kingdom are classified as cities, towns, or communes, according to their populations; they are run by an elected mayor and councillors.

Justice. Thai law has been influenced by the Hindu code of *Manu-smṛti,* which probably was transmitted through the ancient Mon kingdom of central Thailand. Reform in the late 19th century introduced concepts of Western jurisprudence. All judges in the country's courts are professionals, appointed without political consideration; they are bolstered by a system of judge trainees.

Armed forces. Under the king as commander in chief, the army, navy, and air force are assisted by the United States Military Assistance Program. Thai soldiers have fought in Korea and Vietnam, but since 1975 the military has been more fully occupied with protecting its own borders from problems in the neighbouring countries of Cambodia, Laos, and Myanmar.

Education. Children under 15 are required to complete six years of elementary education. Secondary education generally lasts six years and consists of lower and upper divisions, each lasting three years; students at the upper-secondary level have the choice of pursuing an academic or vocational program. Only a small minority of students, however, go on to secondary training. Ramkhamhaeng University in Bangkok, established as an open-enrollment university in 1971, has considerably increased opportunities for advanced education in the country. In addition, several other institutions, not including military academies, offer degrees in undergraduate and postgraduate fields. The oldest and largest of these is Chulalongkorn University in Bangkok, established in 1917.
